Abstract

Background: Inflammatory bowel disease (IBD) requires ongoing monitoring and effective communication between patients and health care providers. Web-based patient portals may enhance engagement, but their association with disease activity remains unclear.

Objective: We aimed to evaluate the association between patient portal messaging frequency and disease activity among patients with IBD.

Methods: We conducted a retrospective cohort study using electronic health record data from an urban academic center. Patients with Crohn disease, ulcerative colitis, or indeterminate colitis were included. Portal messaging frequency over 2 years (July 2023-July 2025) was analyzed. Associations with demographic variables and disease activity were assessed using χ^2 tests (P<.05 was considered significant).

Results: Among 442 patients, 347 (78.5%) sent at least one portal message. Patients sent a mean of 5.27 (SD 7.15) messages over 2 years. High messaging frequency was associated with active disease (P=.047) and age group (P<.001). Patients with active disease were more likely to send ≥16 messages (n=14, 12.5% vs n=18, 6%). No significant associations were found with sex or race.

Conclusions: Higher portal messaging frequency was associated with active disease in IBD. Patient portals may serve as a tool for disease monitoring and early intervention.

Introduction

Inflammatory bowel disease (IBD), encompassing Crohn disease and ulcerative colitis, is a chronic, relapsing inflammatory disorder of the gastrointestinal tract requiring lifelong management. The global burden of IBD has increased substantially, with rising incidence in both Western and newly industrialized countries, reflecting environmental and lifestyle changes [1]. Achieving sustained remission remains challenging due to unpredictable disease flares and complications.

Contemporary IBD management emphasizes a treat-to-target approach, focusing on tight disease control and early detection of inflammation using clinical, endoscopic, and biomarker-based parameters [2]. However, implementation of this strategy is often limited by delays in identifying symptom exacerbations between clinic visits.

Effective disease control depends not only on pharmacologic therapy but also on timely communication between patients and health care providers. Breakdowns in communication during transitions or between visits have been associated with adverse outcomes, including increased hospitalizations and medical errors [3]. In IBD, early patient-reported symptoms frequently precede objective disease worsening, underscoring the need for accessible communication systems.

XSL•FO
RenderX

Digital health technologies, particularly electronic health record (EHR)–integrated patient portals, have emerged as important tools to facilitate patient engagement and intervisit communication [4]. These platforms allow secure messaging, access to laboratory results, and remote monitoring. Their use expanded significantly during and after the COVID-19 pandemic, accelerating adoption of telemedicine and asynchronous care models [5].

In other chronic diseases, such as diabetes and hypertension, patient portal use has been associated with improved adherence, better disease control, and enhanced patient satisfaction [6-8]. Systematic reviews suggest that patient portals can improve health care processes and some clinical outcomes, although effects vary across settings [6].

However, evidence regarding portal use in IBD remains limited and inconsistent. Studies examining digital health interventions in IBD populations are heterogeneous, with variation in study design, definitions of engagement, and outcome measures. A study by Reich et al [9] demonstrated an association between portal messaging and improved quality of life in IBD patients but did not assess disease activity directly.

Importantly, the relationship between portal messaging behavior and objective disease activity remains unclear. Increased messaging may reflect worsening disease, proactive patient engagement, or both. Additionally, demographic patterns of portal use, including age, sex, and race, have not been consistently characterized in IBD populations.

There is limited evidence evaluating whether patient-initiated portal messaging correlates with disease activity in IBD and whether it can serve as a surrogate marker for clinical worsening. This study aims to evaluate the association between web-based patient portal messaging frequency and disease activity among individuals with IBD while also characterizing demographic patterns of portal use.

Methods

Study Overview

A retrospective cohort study was conducted using EHR data from an academic medical center in Washington, DC. Patients with a confirmed diagnosis of Crohn disease, ulcerative colitis, or indeterminate colitis who had at least one outpatient gastroenterology visit during the study period were included. Patients without follow-up within the preceding 3 years were excluded.

Data Collection and Variables

Demographic variables including age, sex, and race were extracted from the EHR. Clinical data were obtained from physician documentation, endoscopy reports, and patient-reported symptoms recorded in clinic notes.

Definition of Disease Activity

Disease activity was categorized as active or in remission based on a composite assessment of clinical documentation. Patients were classified as having active disease if the last clinical note indicated ongoing symptoms, disease flare, or escalation of therapy. Patients without such documentation were classified as being in remission or having unknown disease activity.

Because standardized disease activity indices were not consistently available in the retrospective chart review, the study used our definitions of clinical remission and active disease based on physician documentation and treatment escalation. We recognize that this definition is not a universally accepted measure of remission and may introduce variability in classification.

Portal Messaging Measurement

The EHR includes a web-based patient portal through which patients can send messages to their health care providers. The number of patient-initiated messages sent to gastroenterology care providers over a 2-year period (July 2023 to July 2025) was recorded. Messaging frequency was categorized into predefined groups (0, 1 - 5, 6 - 10, 11 - 15, 16 - 20, and >21 messages) based on the distribution of messaging frequency within the cohort.

Statistical Analysis

Descriptive statistics were used to summarize patient characteristics and messaging patterns. Associations between portal messaging frequency and demographic variables (age, sex, and race) as well as clinical variables (disease activity and IBD subtype) were analyzed using χ^2 tests of association. Statistical significance was defined as $P<.05$.

Ethical Considerations

This study was approved and deemed exempt by the institutional review board at George Washington University. Informed consent was waived due to the study carrying no more than minimal risk to participants. All data were deidentified and kept in password-protected spreadsheets. Study participants did not receive any compensation.

Results

Clinical Characteristics

A total of 442 patients with IBD were included in the analysis. Of these, 182 (41.2%) had ulcerative colitis, 249 (56.3%) had Crohn disease, and 11 (3%) had indeterminate colitis. Regarding race, 196 (44.3%) patients were White, 161 (36.4%) were Black, 7 (2%) were Asian, 28 (6%) were of other races, and 50 (11%) were of unknown race. A total of 253 (57.2%) patients were female and 189 (42.8%) were male. Patients had an in-person or telemedicine visit with a gastroenterology care provider on average 3.2 times during the 2-year study period.

Portal Messaging Patterns

Overall, 347 of 442 patients (78.5%) sent at least one portal message during the 2-year study period. Patients sent an average of 5.27 messages over this time frame. A total of 201 (45.5%) patients sent 1 to 5 messages, 87 (20%) sent 6 to 10 messages, and 59 (13%) sent 11 or more messages. The distribution of messaging frequency is presented in Table 1.

XSL•FO
RenderX

Table . Number of patient-initiated portal messages in patients with inflammatory bowel disease (N=442).

Number of patient-initiated portal messages within the previous 2 years	Patients, n
0	95
1 to 5	201
6 to 10	87
11 to 15	27
16 to 20	14
More than 21	18

Association With Age

Portal messaging frequency varied significantly across age age groups (P<.001). Only 16 of 136 (11.8%) patients aged 40 to 60 years sent ≥6 messages over the previous 2 years, in comparison to 64 of 190 (33.7%) patients aged <40 years and 39 of 116 (33.6%) patients aged >60 years (P<.001; χ^2_1=20.6 and P<.001; χ^2_1=17.5). The distribution of messaging frequency by age is presented in Table 2.

Table . Number of patient-initiated portal messages within the previous 2 years among patients with inflammatory bowel disease by age (N=442).

	Patients by age group (years), n					
Messages, n	<20	20-29	30-39	40-49	50-59	60-69
0	1	12	22	18	10	32
1 to 5	2	39	50	56	36	45
6 to 10	1	13	26	10	2	23
11 to 15	0	5	6	2	0	6
16 to 20	0	4	5	0	1	2
More than 21	0	4	0	1	0	8

Association With Disease Activity

Messaging intensity also differed by disease activity (P=.047; χ^2_1=3.9), with 14 of 126 (11.1%) patients with active disease sending 16 or more portal messages in the last 2 years in comparison to just 18 of 316 (6%) patients in remission or with unknown disease activity. The distribution of messaging frequency by IBD disease activity is presented in Table 3.

Table . Number of patient-initiated portal messages within the previous 2 years among patients with inflammatory bowel disease by disease activity (N=442).

Messages, n	Patients in remission, n	Patients with active disease, n	Patients with unknown disease activity, n
0	57	24	14
1 to 5	134	55	12
6 to 10	58	24	5
11 to 15	18	9	0
16 to 20	6	7	1
More than 21	11	7	0

Association With Sex and Race

No significant associations were observed between messaging intensity and sex, race, or IBD subtype.

Discussion

Principal Findings

This study demonstrates that higher patient portal messaging intensity is associated with active disease in individuals with IBD. Additionally, a bimodal distribution of portal engagement was observed, with higher messaging frequency among younger and older patients compared to middle-aged patients. These findings suggest that patient-initiated portal messaging may serve as a behavioral marker of disease activity and engagement with care.

Comparison With Prior Work

These findings are consistent with prior studies demonstrating increasing use of digital health tools for chronic disease management and the growing role of patient portals in facilitating communication and engagement [4,6]. Previous

XSL•FO
RenderX

work has shown associations between portal use and improved patient-reported outcomes, including quality of life in IBD populations [9]. However, most prior studies have not directly examined disease activity. This study extends the existing literature by demonstrating a measurable association between portal messaging behavior and clinical disease status.

The observed bimodal age distribution aligns with findings from prior studies in both IBD and other chronic disease populations. Increased engagement among younger individuals may reflect greater familiarity with digital technologies, whereas higher engagement among older patients may be driven by increased health care needs and comorbidity burden [6,7].

An important observation in this study is the lower level of engagement among middle-aged patients (aged 40 - 60 years), which contrasts with the higher engagement seen in both younger and older groups. This finding may reflect competing professional and personal responsibilities that limit engagement with health care systems in this population. Alternatively, it may indicate differences in digital health adoption or perceived need for care. While not the primary focus of the study, this pattern highlights a potential gap in digital engagement that warrants further investigation.

Additionally, although higher messaging intensity was associated with active disease, the directionality of this relationship cannot be established. Increased messaging may reflect reactive communication in response to worsening symptoms, proactive engagement in disease management, or a combination of both.

It is also possible that a subset of portal messages reflected symptoms attributable to overlapping irritable bowel syndrome (IBS) rather than IBD activity alone. Because message content was not systematically reviewed, differentiation between IBS-related and IBD-related symptoms was not possible with the current study design. This represents an important limitation and an area for future investigation.

Clinical Implications

These findings suggest that portal messaging may serve as a low-cost and scalable indicator of disease activity in IBD. Increased messaging frequency could potentially be used to identify patients at higher risk of disease exacerbation and to prompt earlier clinical intervention.

From a patient-centered perspective, high message volume may also indicate unmet clinical needs or inefficiencies in communication workflows. For example, some patients with active disease required more than 16 messages over a 2-year period, which may suggest opportunities for improved triage systems, nurse-led protocols, remote symptom monitoring tools, or earlier clinical follow-up to address concerns more efficiently.

Furthermore, the identification of lower engagement among middle-aged patients highlights an opportunity for targeted interventions aimed at improving digital participation and ensuring equitable access to care across age groups [4,6].

Portal use may also reflect patient preference for asynchronous communication compared with telephone-based communication. Factors contributing to portal use may include convenience, faster documentation of concerns, accessibility outside clinic hours, and integration of laboratory and medication records into the EHR.

Limitations

This study has several limitations. First, as a single-center retrospective study, the findings may not be generalizable to other health care settings with different patient populations or care delivery models. Second, disease activity was determined based on clinical documentation rather than standardized indices, which may introduce variability in classification. Third, the content of portal messages was not analyzed, limiting the ability to distinguish between clinically relevant and administrative communication. Fourth, patients who did not activate the web-based patient portal were included in the study, likely impacting the distribution of portal messages. Finally, the temporal relationship between messaging and disease flares was not assessed, precluding conclusions about causality.

Additionally, a baseline comparison of portal use rates among non-IBD gastroenterology populations was not available for this study, limiting contextual interpretation of whether the observed messaging frequencies were unique to patients with IBD or reflected broader portal use trends in gastroenterology practice.

Future research should focus on multicenter studies to validate these findings across diverse populations. Prospective studies examining the temporal relationship between portal messaging and disease activity could help clarify causality. Additionally, qualitative analysis of message content may provide insight into the types of communication that are most predictive of clinical deterioration. Interventional studies aimed at enhancing portal engagement, particularly among underrepresented groups such as middle-aged patients, may further improve patient outcomes.

Conclusions

In conclusion, patient portal messaging frequency is associated with disease activity in individuals with IBD. This finding suggests that digital communication patterns may serve as an important adjunct for disease monitoring and patient-centered care. Leveraging patient-portal data may enhance early detection of disease exacerbations and improve overall clinical management in IBD.

Given the exploratory nature of this work and the study's retrospective design, these findings should be interpreted as hypothesis-generating and supportive of future prospective validation studies.

Funding

This research received no specific funding from any funding agency in the public, commercial, or not-for-profit sectors.

Abstract

Background: Digital decision-support tools for labor care remain limited, with few technologies successfully addressing the complex, time-sensitive decisions required during labor triage. Fit4Labour is a clinician-facing, data-driven research tool, currently under development, that combines computerized cardiotocography interpretation with maternal and fetal risk factors to generate individualized risk scores at labor onset. Its primary aim is to support clinicians in identifying fetuses who may require closer monitoring or expedited delivery, while simultaneously providing reassurance in low-risk cases. By promoting consistent communication and timely escalation of care, the Fit4Labour tool seeks to strengthen clinical decision-making. Understanding and addressing usability and implementation barriers will be critical to its adoption in clinical practice.

Objective: This study aims to evaluate whether a digitally co-developed labor decision-support tool (Fit4Labour) maintains usability and implementation readiness across NHS hospitals with differing clinical contexts.

Methods: We conducted a convergent parallel mixed methods study in 3 United Kingdom hospitals (December 2022 to May 2025). Phase 1 involved iterative co-development with midwives and doctors at Oxford University Hospitals NHS Foundation Trust; Phase 2 validated the locked version at Birmingham Women's and Children's NHS Foundation Trust and Buckinghamshire Healthcare NHS Trust. Participants completed scenario-based usability sessions evaluated with the System Usability Scale (SUS) and Single Ease Question (SEQ), and task completion time, followed by focus groups and interviews analyzed thematically.

Results: Twenty-six health care professionals participated: 12 in co-development (7 midwives, 5 doctors) and 14 in validation (8 midwives, 6 doctors) phases. During co-development at Oxford, the tool met the "excellent" usability threshold (mean SUS 82.1, SD 12.3), indicating readiness for the validation phase. The locked version (v4.0) independently met the "excellent" threshold at both validation sites (combined mean SUS 85.8, SD 10.2; Birmingham 80.7, SD 10.8; Buckinghamshire 90.8, SD 7.2). Task completion times were comparable across validation sites (Birmingham 10.3, SD 1.6 min; Buckinghamshire 9.2, SD 1.9 min), while SEQ scores were consistently high across all scenarios (mean 6.1/7, SD 0.8). Thematic analysis identified 12 themes within 3 domains: clinical integration and workflow, technology adoption and implementation, and patient safety and decision-making. Participants described the Fit4Labour tool as a supportive tool, "like a co-pilot," improving confidence in decisions with the potential to aid triage assessment. Perceived limitations included an incomplete risk factor profile and the need for minor technical adjustments or integration with existing hospital systems.

Conclusions: Through systematic co-development, the Fit4Labour tool met the established usability benchmark at 2 independent NHS hospitals with markedly different clinical contexts. Clinicians viewed the tool as a supportive aid providing a shared language for risk communication and enhanced decision-making while preserving clinical autonomy. Whether these usability findings translate to improved clinical outcomes in real-world practice requires prospective evaluation.

Introduction

Overview

Health care systems worldwide are undergoing rapid digital transformation, with clinical decision-support tools increasingly recognized as valuable tools for improving patient safety and care quality [1-5]. This transformation is particularly important in maternity care, where time-sensitive decisions during labor have profound consequences for both maternal and neonatal outcomes [6-8]. Yet, successful implementation depends not only on algorithmic accuracy, but also on user-centered design: tools must present information clearly, fit seamlessly into workflows, and support rather than disrupt decision-making [9-13].

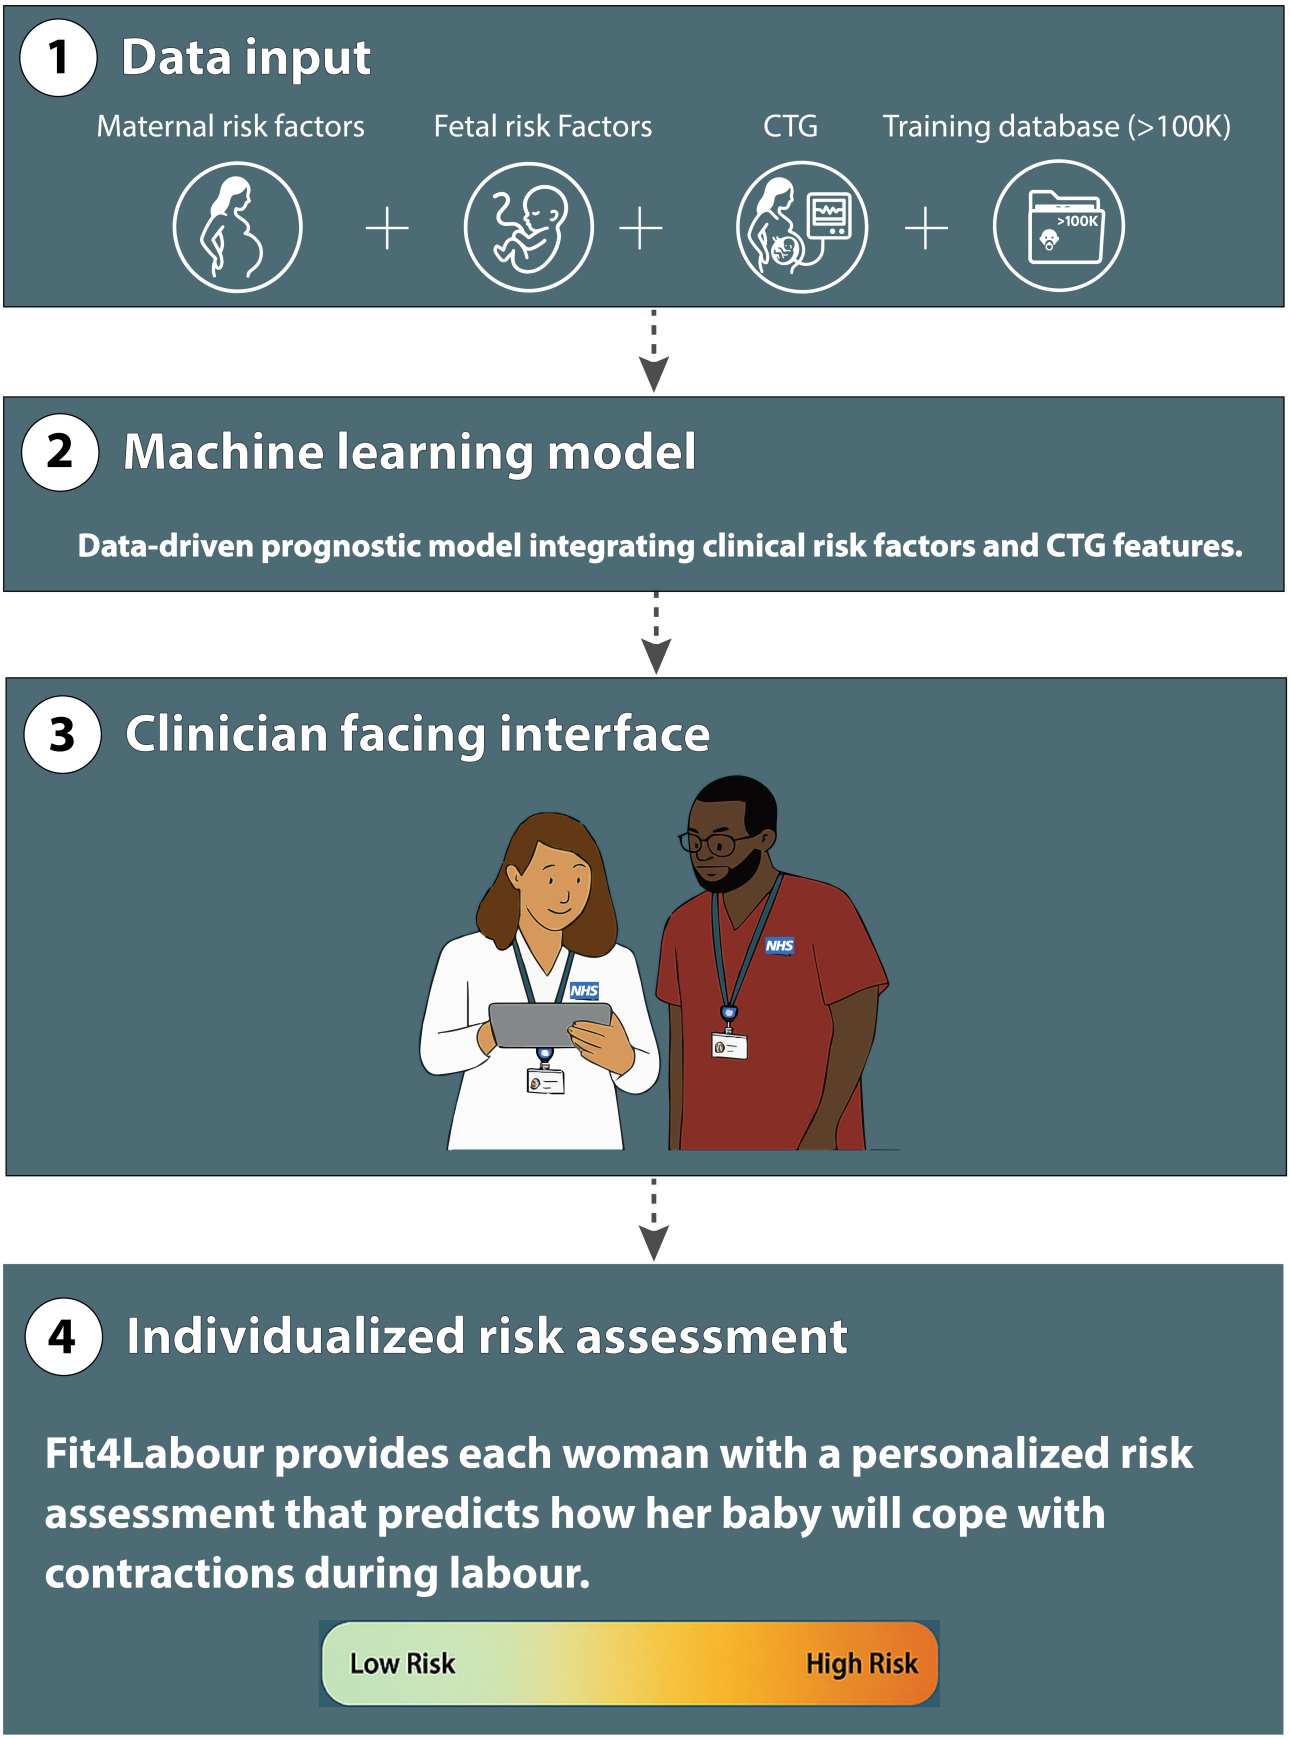
Implementation Challenge in Health Care Technology

Traditional development models in health care technologies often involve limited user engagement until late validation stages, resulting in tools that perform well in controlled settings ("work as imagined") but fail in the reality of busy clinical environments ("work as done") [14-16]. Insufficient investment of time and resources in co-design and usability testing remains a major barrier to adoption. Systematic reviews consistently demonstrate that poor usability is linked to low uptake, which in turn can pose patient safety risks [17-19].

Maternity care poses additional unique challenges as clinicians often manage multiple patients simultaneously with diverse risk profiles, while maintaining high safety standards [20,21]. Front-line clinical staff (eg, midwives and junior doctors) in the United Kingdom (UK) National Health System (NHS) are often key decision-makers in triage, and hold unique insights into workflow barriers; however, their perspectives are frequently underrepresented during the design of new technologies [22,23].

Challenges in Labor Care

Fetal monitoring can be performed using intermittent auscultation or cardiotocography. Cardiotocography, a graphical record of fetal heart rate and uterine contractions over time, remains the standard tool for monitoring during labor [8,24]. However, cardiotocography interpretation demands specialist expertise, and yet, the same trace can be classified differently, which may lead to suboptimal decisions [25-27].



Labor triage involves the rapid assessment of maternal and fetal well-being at the onset of labor to determine appropriate monitoring, the appropriate place for birth, and whether urgent intervention (such as expedited delivery) may be required [22,24,28]. These early decisions shape the entire labor care pathway. Published investigations repeatedly identified that failures during intrapartum monitoring are associated with delays in both decision-making and escalation of care [29,30]. At the same time, modern maternity care increasingly emphasizes shared decision-making, requiring clinicians to communicate individualized risk information effectively to support women's autonomy [7,24,31].

The Fit4Labour Tool Innovation

The Fit4Labour tool (University of Oxford) was designed as a clinician-facing digital system to address these challenges by combining maternal and fetal risk factors (eg, maternal age, diabetes, and meconium-stained liquor) with computerized cardiotocography analysis to generate individualized risk scores indicating the likelihood of fetal compromise during labor (Figure 1). Unlike earlier computerized cardiotocography systems that rely mainly on human pattern recognition, the Fit4Labour tool applies a prognostic modeling approach that integrates multiple clinical risk factors with cardiotocography data to produce standardized, evidence-based predictions of adverse outcomes at delivery [32,33]. Developed by the Oxford Labor Monitoring Group through multidisciplinary, user-centered co-design involving clinicians, engineers, and patient representatives, the tool draws on a dataset of over 147,000 cardiotocographs linked to birth outcomes and prioritizes intuitive use and clear risk communication to support clinicians' intrapartum decision-making [34].

The diagram illustrates how the tool integrates into existing maternity workflows, combining maternal and fetal risk factors with computerized analysis of the cardiotocography trace to support triage, escalation, and communication of risk. CTG: cardiotocography.

This multicenter convergent parallel mixed methods study aimed to evaluate whether the Fit4Labour tool, developed through

XSL•FO
RenderX

intensive co-development at a single NHS hospital, maintained usability and implementation readiness across 2 NHS hospitals with differing clinical contexts.

Methods

Study Design and Conceptual Framework

We conducted a multicenter convergent parallel mixed methods study over a two-and-a-half-year period (December 2022-May 2025) to assess the usability and implementation readiness of the Fit4Labour decision-support tool. Quantitative usability metrics were combined with qualitative user experience data, analyzed in parallel and then systematically integrated. This approach allowed us to explore both the measurable performance and clinicians' lived experience, providing a comprehensive understanding of usability and potential implementation barriers.

The study was guided by human factors engineering principles and we used 3 theoretical approaches (Figure 2). First, user-centered design entails involving midwives and doctors throughout development [9]. We designed the tool based on user feedback, with the aim of aligning its features to clinicians' cognitive workflows and practical needs. Second, Distributed Cognition recognized that clinical decision-making is shared across people, tools such as checklists or cardiotocography traces, rather than occurring solely in individual minds [35]. The Fit4Labour tool was designed to provide both midwives and doctors with the same risk information, creating a shared risk score that supports team coordination and collective decision-making. Third, Sociotechnical Systems emphasized that technology operates within complex systems of people, processes, and environments [12,36]. This framework guided our assessment of whether participating hospitals had the necessary infrastructure, culture, and organizational support to implement the Fit4Labour tool effectively.

The study was conducted in 2 phases. Phase 1 was an iterative co-development process at Oxford University Hospitals NHS Foundation Trust (OUH) (referred to as Oxford throughout the paper), where the tool was refined through multiple cycles of usability testing and direct user feedback. Phase 2 involved multisite validation at Birmingham Women's and Children's NHS Foundation Trust (referred to as Birmingham throughout the paper) and Buckinghamshire Healthcare NHS Trust (referred to as Buckinghamshire), where the locked prototype version of the tool was evaluated to assess its usability and transferability across different organizational contexts.

Study Sites

Hospitals were intentionally selected to capture diverse maternity services and populations within the UK National Health Service. OUH (Oxford) is a large university teaching hospital with a well-established research infrastructure and strong links to the University of Oxford, serving both urban and rural populations. BWC (Birmingham) is a specialist teaching hospital providing high-volume maternity services to an ethnically diverse population, while BHT (Buckinghamshire) is a medium-sized district general hospital broadly representative of typical NHS maternity care, reflecting the realities of routine clinical practice. Together, these sites enabled evaluation across varied demographics, clinical practices, and infrastructure levels, thereby enhancing the generalizability within the NHS hospitals and ethnically diverse populations.

The Fit4Labour Tool

The clinician-facing Fit4Labour tool is a web-based application that runs on tablet devices or computers and can communicate with electronic maternity record systems. It integrates maternal and fetal risk factors with computerized cardiotocography analysis to produce color-coded risk categories (green=low, amber=moderate, red=high) accompanied by a numerical score indicating the risk of severe fetal compromise. Severe compromise is defined as a composite of intrapartum stillbirth, neonatal death (<28 days), neonatal encephalopathy (including hypoxic-ischemic encephalopathy), or neonatal seizures.

The tool displayed time-related changes in risk that updated in real time as the cardiotocography recording progressed, alongside detailed computerized analyses of individual cardiotocography parameters including baseline heart rate variability, accelerations, and decelerations. Reports were generated at 20- and 60-minute intervals and included integrated note-taking and record-storage features to support clinical documentation, handover continuity, and audit processes.

Study Objectives

The primary objective was to evaluate usability and acceptability of the Fit4Labour tool across 3 NHS sites using quantitative metrics (System Usability Scale, Single Ease Question, task completion times) and qualitative assessment of clinician perceptions. Secondary objectives were to explore organizational factors influencing transferability, examine how midwives and doctors perceived and interacted with the tool, assess its perceived potential to enhance patient care, and identify organizational and technical barriers that may impact adoption.

Participants and Recruitment

Participants comprised qualified midwives and doctors currently working in the selected maternity services, with direct patient care responsibilities in labor triage or delivery settings, and the need for and experience in cardiotocography interpretation as part of their clinical role. Department managers distributed information sheets to recruit participants. Three factors determined sample size: Nielsen's guidance for interface evaluation (5‐8 participants per group typically uncover 80%‐85% of usability issues in interface evaluation studies, a pattern following the diminishing returns where each additional participant identifies fewer new problems), thematic saturation requirements for qualitative analysis, and practical constraints of multisite recruitment [37]. Using a relatively small number of samples, our convergent mixed methods design prioritized depth of insight over statistical power, consistent with exploratory implementation research [38,39]. All participants received a small honorarium (Amazon voucher) for their time.

Procedures

Between December 2022 and January 2024, the co-development phase took place in Oxford with participants testing successive prototypes in structured usability sessions. Feedback was sought on the user interface, layout, workflow, data entry, and risk visualization. Development followed a user-centered, multidisciplinary approach with iterative refinement over 4 versions at Oxford. Each version incorporated feedback from midwives and doctors, addressing user interface design, navigation, and risk visualization. Detailed version histories are provided in Table S3 in Multimedia Appendix 1. All design modifications were systematically logged, including user feedback prompting the change, implementation details, and impact assessment on overall functionality. Once usability goals, defined by high ease-of-use ratings, absence of major usability issues, and thematic saturation in qualitative feedback were achieved, the version was locked for validation testing. The locked version represented a stable version with no further interface or algorithmic modifications permitted during the validation phase. From November 2024 to May 2025, the locked version underwent prospective validation at Birmingham and Buckinghamshire. Participants followed the same protocol used at Oxford.

Usability Testing Sessions

Sessions lasted between 60 and 120 minutes and were co-facilitated by a clinical researcher (MT) and an experimental psychologist (XL) with extensive experience in usability testing. All sessions were conducted in dedicated rooms to minimize interruptions and ensure a consistent testing environment.

Testing was done in 2 separate stages (Figure S1 in Multimedia Appendix 1). In the task-based evaluation, participants first viewed a standardized 5-minute introduction video explaining the tool's purpose. The video did not include instructions on how to use the tool, as we sought to evaluate the user's intuitive navigation (Multimedia Appendix 1 video). The users were then given the tool and were asked to enter data for 4 progressive clinical scenarios, simulating common clinic triage tasks. This included baseline clinical risk factor entry, report generation, note-taking, risk factor updates, and advanced report features (Table S1 in Multimedia Appendix 1). Each scenario lasted up to 5 minutes, with facilitators observing silently and recording task completion times, errors, and usability barriers. If a task could not be completed within the allocated time, participants were instructed to move on to the next task.

After completing each scenario, participants were asked to rate the task's difficulty using the Single Ease Question (SEQ), a 7-point Likert scale (1=very difficult, 7=very easy). At the end of all tasks, they subsequently completed the System Usability Scale (SUS), a 10-item questionnaire generating an overall

XSL•FO
RenderX

usability score from 0 to 100 (Figure S2 and S3 in Multimedia Appendix 1).

The second stage was the qualitative exploration, which involved profession-specific focus groups or, where necessary, individual interviews. Discussions followed a structured topic guide exploring ease of use, clinical relevance, workflow integration, training needs, communication implications, and impact on clinical autonomy. All sessions were audio-recorded and transcribed verbatim.

Outcomes

Quantitative outcomes included SUS scores: values below 68 indicating below-average usability, between 68 and 80 indicating good usability, and above 80 indicating excellent usability [40,41]. SEQ ratings were used to assess ease of use following each clinical scenario. Lastly, task performance parameters were evaluated through completion times, error rates, and variability across participants. Qualitative outcomes captured themes relating to clinical integration, technology adoption, patient safety, and decision-making, drawing on data from focus groups and interviews.

Analysis

Quantitative Analysis

Descriptive statistics were reported as mean (SD) or median (IQR) according to the data distribution that was assessed by the Shapiro-Wilk test. No inferential statistical testing was performed. This was a deliberate choice as the primary aim of this study was to establish readiness and understand patterns of usability performance within each phase, rather than test population-level hypotheses. Moreover, phase 1 and phase involved different participants, tool versions, and clinical sites, precluding between-phase comparison being attributed to a single factor. The sample size was deemed sufficient for thematic saturation in the qualitative data. Data analysis and graphical representation were performed using the R software (version 4.5.3; R Core Team).

Qualitative Analysis

Transcripts were analyzed inductively using Braun and Clarke's 6-phase framework [42,43]. Three researchers (MT, XL, and DH) independently coded the transcripts, with consensus meetings to refine the coding framework and resolve any discrepancies. Themes were iteratively developed and mapped to usability and implementation domains. Saturation was defined as the absence of new themes across 2 consecutive coding rounds. NVivo software (Lumivero) was used for coding and data management.

Mixed Methods Integration

Quantitative and qualitative findings were integrated using a convergent parallel design [38]. Independent analyses were brought together in joint displays, with patterns categorized as convergence (alignment of findings), complementarity (mutual enrichment), or dissonance (contradictory insights). This approach enables a richer understanding of usability and implementation than either method alone.

Ethical Considerations

This usability study was conducted independently of, but in parallel with, the Fit4Labour technology evaluation and proof-of-concept study (ethics reference: 22/SC/0097). As this study involved health care professionals evaluating a prototype tool in a simulated setting, and did not involve patients, patient data, or clinical decision-making, formal research ethics committee review was determined not to be required. This was confirmed and agreed with the principal investigator at each of the 3 participating sites prior to recruitment.The study was registered with, and formally endorsed by, the research governance team at each of the three participating sites prior to recruitment, and this determination was further confirmed and agreed with the principal investigator at each site. All participants provided informed consent, recorded at the start of each audio-recorded session, after receiving detailed information regarding the study objectives and procedures, including their right to withdraw at any time without giving a reason. No identifiable patient data were collected or used in this study, and audio recordings and transcripts were stored securely with access restricted to the research team. Participants received a small honorarium (an Amazon voucher) in recognition of their time. Funding for the usability testing was provided by a National Institute for Health and Care Research (NIHR) Invention for Innovation (i4i) Product Development Award (NIHR202117); the funder had no role in study design, data collection, analysis, or interpretation.

Results

Participant Characteristics

Twenty-six health care professionals were recruited across 3 NHS sites: 15 midwives (58%) and 11 doctors (42%). Twelve participants (7 midwives and 5 doctors) contributed to Phase 1 co-development at Oxford, and 14 participants (8 midwives and 6 doctors) to Phase 2 validation at Birmingham and Buckinghamshire. Most participants (22/26, 85%) were women. Participants represented a wide range of seniority, from junior staff to consultant midwives and obstetricians, broadly reflecting the professional mix of UK maternity care (Table S2 in Multimedia Appendix 1). Although 25 participants completed the scenario-based usability testing, 26 took part in the interviews.

The Fit4Labour Tool Developments

The co-development phase at Oxford involved 3 iterative sessions, with each systematically incorporating users' feedback and testing progressively refined versions of the Fit4Labour tool (Figure 2). The first session with midwives (n=4) evaluated version 1.0, followed by a second midwives' session (n=3) a few months later testing version 2.0, and finally, version 3.0 was tested by doctors (n=5). This led to the final locked version 4.0, which was then tested in the 2 validation sites (Birmingham and Buckinghamshire). Detailed systematic documentation of design modifications is provided in Table S3 in Multimedia Appendix 1 and examples of user interface improvements in Figure S5 in Multimedia Appendix 1.

XSL•FO
RenderX

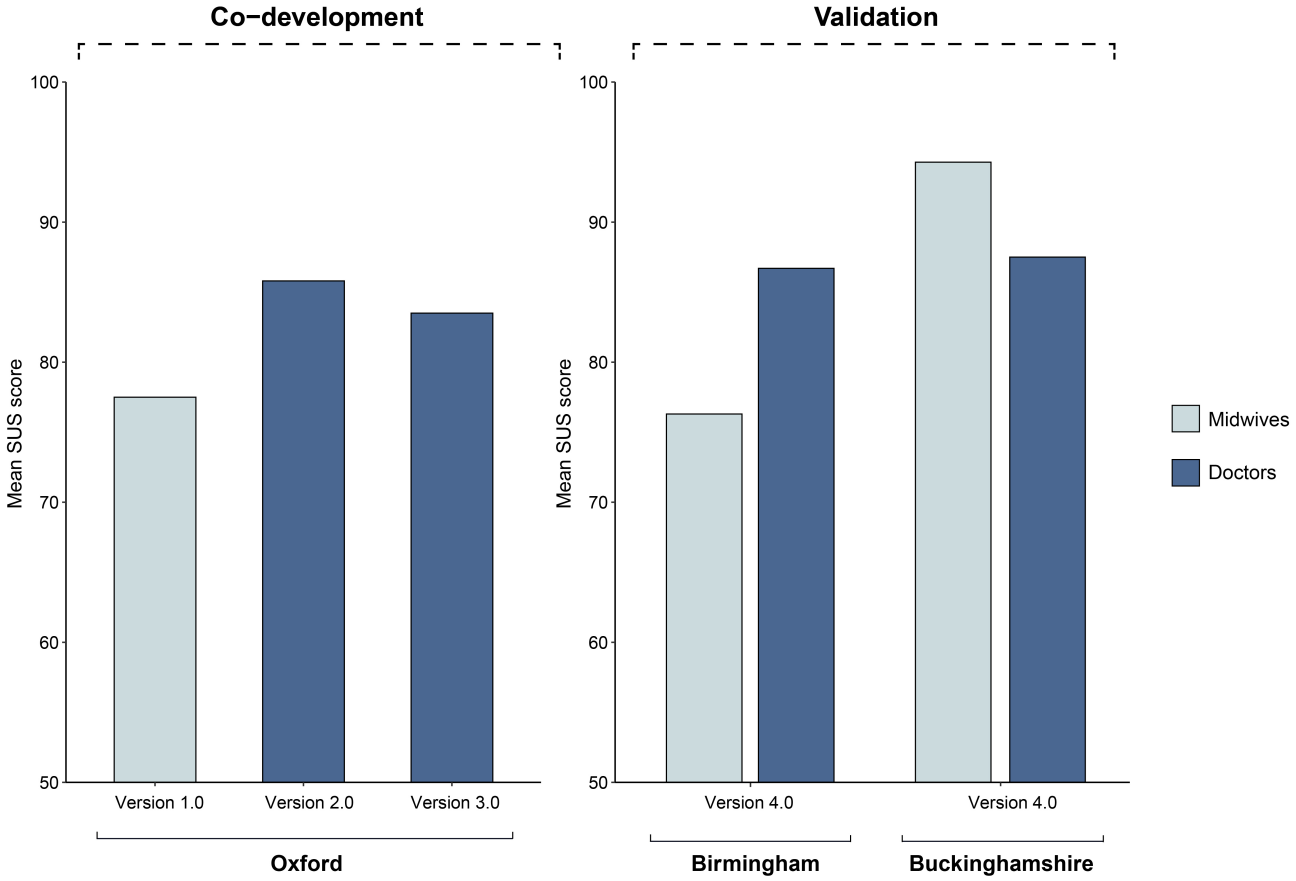
Quantitative Findings

System Usability Scale (SUS)

During the co-development at Oxford, the initial version (1.0) had a mean SUS of 77.5 (SD 15.1; rated as "good"), and by version 3.0 this had reached 83.5 (SD 9.1; rated as "excellent"). The co-development phase using the locked version (v4.0) had an overall mean SUS of 82.1 (SD 12.3) (Table 1, Figure 3), which indicated that the threshold for the locked version had been met (SUS>80).

Table . System Usability Scale scores by study phase and site. Learnability scores derived from System Usability Scale items 4 and 10.

Phase, site, and professional group	Participants, n	Version tested	SUS[b] score, mean (SD)	Range	Learnability, mean (SD)	Ratings[c]
Co-development						
Oxford						
1st Midwives session	4	v1.0	77.5 (15.1)	62.5 - 95	81.2 (16.1)	Good
2nd Midwives session	3	v2.0	85.8 (13.7)	70 - 95	79.2 (19.1)	Excellent
Doctors	5	v3.0	83.5 (9.1)	72.5 - 97.5	87.5 (12.5)	Excellent
Co-development total	12	v1.0 - 3.0	82.1 (12.3)	62.5 - 97.5	83.3 (14.4)	Excellent
Validation						
Birmingham						
Midwives	4	v4.0	76.3 (11.4)	65 - 90	62.5 (22.8)	Good
Doctors	3		86.7 (6.6)	77.5 - 92.5	75 (33.1)	Excellent
Site Subtotal	**7**		80.7 (10.8)	65 - 92.5	67.9 (25.9)	Excellent
Buckinghamshire						
Midwives	3	v4.0	94.2 (5.1)	87.5 - 100	95.8 (7.2)	Excellent
Doctors	3		87.5 (8.2)	77.5 - 97.5	95.8 (7.2)	Excellent
Site subtotal	6		90.8 (7.2)	77.5 - 100	95.8 (6.5)	Excellent
Validation total	13	v4.0	85.8 (10.2)	65 - 100	80.8 (23.7)	Excellent
Overall study (all participants[d])	25	v1.0 - 4.0	83.8 (11.3)	62.5 - 100	82 (19.5)	Excellent



[b]SUS: System Usability Scale.

[c]Interpretation thresholds: <68=below average, 68–80=good, >80=excellent.

XSL•FO
RenderX

Figure 3. SUS scores by study phase and site. During co-development, scores reflect iterative refinement across successive versions. During validation, the locked version (v4.0) independently met the "excellent" threshold at both sites. SUS: System Usability Scale.

The final locked version 4.0 independently met the "excellent" usability threshold during validation testing at 2 distinct sites, with a combined mean SUS score of 85.8 (SD 10.2), but with some intersite variability (Birmingham 80.7, SD 10.8 vs Buckinghamshire 90.8, SD 7.2). The SD of 10.2 within this phase reflects a relatively narrow spread of individual scores, suggesting a more predictable and uniform user experience across participants and sites.

Learnability scores (SUS items 4 and 10) showed an overall mean of 82 (SD 19.5). Co-development mean scores were 83.3 (SD 14.4) (Oxford) and validation mean scores were 80.8 (SD 23.7). Buckinghamshire showed a mean of 95.8 (SD 6.5), while Birmingham showed greater variability at a mean of 67.9 (SD 25.9). Professional group differences were modest (doctors: mean 87.5, SD 12.5; midwives: mean 80.4, SD 15.9 at Oxford; Table 1).

Single Ease Question (SEQ)

Task difficulty ratings demonstrated that participants perceived most scenarios as being "very easy" across all versions (mean SEQ 5.8 - 6.3 for Scenarios 1 - 3) (Table 2, Figure 4). Scenario 4, covering advanced functions, showed more variable ratings during co-development (v1.0 mean SEQ 5, SD 1.4; v2.0 mean SEQ 4.7, SD 1.2; and v3.0 mean SEQ 5.6, SD 0.7). In the validation phase, the locked version received SEQ ratings of mean 5.9 (SD 0.9) (Birmingham) and mean 6.3 (SD 0.8) (Buckinghamshire) for Scenario 4, indicating that advanced functions were perceived as easy to use. Overall, both validation sites demonstrated comparable ratings across all scenarios (Birmingham SEQ 6.2 vs Buckinghamshire SEQ 6.3), suggesting that version 4.0 had consistent perceived ease of use across scenarios.

Task Efficiency and Errors

Cumulative task completion times in the co-development phase in Oxford ranged from 7 to 18 minutes, with a mean of 11.8 (SD 2.5) reflecting expected variation during refinements across successive prototype versions and iterative designs (Table S4 in Multimedia Appendix 1).

During the validation phase, the locked version 4.0 was completed in a mean of 9.8 (SD 1.8) minutes overall (Figure 5). Despite testing in different clinical environments and with different digital infrastructure, both validation sites had comparable completion times (Birmingham 10.3, SD 1.6 min and Buckinghamshire 9.2, SD 1.9 min), suggesting consistent and transferable usability of the locked version across sites.

XSL•FO
RenderX

Figure 5. Task completion times (minutes) for all 4 simulated clinical scenarios completed sequentially during usability testing across study phases and sites. Each bar represents the total time taken to complete the entire set of 4 scenarios, not the time required to use the Fit4Labour tool in real clinical practice for 1 patient.

Professional Group Comparisons

Usability was comparable between midwives and doctors. Doctors reported slightly higher SUS scores (mean 87.1, SD 8.2 vs mean 83, SD 13.8) and faster completion times (9.3 versus 10.1 min), but differences were modest. Midwives had higher variability in both. SEQ ratings were also very similar, indicating intuitive usability across professional groups.

Qualitative Findings

Thematic analysis identified 12 themes grouped within 3 domains: clinical integration and workflow, technology adoption and implementation, and patient safety and decision-making (Table 3). All thematic summaries and supporting quotes are presented in the Supplementary Analysis 1 - 3 and Figure S4 in Multimedia Appendix 1.

XSL•FO
RenderX

Table . Thematic framework showing the 3 domains and 12 themes identified through qualitative analysis across study sites. Summary of the 12 themes organized under 3 domains: clinical integration and workflow, technology adoption and implementation, and patient safety and decision-making.

Domain and theme number	Theme name	Description
Clinical integration and workflow		
1	Risk factors and clinical comprehensiveness	Need for more risk factor options (eg, IUGR[a], reduced fetal movements) and complex combinations to improve accuracy and avoid underestimating risk.
2	Timeline and workflow integration	Report timing options (20 versus 60 min) and workflow challenges including room availability, resources, and staffing constraints.
3	Screening and triage effectiveness	Value in objective screening and triage with color-coded risk stratification (green, red, amber) for prioritizing care.
4	Escalation support for midwives	Enhanced midwife-doctor communication, confidence building for junior staff, and structured escalation protocols.
Technology adoption and implementation		
5	Training and digital confidence	Digital skills vary; success linked to training champions, mandatory sessions, and understanding tool rationale.
6	Ease of use	Intuitive design, straightforward interface, easy demographic input, and successful co-development outcomes.
7	Technology infrastructure barriers	Internet connectivity, Wi-Fi issues, device charging, CTG[b] compatibility, and hardware availability.
8	Digital overload and change management	Too many tools and software can overwhelm; resistance to change needs addressing through buy-in engagement strategies.
Patient safety and decision-making		
9	Decision-making safety net	"Co-pilot" for clinical support, especially valuable in gray areas of CTG interpretation and safety net for junior staff.
10	Risk communication and intervention requests	Support for informed patient counseling with individualized risk information and transparent communication strategies. Concerns about sharing risk information could increase patient requests for interventions.
11	Clinical autonomy and professional responsibility	Tool should support and not replace clinical judgment; concerns around medico-legal risk and deskilling.
12	System-wide implementation and organizational adoption	Requires strong implementation planning, organizational readiness, and consistent departmental adoption and unified protocols.

[a]IUGR: intrauterine growth restriction.

[b]CTG: cardiotocography.

Clinical Integration and Workflow Domain

Across all sites, participants described the Fit4Labour tool as a valuable screening and triage aid, with color-coded risk stratification enabling rapid and intuitive prioritization. One Oxford doctor explained that the colors "acts as a powerful shortcut… one of the fastest and easiest ways to express risk."

The tool was also seen as an effective escalation support mechanism, particularly for junior midwives who valued having objective evidence when calling senior staff: "You feel more confident having documentation that says you need to seek urgent medical advice" (Midwife, Oxford). Similarly, a Buckinghamshire midwife highlighted that the outputs facilitated communication by noting that "the Fit4Labour tool is one language…It helps put into words when you are not happy with a trace."

XSL•FO
RenderX

However, limitations were also noted, including an incomplete risk factor profile, such as the absence of reduced fetal movements, small-for-gestational-age, previous stillbirth, and antepartum hemorrhage. Clinicians felt that these omissions could undermine accuracy and provide false reassurance, with one Oxford doctor commenting that "missing risk factors gives an impression of being very accurate and specific but may not be if you don't input certain combinations." Views on workflow integration varied, with some suggesting that 60-minute reports were impractical in fast-turnaround triage but potentially feasible in induction bays or antenatal wards.

Technology Adoption and Implementation Domain

Ease of use was widely recognized by all participants and was commonly described as being "very intuitive and straightforward." A midwife at Oxford noted its accessibility even when fatigued, explaining that "it works for tired brains." Some participants with visual impairments or neurodivergent profiles, including those who were color-blind or dyslexic, commented positively on accessibility, with one noting, "I can read it really clearly, I'm dyslexic."

Nonetheless, a common theme was that structured training was essential given variation in digital literacy. A Birmingham doctor observed that "people that struggle with technology will still struggle because their confidence with IT is low … it's not that this is difficult to use." Suggested strategies included champion-led training and mandatory education programs. "People are always anxious with new technology, it needs mandatory training to use it properly, more reassurance to not miss things before using it" (Oxford Midwife).

Perceived implementation challenges extended to both infrastructure and organizational culture. Participants raised concerns about digital overload and imposed software changes in the NHS together with the need for senior buy-in, with one participant in Birmingham noting that "nobody likes change… you'll need a lot of buy-in from senior people... it'll snowball, just like iPhones when they came in.." Another common topic was infrastructure constraints, such as poor Wi-Fi, delays in IT support, missing chargers, and limited hardware, which was cited in Birmingham ("Wi-Fi doesn't work, and you can't see the CTGs"). In contrast, Buckinghamshire participants reported implementation would likely be easier as the hospital was already paperless.

Patient Safety and Decision-Making Domain

A prominent theme was the "co-pilot in a plane" analogy, first raised at Oxford, framing the tool as a supportive safety net rather than a replacement for clinical judgment, with a Birmingham doctor emphasizing that "the physician still has the ultimate decision-making." The Fit4Labour tool was seen as particularly reassuring for junior staff and when presented with complex or ambiguous cases.

Participants valued the Fit4Labour tool to facilitate risk communication with patients, providing a "common language" for explaining probabilities and counseling women requesting care outside guidelines: "We are not informing patients of their real risks because we don't know, but this is what Fit4Labour can bring" (Doctor, Oxford). Some clinicians cautioned that transparent risk data might increase cesarian requests "for the price of honest communication of risk," while others felt it would reduce paternalism and enhance women's autonomy. Buckinghamshire participants emphasized its role in countering misinformation, particularly the perception that cesarian birth is inherently safer: "Patients think c-section is the safer option, often misled by social media; the tool can help address this and decrease requests."

Concerns regarding over-reliance and deskilling were also raised, with one participant warning that "it can deskill people… you will take shortcuts after a while." *Moreover,* participants highlighted the need for clear protocols to ensure the tool complements rather than replaces expertise. Perspectives evolved across sites, shifting from early skepticism about being "told what to do by a machine" to recognition of the tool as "an important piece of the jigsaw." Birmingham participants stressed balanced integration, underscoring that "your clinical judgment is always going to be important—see the patient beyond the technology." They also noted potential to rebuild trust in maternity care, with one participant observing that "maternity is in the public eye because of serious incidents and poor care. Social media doesn't help. Trust is broken. Fit4Labour can decrease this."

Mixed Methods Integration: Joint Display Analysis

Integration of quantitative and qualitative findings revealed strong convergence, with both complementary and contrasting insights (Table 4).

Convergence (direct alignment) was evident as high SUS and SEQ scores aligned with qualitative reports of intuitive design and ease of use, while completion times paralleled clinicians' descriptions of smoother workflows, which may translate to more efficient practice.

Complementarity (mutual enhancement) also emerged, with quantitative improvements in task completion times complementing qualitative concerns about resource constraints and highlighting both usability and systemic challenges. Quantitative differences between midwives and doctors were minor, but differences became evident for qualitative themes around escalation support and risk communication.

Dissonance (contrasting perspectives) appeared in 2 key areas: while learnability scores were high, participants still requested structured training, indicating that initial perceived ease of use of the Fit4Labour tool does not eliminate the need for formal instruction regarding its clinical application. Similarly, strong usability ratings contrasted with concerns about incomplete or "missing" risk factor coverage—highlighting that usability alone does not guarantee clinical comprehensiveness and further understanding of the limitations of the tool is needed.

XSL•FO
RenderX

Table . Mixed methods integration summary: convergence, complementarity, and dissonance across findings. Joint display illustrating alignment between quantitative and qualitative results, highlighting usability, workflow efficiency, and training needs.

Integration pattern and key findings	Evidence
Convergence	
Excellent usability	Validation phase SUS[a] scores (mean 85.8, SD10.2) independently met the "excellent" threshold and aligns with qualitative feedback stating both “very intuitive” and “easy to use.”
Co-development progression	SUS scores across co-development versions reflect iterative refinement reaching the excellent threshold by v3.0, consistent with participants’ growing familiarity with the tool’s ’co-pilot’ function.
Advanced feature complexity	More complex scenarios (eg, 4) had lowest scores (mean 5.7, SD 1.0), which aligns with concerns regarding the need for “structured and mandatory training.”
Complementarity	
Workflow integration	Within the validation phase, task completion times of 9.8 minutes were broadly feasible.
Performance predictability	Narrow SD (1.8 min) within the validation phase supported workflow consistency needs for ’rapid turnover in triage.
Professional group needs	Quantitative differences between midwives and doctors complemented qualitative emphasis on escalation support.
Infrastructure feasibility	Fast completion times (9.8 min) supported feasibility despite “Wi-Fi,” “charging,” and “compatibility” concerns.
Dissonance	
Learning versus training	High learnability scores (89.6%) contrasted with participants' expressed need for extensive training, reflecting the complexity of using the tool in clinical practice
Performance versus comprehensiveness	Excellent usability scores contrasted with concerns regarding “limited risk factors profile.”

[a]SUS: System Usability Scale.

Discussion

Main Findings

This multicenter mixed methods study demonstrated that the Fit4Labour tool developed through intensive co-design at a single NHS hospital independently met the “excellent” usability threshold (SUS >80) in simulated testing conditions at both validation sites, with consistent task completion times across 2 hospitals with different organizational contexts and digital maturity. Birmingham midwives reported lower usability scores (mean 76.3, SD 11.4), though still within the ’good’ range. This likely reflects the more critical evaluation standards based on their extensive clinical experience with existing triage systems, which strengthens the robustness of our validation findings.

Qualitative data reinforced these findings: participants described the Fit4Labour as a helpful triage and escalation tool, particularly for junior staff and as a shared “one language” for risk communication across professional boundaries. The spontaneous “co-pilot” analogy indicated that clinicians viewed the tool as supportive rather than substitutive, preserving autonomy while easing cognitive load. This preference for augmentation over automation mirrors findings from emergency triage settings, where professionals and patients alike favor hybrid digital-human approaches over fully automated solutions [44]. Although midwives and doctors have distinct roles, both groups reported that the interface met their needs, suggesting that a single design can accommodate diverse professional requirements in simulated testing conditions.

Clinicians also identified areas for improvement, including incomplete risk factor profile coverage, infrastructure barriers that may complicate seamless integration, and the need for structured training to support consistent use.

Comparison With Prior Work

Earlier evaluations of computerized cardiotocography systems in randomized controlled trials have shown limited benefit, with no clear improvements in neonatal outcomes or reductions in unnecessary interventions [45,46]. Systematic reviews suggest that for decision-support tools to make a real difference, they must be interpretable, reproducible, and trusted by clinicians, rather than simply replicating the same inconsistencies seen in human interpretation [45,47,48]. Fernandes et al [49], in a systematic review of intelligent clinical decision support systems for emergency triage, found that many such systems lack a formal implementation phase and that validated systems consistently improved clinician decision-making; this study directly addresses this gap by combining algorithmic development with structured multicenter usability evaluation.

The Fit4Labour tool represents a promising evolution in this field. Unlike earlier systems based purely on human

XSL•FO
RenderX

cardiotocography pattern recognition, it is a prognostic model trained on data from a large, multicenter clinical database, allowing it to produce standardized, evidence-based risk scores [32,33]. By providing clear, data-driven outputs, clinicians perceived the tool as having the potential to reduce variation in cardiotocography interpretation and to support less experienced staff, while complementing rather than replacing senior clinical judgment, perceptions that align with the tool's design intent but require prospective clinical evaluation to confirm.

These advantages are particularly relevant in the current maternity safety landscape. The UK Healthcare Safety Investigation Branch recently highlighted how unpredictable workloads and a constant need to juggle tasks in labor wards can compromise situational awareness and delay recognition of fetal compromise [50]. Participants in this study felt that the Fit4Labour tool could help maintain an overview of the full clinical picture, reduce cognitive load, and minimize the risk of overlooking important patient information. By alerting users when data is missing or incomplete, the tool also aligns with human-factors principles of error-tolerant design [51].

Similarly, national inquiries such as Ockenden and MBRRACE have underscored the role of poor communication and delayed escalation in adverse outcomes [29,30]. These findings resonate with observations from our study, where participants described using vague, non-specific expressions over the phone (eg, "I'm not happy with this trace") when escalating concerns about cardiotocography traces. Clinicians suggested that a numeric risk score could help reduce subjectivity in intrapartum communication, though this needs to be confirmed in adequately powered prospective studies.

Previous evaluations of computerized cardiotocography systems have reported variable user acceptance due to unclear risk calculations and scoring methods [45,52,53]. In contrast, participants found the Fit4Labour tool intuitive and transparent, which likely contributed to its positive usability scores. They also expressed interest in greater clarity regarding how individual maternal and fetal factors influence the overall risk score, including the relative weight of each contributing variable. Showing how these factors, together with cardiotocography interpretation and population data, feed into the score could help clinicians better understand and trust the tool's output, rather than viewing it as a "black box."

Finally, participants valued the unified interface that supported both midwives and doctors. Our findings indicate that a shared, role-sensitive interface can accommodate diverse professional needs while promoting interprofessional communication. This aligns with human-factors literature advocating shared mental models to bridge doctor–midwife silos, reduce fears of hierarchical barriers when escalating, and ensure complete, consistent communication in high-risk settings [54,55]. The slightly lower scores observed among senior midwives at Birmingham are consistent with evidence from emergency department settings, where senior physicians have been shown to report greater frustration with health IT systems than residents, attributed to higher expectations shaped by prior workflows. [56]

Human Factors Innovation: Cognitive Support and Communication

Intrapartum care involves complex decisions under uncertainty, where cognitive load, fatigue, and time pressure can compromise situational awareness. Participants described the Fit4Labour tool as "working for tired brains," highlighting its perceived value under conditions of fatigue, multitasking, and workload pressures, particularly relevant in maternity care. The design also appeared to support progressive disclosure: junior staff could rely on simple, color-coded outputs for rapid decision-making, while senior clinicians valued the ability to review detailed cardiotocography metrics and contributing risk factors. This layering helped ensure that transparency and autonomy were maintained without overloading users. In addition, when information was incomplete or omitted, the tool prompted users to add missing data, helping to reduce errors.

Clinical Integration and Implementation Considerations

In our analysis of over 147,000 births, the Fit4Labour algorithm identified about 1 in 3 babies who later showed signs of severe compromise, using only the first 20 minutes of cardiotocography at the start of labor [34]. Many of these babies were not recognized until 8 - 10 hours later, when emergency intervention was needed, suggesting that harm experienced during the birth process might be curtailed or even prevented. Although these results come from retrospective cohort analysis rather than real-time use, participants suggested that making risk visible, readily available, and quantifiable could support earlier and more consistent decision-making, especially when early cardiotocography changes are subtle. With maternity-related litigation in the UK now exceeding £37 billion (more than the annual cost of running maternity services), there is an urgent need for preventive, evidence-based innovations that reduce avoidable harm and help rebuild trust in care [57, 58].

Participants across all sites emphasized that structured clinician education remains essential for effective and consistent implementation. Training should go beyond button-clicking or navigation (interface use), focusing on supporting decisions and helping clinicians interpret risk, and communicating effectively with women. This approach ensures that the Fit4Labour *tool* outputs are translated into safe, evidence-based care rather than reducing decision-making to a "tick-box" exercise.

Interestingly, over nearly 2 and a half years of sessions, a noticeable shift in participants' views emerged, reflecting the broader uptake of digital technologies and AI in health care, with early anxieties about "being told what to do by a machine" evolving into recognition of a novel digital tool as a potentially "important piece of the puzzle" that enhances, rather than constrains, professional autonomy. This gradual shift also highlights increasing confidence in technology and the potential of digital tools to support decision-making and improve escalation pathways [59]. This trajectory is consistent with Longoni et al.'s framework, in which resistance to medical artificial intelligence is primarily driven by "uniqueness neglect," the concern that algorithms cannot account for individual patient characteristics. Fit4Labour tool's transparent,

XSL•FO
RenderX

interpretable outputs and preservation of clinical autonomy directly address this concern. [60]

Organizational readiness is likely to play a pivotal role in adoption. Digitally mature sites, such as Buckinghamshire, noted that the Fit4Labour tool could be easily integrated into existing workflows, while others cited unreliable Wi-Fi, limited computer access, poor and delayed IT support, and competing software as major barriers. These findings echo 'Consolidated Framework for Implementation Research (CFIR) v2.0,' emphasizing that infrastructure, culture, and implementation support, through training, local champions, and change management, are as important as usability for successful adoption [61].

Equity considerations also featured prominently in group discussions. Clinicians acknowledged the steps taken during co-development to promote inclusiveness in the user interface. These included design choices tested for accessibility among color-blind and dyslexic users, adaptations for staff wearing gloves when using touch tablets, such as larger buttons, and adjustments to font and button sizes to accommodate differences in visual acuity and hand size. However, participants also highlighted areas for further improvement. The current version is available only in English, which may create barriers for clinicians when explaining risk to non–English-speaking patients. Participants noted that using an interpreter or relying on a family member for translation, particularly over the phone, can make it more difficult to use the tool effectively in real time. Cultural factors may also influence how risk is communicated and perceived, underscoring the need for continued research and iterative refinement. Finally, participants noted that ethnic minority groups were not specifically represented and are likely underrepresented in the dataset used to refine the Fit4Labour algorithm, which could limit its generalizability. Ensuring inclusive design and representative data will be essential to prevent the reinforcement of existing inequities in maternity care [62].

Practical Implication for Digital Health Tools Development

Digital health projects often allocate significant resources to local customization (often between 15% - 20% of implementation budgets) [63-65]. In this study, the Fit4Labour tool maintained high usability across 3 hospitals with different organizational contexts and IT infrastructures when tested in the same version. This observation raises a practical question of whether intensive co-development at the outset might reduce the need for postdeployment customization. However, establishing this would require prospective studies comparing implementation costs and outcomes for tools developed with versus without intensive participatory design.

Future Research

Our team will conduct a regulated clinical evaluation of the Fit4Labour tool across multiple NHS sites to assess real-world safety, usability, and workflow integration, in line with Medicines and Healthcare products Regulatory Agency requirements for medical device approval [66]. This study will focus on outcomes such as escalation timeliness, reliability of communication, handover quality, and patient safety indicators.

We will also examine factors influencing sustained use and implementation, including the impact of structured training, local clinical champions, and integration into existing hospital systems. In parallel, our team will build on early health economic modeling to assess whether the usability patterns observed in this study translate into measurable cost savings and better clinical outcomes.

Beyond our own work, external validation in non-NHS health care systems is an important next step to determine whether the tool's core design principles transfer to other diverse health care contexts.

Finally, we will continue to engage directly with women, families, and PPI panels to explore how different ways of presenting risk information affect perception, autonomy, and trust. Embedding patient perspectives throughout these evaluations will help ensure that digital tools strengthen shared decision-making and enhance both safety and the experience of care.

Strengths and Limitations

This study has several strengths. The multicenter design, spanning 3 NHS hospitals with different organizational contexts and levels of digital maturity, provided a robust test of both usability and scalability across diverse settings. The mixed methods approach enabled convergence of quantitative usability metrics with qualitative insights into workflow, communication, and professional practice. Importantly, the locked-version (v4.0) validation offered a more rigorous test of scalability across diverse settings than is usually attempted in health care technology evaluations.

Our study also has important limitations. Usability testing was conducted in structured environments rather than during real-time clinical care, which may have increased observed task efficiency. However, as all sites used the same testing protocol, the relative comparisons between validation sites remain valid, even if absolute values might differ in clinical practice. Recruitment through departmental managers could have favored digitally confident clinicians, although efforts were made to capture a range of roles and experience. The involvement of members of the development team in evaluation may also have introduced bias, but this was mitigated by standardized protocols and independent analysis. The relatively small sample size (n=26) is consistent with Nielsen's guidance for usability studies and similar mixed methods implementation studies. No inferential statistical testing was performed, which is consistent with the exploratory descriptive aims of this work. Moreover, phase 1 and phase 2 differed simultaneously in tool version, participants, and clinical site, making between-phase inferential comparison inappropriate. Finally, the study was confined to NHS hospitals in the United Kingdom, which limits direct generalizability to health care systems with different funding models, workforce structures, technological infrastructures, or cultural norms. However, the 3 sites were selected to capture meaningful variation in organizational context and digital maturity, and the human-factors frameworks and usability

XSL•FO
RenderX

instruments applied are internationally validated. The core challenges addressed, variable cardiotocography interpretation, escalation delays, and risk communication, are not unique to the NHS and have been documented in maternity systems internationally. Future evaluation in non-NHS settings will be essential to establish broader applicability.

Conclusions

This study demonstrates that systematic co-development, grounded in human-factors principles, can produce clinician-facing decision-support tools that independently meet established usability benchmarks across NHS hospitals with different organizational contexts and digital maturity. The locked version (v4.0) showed high usability at both validation sites (SUS mean 80.7, SD 10.8 Birmingham vs SUS mean 90.8, SD 7.2 Buckinghamshire). Clinicians described the Fit4Labour tool as a supportive, like a "co-pilot" rather than a replacement for clinical judgment, and that it provided a shared language for risk communication with potential to strengthen confidence in escalation decisions. Other factors, such as organizational readiness, structured training, and adequate infrastructure support, will be important enablers of adoption. Whether usability in simulated settings translates to improved clinical outcomes in real-world practice, and whether these findings generalize beyond NHS settings, requires prospective evaluation.

Acknowledgments

We thank the Patient and Public Involvement panel from the Oxford Labor Monitoring Group for their advisory role throughout this study. We are grateful to all participating health care professionals, including midwives and doctors across the 3 participating hospitals within the National Health Service (NHS) in England, who provided invaluable feedback during system testing. Special thanks to the clinical managers, research midwives, and fetal monitoring midwives who facilitated this multisite study through their organizational support and coordination of testing sessions. We also acknowledge Dr. Sandra Morales Rios, researcher at the University of Oxford, for contribution to qualitative data coding and interrater reliability assessment.

Funding

This study was supported by a National Institute for Health and Care Research (NIHR) Invention for Innovation (i4i) Product Development Award (NIHR202117). The views expressed are those of the authors and not necessarily those of the NIHR or the Department of Health and Social Care.

Authors' Contributions

MT and XL designed and conducted the usability testing sessions and focus groups, extracted quantitative data, and performed qualitative coding analysis. MT conducted the statistical analysis of usability metrics and completion time data. DH contributed to qualitative data coding and provided interrater reliability validation. KG and JT served as the tool developers and software engineers, implementing iterative design modifications based on user feedback and providing technical support throughout the co-development process to enhance the Fit4Labour system. AG conceived the original Fit4Labour tool concept and provided overall oversight and strategic guidance for the project. All authors made substantial contributions to manuscript preparation, critically reviewed the content, and provided final approval for publication.

Conflicts of Interest

All authors are or have been members of the Oxford Labor Monitoring Group at the University of Oxford, which conducts research on intrapartum fetal monitoring and decision-support tools. This study involved usability testing and evaluation of the Fit4Labour tool, which may be commercialized in the future through a planned company called Safer Birth. No commercial entity provided funding for this research, and the potential for commercialization did not influence the study design, data analysis, or interpretation. All results are reported transparently, regardless of their implications for future commercialization. JH is supported by a UKRI Future Leaders Fellowship (MR/Y033833/1).

Abstract

Background: Overdose fatality reviews (OFRs) are an important public health tool for developing local overdose prevention strategies by reviewing individual overdose cases. While this approach offers a rich, contextual understanding of drug overdose factors in communities, it examines a small number of cases, providing limited insight into broader population-level risk patterns. To complement OFRs, we developed a real-time dashboard that visualizes trends about 5 key "touchpoints" (ie, interactions with medical and justice services preceding overdose). We then trained local OFR teams to use this dashboard to identify prevention opportunities.

Objective: This study examines the integration of population-level data into OFR practices, as well as the tensions that emerge between OFRs' traditional case-driven review processes and the statistical, population-level analysis typical in public health. We analyze how and when the dashboard was used in meetings, determine the extent to which the data informed recommendations, and identify barriers that prevented the broad uptake of this intervention.

Methods: We observed 26 OFR meetings across 11 counties in Indiana over 10 months, from November 2024 to September 2025, during which teams conducted case reviews and developed recommendations. We documented instances of dashboard use as well as "missed opportunities," in which relevant population-level data were available but not incorporated into the discussion. We also conducted semistructured interviews with OFR team members (n=7) to understand their perceptions of the dashboard, including its usefulness, usability, and adoption barriers.

Results: Despite its intended role, the dashboard was rarely integrated into OFR meetings; it was used only 10 times, compared to 114 missed opportunities in which relevant data could have informed discussions. Interviews revealed that this limited uptake was not solely due to usability barriers but reflected a deeper tension between 2 distinct analytic approaches. OFR teams prioritized narrative-driven case reviews that were grounded in empathy, local knowledge, and lived experience. This approach seemed at odds with the population-level visualizations shown in the dashboard, which required statistical abstraction and interpretation. Other barriers identified included limited time and resources, staff turnover, and varying levels of data fluency, which made it difficult for teams to confidently interpret the dashboard despite training.

Conclusions: The results highlight a tension between case-based and data-driven approaches to overdose prevention. These approaches are grounded in different workflows, values, and motivations, making it challenging for OFR teams to maintain their traditional, empathetic review practices while incorporating population-level trends. Our findings indicate the need for data tools that bridge these approaches, such as visualizations that connect aggregate patterns to individual cases. The results also underscore the need for additional support and training for teams, such as dedicated data specialists who interpret population-level trends and provide insights to augment team discussions and inform prevention strategies.

Introduction

The United States has seen a dramatic rise in drug overdoses over the past two decades, from 6.1 to 32.4 deaths per 100,000 people between 2001 and 2021 [1]. Although overdose fatalities have declined recently, the number remains high [2,3]. The response to this epidemic is further complicated by variations in risk factors across regions [4] and subpopulations [5]. Addressing this crisis thus requires data- and evidence-informed interventions tailored to the needs and challenges of local communities.

To encourage effective local overdose prevention, the Centers for Disease Control and Prevention has promoted local overdose fatality review (OFR) teams, first implemented in Maryland in early 2014 [6]. These teams unite public health, law enforcement, and emergency response stakeholders to review overdose cases. By analyzing decedents' histories and their interactions with services, teams can identify risks and gaps and recommend targeted prevention strategies [7]. Although some OFR teams have generated effective recommendations [6], this review model typically draws insights from only a handful of cases (2 - 3 per month or quarter) [8]. Such reviews provide rich qualitative insights into system and service gaps in local communities but may lead to recommendations that overlook broader overdose risk factors. Although some teams supplement their case reviews with quantitative data, these analyses are often based on small sample sizes, offering only a partial picture. This limitation presents an opportunity to enhance the OFR model by incorporating population-level data through a real-time dashboard, enabling more comprehensive, data-driven recommendations.

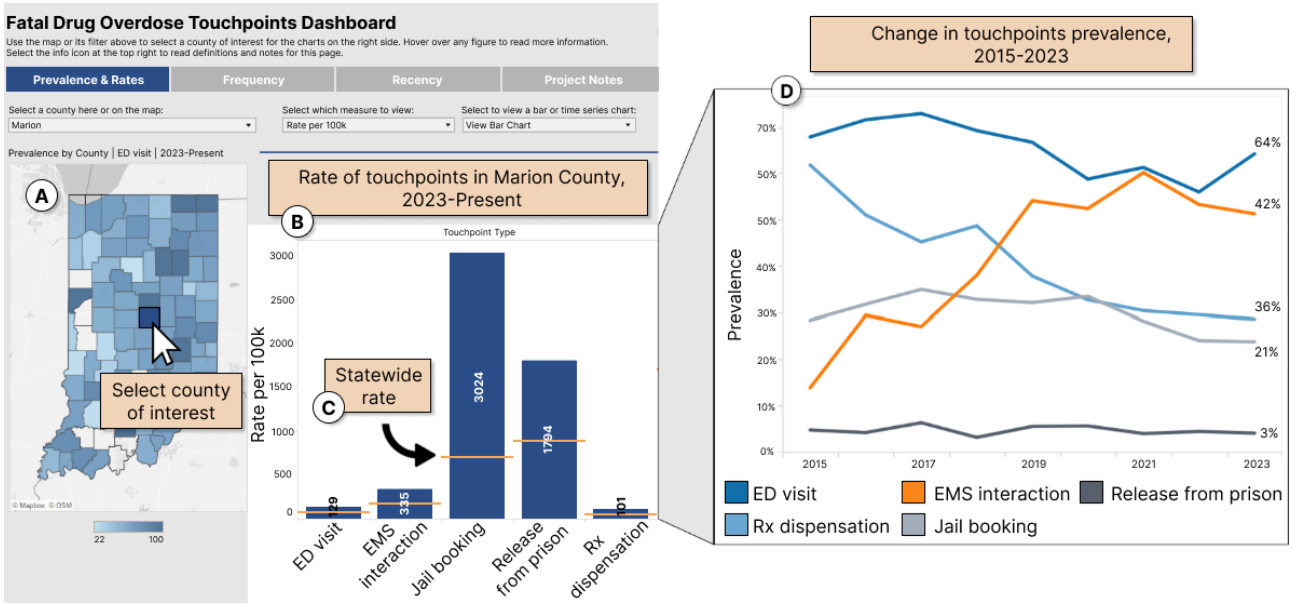
To address this opportunity, we partnered with the Indiana state government starting in September 2022 to develop and deploy a dashboard that provides OFR teams with real-time data about touchpoints—events and services individuals interact with *before* experiencing a fatal overdose [9,10]. The dashboard provides statistics about key touchpoints, including interactions with emergency and medical services and justice systems [11]. To introduce local OFR teams to the dashboard and provide guidance on using its data, we invited participating teams to a 2-day training workshop focused on population-level data use and evidence-based overdose prevention.

While dashboards have found success in public health settings [12-15] and are extensively used to monitor overdose trends [16-18], their use by OFR teams has received little attention. Even when team members receive training on integrating the dashboard, it represents a new, potentially fundamental change to the OFR process. Teams can also be highly diverse, including many stakeholders with no formal training or experience in data analysis. Thus, it is important to understand how data-driven approaches to overdose prevention are adopted within OFRs, including potential barriers to their uptake.

The goal of this study is to evaluate how well OFR teams can integrate a population-level touchpoints dashboard into their existing practices and whether they can inform their recommendations using touchpoint data alongside traditional case reviews. Specifically, we ask: (1) How frequently do teams consult the dashboard during OFR meetings? (2) To what extent do team members draw insights from dashboard data to make actionable recommendations for preventing overdoses? (3) What challenges do OFR teams face in effectively incorporating the dashboard into their existing workflows? To answer these questions, we observed OFR team meetings and analyzed their dashboard use, as well as any missed opportunities. We then followed up with interviews with team members to better understand their perceptions of the dashboard's utility and the barriers they faced in fully using it.

Methods

Study Setting



The study took place in the state of Indiana as part of the FORTRESS (Fatal Overdose Review Teams: Research to Enhance Surveillance Systems) project. Indiana has encouraged and expanded the use of local OFR teams in recent years, with teams organized at the county level. Most teams convene to review cases in a single county, but some teams oversee multiple jurisdictions, particularly in rural, low-population areas of the state. Organizational support and resources for OFR teams are provided by the Indiana Department of Health (IDOH).

The touchpoints dashboard used in this study was designed and developed through a user-centered design process that included formative focus groups with OFR experts to identify data needs, followed by an iterative design and feedback process. The expert group included experienced OFR practitioners as well as early developers of the OFR model from across the United States. The dashboard uses a record-linking process, integrating state mortality and administrative datasets to assemble a history of decedents' interactions with touchpoints and covers all overdose fatalities in the state between 2015 and the present. The focus on visualizing touchpoints that precede overdoses, as opposed to showing overdose trends [16-18], is meant to encourage a prevention-oriented mindset, consistent with the goal of OFRs. Five touchpoints are included in the dashboard: visits to the emergency department (ED), encounters with emergency medical services (EMS), dispensation of prescription drugs (Rx), jail bookings, and releases from prison. The dashboard supplies aggregate statistics displaying decedent data in the 12 months preceding their fatal overdose. These include the prevalence of these touchpoints (eg, percentage of decedents who had visited the ED in the year preceding their fatal overdose), and the rate of overdose among all touchpoint users (eg, the fraction of prison releasees who went on to experience a fatal overdose in the 12 months following their release). These two metrics help teams estimate both the potential reach of interventions in their community (prevalence) and the relative risk associated with specific touchpoints (rate). Additional measures provided by the dashboard include touchpoint frequency (average number of encounters) and the mean time between the last touchpoint interaction and death. Crucially, the dashboard, first deployed in 2023, breaks down all statistics by county, allowing teams to view data in their locality. Figure 1 illustrates two views from the dashboard. Full details can be found in Salvi et al [11]. The dashboard data are continuously

XSL•FO
RenderX

refreshed in (near) real time, approximately every 1 to 2 weeks for most touchpoints.

Figure 1. The FORTRESS (Fatal Overdose Review Teams: Research to Enhance Surveillance System) dashboard [19] shows overdose touchpoints in Indiana at the county level. The dashboard provides data on 5 touchpoints: interactions with the emergency health services (ED and EMS), legal systems (jails and prisons), and the dispensation of scheduled drugs. Visualizations illustrate the spatial distribution of touchpoints in the state (A), the rate of touchpoints in the selected county (B) versus the state average (C). The dashboard can also show how the prevalence and rates of touchpoints have changed over time, both within counties and across the whole state (D). ED: emergency department; EMS: emergency medical services; Rx: medical prescription.

Recruitment and Implementation Strategy

We recruited OFR teams for the study by reaching out to all active teams within the state. The list of active teams and their contacts was provided by IDOH. At the start of recruitment in February 2022, Indiana had nearly 2 dozen active OFR teams, with 5 more teams expected to begin meeting within the year. Of these teams, 19 responded to our recruitment and provided consent and letters of support to participate in the study. The recruited teams represented a variety of counties within the state, including both rural and urban communities. Recruited OFR teams were organized and introduced to the study using a stepped-wedge cluster design [20], in which 3 cohorts received training in successive waves (in October 2024, May 2025, and October 2025). Cohort 1 included 6 OFR teams, Cohort 2 included 8, and Cohort 3 included 5. Each training session lasted 2 days and covered dashboard functionality and data interpretation, evidence-based prevention practices, and strategies for developing actionable recommendations. Two members from each team, including the facilitator, were invited to participate in the training.

This study includes only observational and interview data from Cohorts 1 and 2, as Cohort 3 had not yet been observed at the time of writing. We sampled 11 OFR teams from the first 2 cohorts: 5 from Cohort 1 and 6 from Cohort 2. Teams were selected based on meeting schedules and the observer's availability. The observer attempted to maximize the number of meetings observed by attending as many meetings as feasible within the study period. All 11 teams observed had completed the 2-day training. Observations for Cohort 1 teams were conducted between November 2024 and September 2025, and for Cohort 2 teams between July 2025 and September 2025.

Following observations, we recruited 7 OFR team members for one-on-one interviews via email. We identified prospective interviewees through OFR team mailing lists and sent recruitment messages that included the purpose, duration, compensation, and a formal information sheet. We reached out to 9 members, 7 of whom ultimately responded and agreed to participate in the interview. Recruitment prioritized facilitators, given their depth of experience with the OFR process and their key role in conducting the meetings, although participation was not limited to them.

Data Collection

Meetings primarily covered overdose cases, with some also covering suicide cases (which we did not analyze), lasting 2 hours on average. A member of the research team (the first author) attended all meetings as an observer and documented the discussions by taking notes on dashboard use and missed opportunities. The same researcher then conducted semistructured follow-up interviews with 7 members from different OFR teams. Interviews represented diverse professional backgrounds and varying levels of experience with data. Interviewees included a registered nurse (RN), a police social worker (PSW), a nonprofit organization director, a behavioral health data analyst, a medication-assisted treatment (MAT) specialist, and OFR facilitators (see Table 1). The interviews were conducted over Zoom and lasted 20 to 30 minutes. Interview questions focused on participants' experiences with data, their perceptions of dashboard usability and utility, and the barriers they faced to its use (see Multimedia Appendix 1). This paper reports on insights from both observational studies and interviews [21,22]. This combination has been proven useful [23-25], particularly for evaluating dashboard use and utility for making data-driven decisions [26].

Table . Summary of interview participants' backgrounds and data experience.

Participant ID	Role/background	Extent of data experience	Served as OFR[a] facilitator?
P1	Nonprofit organization director	Research assistant with data analysis experience during undergraduate and graduate studies	Yes
P2	Project manager	No data tool training apart from FORTRESS[b]	No
P3	Behavioral health data analyst	No data tool training apart from FORTRESS	Yes
P4	OD2A[c] contractor	Previous experience with similar dashboards	Yes
P5	MAT[d] specialist	OFR training in addition to FORTRESS training	Yes
P6	Registered nurse	Graduate degree in statistics	Yes
P7	Police social worker	Extensive experience in data (collection and analysis)	Yes

[a]OFR: overdose fatality review.

[b]FORTRESS: Fatal Overdose Review Teams: Research to Enhance Surveillance System.

[c]OD2A: Overdose Data to Action.

[d]MAT: medication-assisted treatment.

Data Analysis

During the observations, we recorded instances in which the team's discussions and case reviews referenced 1 of the 5 touchpoints on the dashboard. Specifically, we noted: (1) dashboard use, where teams consulted the dashboard, for example, by looking up the prevalence or rates of touchpoints, (2) missed opportunities, where the discussion revolved around touchpoints for which there were data in the dashboard but where teams did not make an attempt to consult those statistics, and (3) nondashboard touchpoints (eg, housing-related) that the team discussed but for which there were no quantitative data. In addition to case discussions, we also analyzed the team's recommendations, focusing on dashboard use and missed opportunities. To analyze meeting data, we developed a codebook through an iterative coding process. We started with an initial set of codes that covered touchpoints referenced during the meetings, dashboard uses, and recommendations made. The codebook was refined iteratively and expanded to identify more specific types of dashboard use and missed opportunities. Meeting notes and observations were entered into an Excel sheet and assigned appropriate codes.

For the interview data, we used thematic analysis to identify recurring themes [27]. The interviews were video-recorded and transcribed. Interview questions suggested preliminary thematic categories related to dashboard usability, how it complements case reviews, challenges, and future improvements. We supplemented these with an open coding process to identify and tag additional topics that emerged from participants' responses. We then iteratively refined the codes, developed a codebook, and grouped the final codes into 3 broad themes relating to (1) the extent of dashboard use during and outside meetings, (2) advantages of the dashboard, and (3) challenges in using and interpreting the dashboard. See Checklist 1 for the completed Consolidated Criteria for Reporting Qualitative Research (COREQ) checklist for the study design and analysis.

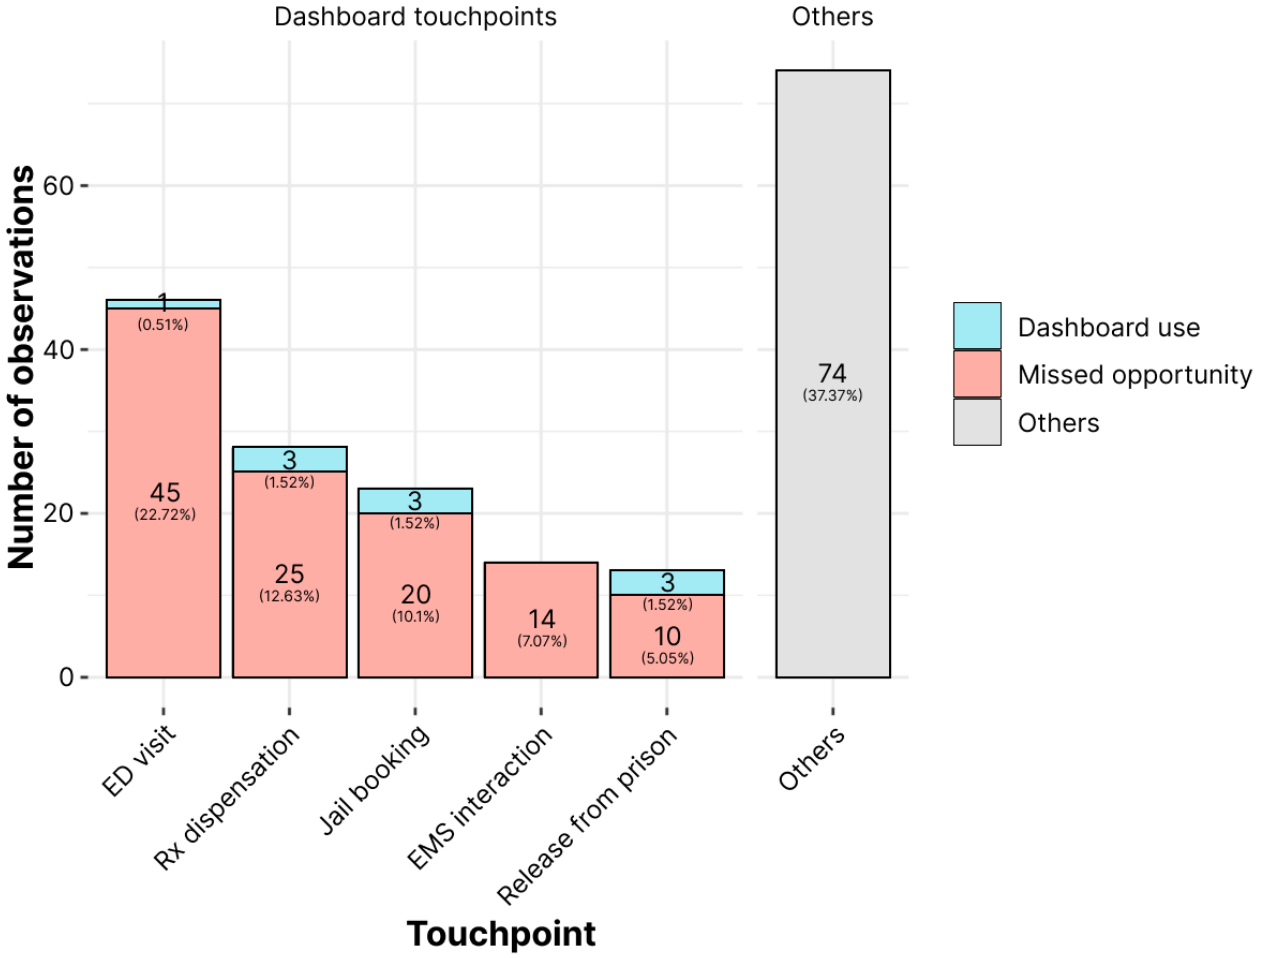
Ethical Considerations

This study was reviewed and approved by the Indiana University Institutional Review Board (15922). Participants in the interviews received an information sheet explaining the study goals and procedures before agreeing to take part. Participants received a US $40 gift card as compensation for the interviews. The dashboard displays only aggregate, population-level visualizations. No individual records were displayed in the dashboard to preserve anonymity.

Results

Dashboard Usage and Missed Opportunities

We first present our observations from OFR meetings on dashboard use and nonuse. Each OFR meeting typically lasted 2 hours, during which teams discussed 2 to 3 decedent cases. We observed a total of 48 overdose cases being discussed. The case reviews covered decedents' demographic backgrounds, obituaries, toxicology reports, medical histories, prescriptions for controlled substances and other medications, justice involvement, and next-of-kin interviews. Based on these, a timeline was constructed for each decedent that highlights the major events and touchpoints in their lives. The team discussed the case, identified service gaps, and recommended programmatic changes or policies to prevent future overdoses. Out of the 26 meetings we observed, the dashboard was used in only 2 meetings, where it was referenced either during case reviews or for making recommendations. Some meetings (10/26, 38.46%) also included a discussion of the county's overdose trends and counts, typically using historical data from prior years obtained from the coroner's office. However, none of this



XSL•FO
RenderX

data overlapped with or provided detailed touchpoint metrics like those available in the FORTRESS dashboard.

To identify where the dashboard had been—or could have been—used, we coded all touchpoint occurrences in cases where the dashboard provides data. Recall that the dashboard provides data about 5 touchpoints. The most frequently occurring touchpoint was an ED visit, which occurred in 37.1% (46/124) of cases. This was followed by Rx dispensation (28/124, 22.58%), jail bookings (23/124, 18.55%), EMS interactions (14/124, 11.29%), and releases from prison (13/124, 10.48%).

In addition, we identified 74 other touchpoints (ie, interactions with systems such as mental health support, temporary housing, and system enhancements) for which the dashboard does not provide data. When OFR teams encountered 1 of the 5 touchpoints in a case, they used the dashboard 10 times across all observed meetings. By contrast, we identified 114 missed opportunities in which cases included touchpoints for which the dashboard provides data, but the information was not looked up or used during the discussion. Figure 2 illustrates the frequency of data use and missed opportunities across the 5 touchpoints.

Figure 2. Frequency of touchpoints from all observed meetings. ED: emergency department; EMS: emergency medical services; Rx: medical prescription.

Although limited, the use of the dashboard during meetings ranged from simple data readouts to contextual interpretation of the data and, in some cases, to generating actionable recommendations. At a basic level, there were 2 instances in which teams simply read data aloud when a case included 1 of the 5 touchpoints. For example, in one meeting, the facilitator distributed printouts showing the prevalence and rate of fatal overdoses associated with the ED touchpoint, noting that their county had a higher prevalence (73% of decedents had visited the ED in the year prior to death, compared to 64% statewide). This data, however, were not taken up further in the discussion. In a more interpretive use pattern, there were 4 instances in which teams engaged with the data by drawing on local knowledge to make sense of population-level trends in their community. For example, in one meeting, the team noted that individuals released from prison had a higher rate of fatal overdose in their county (1067 per 100,000 releases, compared to 704 statewide). This prompted a discussion of this elevated risk, with team members attributing it to factors such as lack of housing, limited support services, and barriers like suspended driver's licenses upon release. At the highest level of use, we found 4 instances in which teams translated observed patterns into recommendations. In one case, a team noted a higher prevalence of Rx dispensation for scheduled drugs among decedents in their county (56% vs 45% statewide), and identified a gap in what they described as a "transactional" system of care. They recommended educational initiatives and training for pharmacists to better support individuals in situations such as when medications are unavailable. In another instance, after observing a higher prevalence of jail bookings in their county (37% vs 25% statewide), a team recommended educating

XSL•FO
RenderX

incarcerated individuals about changes in their drug tolerance following release.

Overall, dashboard use was rare during OFR meetings: teams used it only 10 times. Most of our 114 observations were *missed opportunities*, where teams did not consult available population-level dashboard data during discussions or recommendations about touchpoints in decedents' cases. For example, in one meeting, the team reviewed a case where the decedent had a jail booking, 4 ED visits, and a prescription refill in the 12 months prior to their fatal overdose, yet the discussion centered on childhood factors and substance use disorder history. By contrast, the dashboard indicated that the county had a substantially elevated overdose rate following jail bookings (992 per 100,000 vs 469 statewide) and a slightly elevated Rx dispensation prevalence (40% vs 35% statewide). These data could have supported recommendations targeting more immediate intervention points, such as jails or pharmacies. In another meeting, despite a decedent having 18 ED visits and an EMS interaction in the prior year, the team focused on the decedent's failure to use peer recovery programs rather than on the high-risk touchpoints themselves. The dashboard, by contrast, showed above-average county rates for both ED visits and EMS interactions and indicated that 25% of decedents with these touchpoints fatally overdosed within 2 weeks. These 2 examples illustrate missed opportunities to use dashboard data to identify and prioritize touchpoints based on their risk (rate), reach (prevalence), and immediacy (recency).

Barriers to Integrating Population-Level Data in OFRs

Overview

We now discuss themes that emerged from interviews with OFR team members, including barriers to integration and future opportunities for data-driven prevention. Interviews shed light on several reasons behind the limited use of the dashboard during meetings. Reported barriers included tensions between case-based review and population-level analysis, varying levels of data literacy among team members, and limited time and resources.

Tension Between Case-Based Review and Population-Level Analysis

Participants highlighted a key distinction between OFRs, which focus on the detailed examination of a select few decedent cases, and the population-level data analysis provided by the dashboard. They contrasted OFRs' case-specific, narrative-driven analysis with the broader, aggregate approach typical in academic and public health settings. This contrast implies that OFR members apply mental models and analytical processes that differ from how the data are presented in the dashboard:

> *People we work with don't think or talk about data in the same way, so we don't think about what a quartile or an odds ratio is. At least not in the way it's supposed to. And that's some of the potential disconnect between something that is research–based and fact–based, and how we think of it in academia versus the random person on the street that will easily say, that's 5 times more likely. And that's not actually what they mean, but when it's used in that academic setting, it can get a little bit lost in translation.* [P1, nonprofit director]

Another aspect of the tension between approaches is the inherently empathetic nature of OFR case reviews, which is central to how teams understand cases. Team discussions focus on decedents' lived experiences, using that perspective to identify the challenges they faced and the factors that may have contributed to their overdose. In some instances, team members even recognized the individuals being discussed or knew their families. This empathy and attention to individuals can feel at odds with the statistical abstraction of population-level data:

> *What gives people motivation to work on top of their day-to-day workload on a goal is, their hearts, right? So, we just looked at the life and death of this individual we need to change X, Y, and Z, and these are the numbers to support it. I think that's where data usually falls short. Because we were looking at this qualitative section of this life; details that the numbers are missing... that's the SOFR [Suicide and Overdose Fatality Review] magic right there.* [P5, MAT specialist]

Limited Data Literacy and Tacit Knowledge

All participants highlighted limited data literacy as a key barrier, making it difficult for them to confidently draw appropriate inferences from the dashboard. They pointed out that the OFR teams comprise members from diverse backgrounds, many of whom do not possess data analysis skills:

> *Most of the room aren't data people. They want to focus on the case, what happened, and how can we make this better for our county. When people ask for data, they want to know, but in a way that they can digest it. So, if we get too into numbers and aggregate, we lose people.* [P5]

Participants noted that this limited experience raised a concern that the data could be misinterpreted, even with tooltip-style annotations and training videos included with the dashboard:

> *We had a disagreement of what this actually means, and how do we actually interpret it? Because it has lots of data, that's just really easy to get wrong.* [P1, nonprofit director]

Participants also noted how interpreting the dashboard can be particularly challenging in small counties with lower populations:

> *You have to really explain rate per 100,000... we're working in rural areas where we have, 8 [overdoses] total in a year, but then we're looking at numbers in the 50s and 60s, and so they're like, wait, what's happening? So, it isn't something that someone could just pick up and understand.* [P5, MAT specialist]

Participants also noted that many OFR members have a qualitative understanding of the key touchpoints in their community and do not feel the need to consult a dashboard to confirm their knowledge with raw numbers.

XSL•FO
RenderX

> *We talk commonly in our meetings, [that] person was released from jail and died of an overdose 24 hours later. That's common, we know that a lot of people do that, but we don't put a specific number on it. We all see those issues happening every day, and we don't need to say, 1 in 10 people getting released will experience this. Because of the work, we know the parameter without being able to put a specific number on it. There's definitely value to know the actual statistics so we can keep educating the community and justifying the cause. But it just takes more time.* [P7, PSW]

Perceived Data Stagnation and Insufficient Granularity

Although the dashboard updates in near real time, participants noted that its data rarely changed between meetings, as touchpoint prevalences and rates tend to remain stable over several months within most communities. This apparent stagnation appears to reduce the incentive to consult it regularly:

> *We don't need [the dashboard] all the time... ultimately, with this data, I doubt they're changing drastically month to month. Once we've identified what our patterns are, that's probably where it's staying. And so, I think we use it when we need it, but when we need it is not a weekly or even usually a monthly thing.* [P1, nonprofit director]

> *It's cumbersome to look at the dashboard at each meeting, because we're not going to see a lot of change in the numbers. So, I try to space [usage] out [so teams] not looking at the same graph, the same numbers, the same data each time.* [P5, MAT specialist]

One participant stated that they never used the dashboard because the data were not granular enough for their needs. While the dashboard breaks down touchpoints by county, consistent with how OFR teams are organized, larger urban counties tend to dedicate meetings that focus on risks for specific demographic groups or locales (eg, veterans, African American males over 50, overdoses at motels or hotels). This level of detail is not available in the dashboard:

> *It [the dashboard] kind of presents some general ideas and directions for us to go, but typically our meeting themes are more granular and more subsect from the dashboard.* [P4, Overdose Data to Action contractor]

Impact of Staff Turnover and Resource Constraints

Participants noted staff turnover and lack of resources as barriers to consistently incorporating the dashboard into meetings. They cited members leaving the team, facilitators having to manage multiple county meetings, and leadership and funding changes:

> *We had built out a "here's how we could use it, and here's what we should use it for". That got derailed when my staff person left. It needed somebody that wasn't me to carry [the dashboard implementation] out... With some of the staff turnover, we have used it less.* [P1, nonprofit director]

> *IDOH covers the OFR teams, and there has been so much structural change over the last few years as far as leadership, it is difficult [for facilitators] to figure out who's in charge, who do I go to [for directions].* [P6, RN]

Participants also highlighted the high workload and the lack of time and resources as additional barriers:

> *...people are pretty worn out. It was a hard time already doing all of this work, and now with all the funding cuts and the upheaval of nonprofits, they're not quite sure which direction to go, so FORTRESS is a great dashboard, but sometimes it's just one more thing [to learn and use].* [P6]

Importantly, one participant felt that dedicating a portion of the meeting to analyzing the dashboard data would, in effect, reduce the time available for case review, discussions, and/or recommendation making:

> *I think one is time constraint. Do we do it at the beginning, middle, or have specific meetings? Every meeting feels different, the cases flow differently. It also depends on everyone's vibe. We do two cases in two hours, and we are usually left with very little time to discuss recommendations.* [P5, MAT specialist]

Opportunities for Leveraging Population-Level Data in Prevention

Overview

Despite the obstacles to integrating the dashboard into OFR practices, participants highlighted several value points, both in and outside meetings, particularly in making local touchpoint data more accessible and serving as a resource for advocating policy changes.

Increasing Engagement Through Data

Participants noted that the dashboard can provide additional perspectives during meetings, particularly for touchpoints where representative stakeholders are absent:

> *The biggest thing is who's not at the table that can speak to that data intimately. We don't have EMS services at our table, so when we're going through recommendations, we don't have that viewpoint. So, when we're reflective on FORTRESS data, we can kind of talk to that.* [P6, RN]

Conversely, it was noted that the dashboard can help identify prevention and improvement opportunities, especially when stakeholders who can understand the data and influence change at specific touchpoints are present at the meeting:

> *If there are people in the room that have that ability to have impacts... having somebody in the room who can see the data, understand the data, and change something in my office. That's where I think it's [dashboard] most impactful.* [P1, nonprofit director]

Access to Local, Timely Data

Even without full integration of the dashboard into OFR practices, team members recognized a key benefit: centralized

XSL•FO
RenderX

access to comprehensive, timely, local-level data that may otherwise be difficult to obtain. Participants highlighted the value of the dashboard's high-level county data, particularly for smaller counties with limited access to hospital and prison information:

> *We're in a smaller community... data that the FORTRESS dashboard uses isn't usually data we have great access to like, Department of Corrections and EMS data. So it provides that guidance.* [P1, nonprofit director]

Participants also cited the dashboard's consistent updates as a major advantage (weekly for most data), even though they might not necessarily be needed during the meetings but for external needs such as pushing policies:

> *What makes the dashboard really nice is that it is current data. I think a lot of boots on the ground in the community, or at least entities like us need up-to-date data at the drop of a hat for an XYZ reason.* [P1, nonprofit director]

They noted the convenience of having all relevant data compiled in one place, explaining that this made it easier for teams to quickly spot trends and patterns that might have otherwise gone unnoticed:

> *[Looking at] the prevalence, we were kind of like, whoa, I had no idea it was like this. So, we always hear about it, but to actually see the data, it was really eye-opening.* [P3, behavioral analyst]

From Data to Action

Participants' comments suggested that the dashboard has the potential to achieve its intended purpose. Three participants noted that it can help address limitations of the case-based review process by encouraging teams to consider how prevention opportunities might apply more broadly, beyond individual cases. As one participant explained:

> *In our county, there are people coming out of prison, and we don't have a lot of information, so I think that that would be a good opportunity to bring [the dashboard] up. What can we do, maybe not for this specific case, but for this population in general, how can we reach them?* [P3]

Five participants noted that the dashboard can be a valuable tool for translating data into actionable insights, particularly for informing policy and programmatic decisions, although they recognized that realizing these opportunities often depends on external constraints, such as funding:

> *The dashboard could really be useful if we get a state-level OFR partner group, where we were going to try to present things to policymakers, [eg,] being able to show we need to give a lot more support to our justice-involved individuals. That is a really clear takeaway from this dashboard... nice to have that kind of data there and visualized.* [P4]

> *When I was looking through the dashboard, I could think, we have 10 different initiatives that would be good at addressing what the data was saying. I think the question is always funding, right? So, we can look at the dashboard and say, I can envision XYZ, but we need the dollars to do it.* [P7]

Other Dashboard Uses

Participants reported ways to use the dashboard that we did not observe directly, such as prioritizing recommendations:

> *We had a recommendations meeting, that's how we decide what recommendations to move forward on. We decided to focus on jail discharges, because that was huge... [and] this is a recommendation we can reach the most people with. I think it has been really impactful, because we had a lot of recommendations, and we were kind of like, where do we start?* [P3, behavioral analyst]

Participants also reported use outside of OFR meetings to provide the data to support for certain recommendations and initiatives:

> *I had pushed for having Narcan and test strips in our lobby and there was a lot of pushback against it. Through FORTRESS, [for] the first time I've been able to point to a statistic and say, 'this is why it's so important that we have this in the lobby.'* [P7, PSW]

Discussion

Principal Findings

OFR teams are an increasingly important public health intervention for preventing overdoses through locally tailored strategies. Traditionally, these teams conduct case reviews for a small number of decedents to identify system gaps, risk factors, and corresponding prevention opportunities within their communities. The FORTRESS dashboard was designed to augment this case-based review process by incorporating population-level data on touchpoints that precede overdoses. This study sought to examine the extent to which teams integrated the dashboard into their workflows, identify barriers to its use, and highlight opportunities for more effective integration.

Over a 10-month period, we observed 11 OFR teams in 26 meetings and found limited integration of the dashboard into those meetings. Specifically, teams consulted the dashboard in only 8% (2/26) of instances where it could have informed a case discussion or recommendation. In those few instances, dashboard use ranged from simple data lookup to informing concrete recommendations, suggesting that it can support both basic and more advanced analytical needs. However, overall uptake was limited, as teams frequently discussed touchpoints for which the dashboard provided relevant data but did not appear to use it. In effect, we observed many more missed opportunities to incorporate population-level insights into teams' discussions than actual uses. Interviews with team members uncovered several barriers to this limited uptake, as well as opportunities to improve integration.

Barriers and Opportunities

Interviews suggest that OFR teams have a strong preference for traditional case-based discussion. The OFR review process is

XSL•FO
RenderX

inherently qualitative, relying on narratives to reconstruct the decedents' timelines and to understand key events, gaps, and factors that may have contributed to their overdoses. Teams also routinely draw on next-of-kin interviews, often attempting to interpret cases from the decedent's perspective. This approach is deeply contextual, empathetic, and centered on individual lived experiences. Yet, this mode of sense-making can seem at odds with population-level analysis, in which individual experiences are abstracted into aggregate statistical measures. As a result, the case-based model for OFRs, while effective for generating contextual insights, may inherently discourage engagement with quantitative data, keeping teams focused on individual cases rather than broader risk patterns.

The current dashboard design, which separates population-level data from case-specific details, may have limited its use. Pisani et al [28] showed that data decoupling can increase OFR teams' cognitive load and recommended integrating population-level data with case-level modeling tools within a single dashboard. Our findings support this approach but further indicate that visualizations should directly merge aggregate data with anonymized case details. For instance, a timeline view could show a decedent's touchpoints while embedding population-level metrics within the same view. In such a design, individual touchpoints could be shown as points along a timeline, with their size reflecting prevalence among county residents (eg, larger points indicating more common occurrences) and color representing overdose risk (eg, deeper red indicating higher rates). By linking individual trajectories with broader population-level data in a single view, such visualizations could help teams better identify population-level patterns during discussions. This approach may also align better with existing OFR workflows, which focus on case narratives, making adoption more likely, as tools that match established practices are readily accepted [29].

Another consistently cited barrier to adoption is the limited data and visualization literacy among team members. OFR teams include stakeholders from diverse fields, such as social work, coroner services, and law enforcement, with varying levels of data expertise. Thus, difficulty in interpreting population-level data remains a key factor limiting dashboard use. These challenges are consistent with evaluations of public health dashboards, which indicate that users often struggle to interpret visualizations without support [13,30-32]. However, previous studies show that visualization skills can be effectively learned through video and interactive tutorials [33] and that users with low data literacy benefit from storytelling or narrative elements included in the dashboard [34]. In response, we developed additional training materials in the form of short videos that demonstrate how to interpret the dashboard and apply its data to make actionable recommendations.

Barriers appear to extend beyond data literacy. Some participants described the dashboard as an added burden alongside existing case-review responsibilities, leading to reluctance to engage with it. Others felt they already had sufficient knowledge of local risk factors and did not see the need to consult the dashboard, further limiting its uptake. One potential solution is to designate a dedicated data analyst within OFR teams to explore population-level data, interpret trends, and communicate key findings to the group. This approach allows other team members to focus on case discussion and recommendation-making rather than data interpretation [35,36]. Some teams that we observed have already adopted a similar model by appointing a "data specialist" to review external data sources. Traditionally, this role has involved working with tools such as REDCap databases, which provide limited quantitative information on reviewed cases. Expanding this role to include dashboard use, supported by additional training, could enable teams to better leverage it. This approach may help address both data literacy challenges and time constraints, possibly facilitating more effective integration.

A notable finding from our observations was the frequent missed opportunities to leverage the dashboard during meetings. Often, teams encountered touchpoints for which relevant data were available but did not consult the dashboard to inform their discussions or recommendations. This pattern indicates a need for more immediate support in identifying when and how to apply the dashboard. To address this, we began experimenting with a real-time feedback approach in which research team members observe OFR meetings and provide prompt, specific feedback afterward—highlighting missed opportunities and proposing ways to integrate dashboard data into the discussion. This approach builds on prior work showing that real-time feedback can help users overcome visualization literacy barriers [37] and that timely audit-and-feedback encourages change [38,39]. By clearly linking case discussions to relevant data features, this strategy may enhance teams' use of population-level data.

While our observations showed limited uptake by OFR teams, we believe that providing near real-time data on overdose touchpoints can still be valuable to other localities or states. However, to increase the chance of use during meetings, the dashboard can benefit from several modifications, including innovative visualization designs that combine population-level data with case data, such that teams can more readily integrate the two into their review process. Another potential opportunity lies in the use of large language models to provide a more user-friendly chat interface for accessing and interpreting the data provided by the dashboard [40-42]. In particular, large language models can also provide a bridge between case narratives and aggregate data, helping team members leverage both analysis modalities to make actionable recommendations [43,44]. Additionally, improving training for OFR team members on data use and incentivizing evidence- and data-driven recommendations could encourage further adoption.

Limitations

This study has several limitations that need to be considered. While we observed dashboard use during OFR meetings, we do not know how often or in what ways the dashboard is used outside those meetings. Therefore, we cannot fully determine how much it indirectly influences decision- and recommendation-making. Interview comments indeed suggest that the dashboard may have been used in other ways. Moreover, not all OFR members at the meeting were trained in dashboard use. Interviews suggest that some of the members who attended our 2-day training workshop may have left the team before our

XSL•FO
RenderX

observations. Staff turnover could thus limit dashboard use during meetings. Additionally, only a subset of OFR teams in Indiana was observed, so the discussions and practices observed may not represent all OFR teams. Similarly, the interview findings were based on 7 participants, whose experiences and perspectives may differ from those of other OFR members not included in the study. The limited sample may have biased the themes identified in the study. Still, this study highlights a need for ongoing support and training to help OFR teams generate data-informed prevention strategies.

Conclusions

This study examined whether OFR teams can effectively integrate a population-level touchpoints dashboard into their meetings to support data-driven recommendations. Our observations suggest that, while the dashboard can help teams generate useful insights and inform recommendations, its use during meetings was infrequent. Interviews with team members point to a tension between the case-based review model of OFRs and the population-level, data-driven approach afforded by the dashboard, with members struggling to incorporate the latter into their existing practices. Team members also cited limited data literacy, as well as time and resource constraints, as barriers to its use. These findings suggest a need to design data tools that better bridge the gap between case reviews and quantitative, epidemiologic analyses—for example, through visualizations that integrate individual case information with population-level metrics. Providing additional support and training for dedicated "data specialists" within teams may also help them leverage data and generate evidence-based recommendations, potentially leading to stronger prevention strategies at the local level.

Acknowledgments

The authors thank the Indiana Management Performance Hub, the Indiana Department of Health, the Department of Homeland Security, the Indiana State Police, the Professional Licensing Agency, the Department of Correction, and the Governor's Drug Prevention, Treatment, and Enforcement Office for providing data for use in the dashboard and for their feedback. We are also grateful to the overdose fatality review (OFR) team members whose participation made this study possible. The contents of this publication are solely the responsibility of the authors and do not necessarily represent the official views of the National Institutes of Health or participating organizations. A generative artificial intelligence tool, Grammarly, was used for proofreading and minor language refinement. All content was reviewed and verified by the authors, who take full responsibility for the accuracy and integrity of the manuscript.

Funding

This research was funded by the National Institute on Drug Abuse/National Institutes of Health Helping to End Addiction Long-term Initiative through the Data 2 Action program under award numbers R61DA057660 and R33DA057660 (2022-2027) in the amount of US $4,901,551.

Data Availability

The video recordings and interview data generated and analyzed during this study are not publicly available to protect participants' confidentiality. The deidentified transcripts of the interviews can be provided from the corresponding author on reasonable request. The notes and analyses of observations of OFR meetings conducted are not publicly available due to the confidentiality agreements signed with all OFR teams. The data that support the findings of this study are available in the National Addiction & Health Data Archive Program [45].

Authors' Contributions

AS conducted the observations and interviews, analyzed the data, and wrote the manuscript. CH analyzed the data and edited the manuscript. ALD designed the study and edited the manuscript. MCA, BR, and KR conceptualized the research, designed the study, and edited the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Large language models can generate fluent summaries of longitudinal medical records, but in high-stakes clinical settings, verification burden remains a barrier to trust. Existing provenance mechanisms such as document-level citations and section references often require manual search within long, fragmented notes, limiting their usefulness during time-constrained workflows for clinicians.

Objective: This study aimed to design and evaluate a sentence-level provenance interface ("click to inspect") that enables rapid verification of AI-generated longitudinal medical record summaries at the level of individual statements.

Methods: Between November 2023 and January 2024, we conducted a formative usability study using remotely moderated usability sessions via Zoom to evaluate a web-based sentence-level provenance interface for AI-generated longitudinal medical record summaries. A convenience sample of clinicians was recruited through email outreach to academic and professional networks across the United States. Formative usability testing was conducted with 46 clinician interactions using synthetic longitudinal patient charts. Participants included medical students, residents, and attending physicians across multiple specialties, including internal medicine, dermatology, radiology, plastic surgery, anesthesiology, interventional radiology, obstetrics and gynecology, and family medicine. Usability was assessed using the System Usability Scale and net promoter score, alongside qualitative feedback.

Results: Clinicians reported high usability (mean System Usability Scale score 86.25, SD 7.77; 95% CI 83.96 - 88.54 from 46 participants) and a positive overall experience (net promoter score of 35; 22/46, 47.8% promoters; 18/46, 39.1% passives; and 6/46, 13% detractors). Participants described rapid access to supporting evidence as critical for trust calibration during first-pass chart review. Qualitative feedback identified friction in traditional citation-based interfaces and supported sentence-level inspectability as a low-friction verification mechanism.

Conclusions: Sentence-level provenance transforms AI-generated summaries from static narratives into interactive verification tools. An approach that enables rapid, selective inspection of individual claims during longitudinal chart review may reduce verification burden and support calibrated reliance in high-risk clinical contexts.

Introduction

Background

Large language models can generate fluent summaries of long clinical text, yet in high-risk domains such as health care, trust depends not only on accuracy but also on verifiability [1,2]. This is especially true for longitudinal medical record summaries, which condense years of fragmented documentation into a single narrative [3]. Unlike encounter summaries written immediately after care [4,5], longitudinal summaries often serve as a clinician's first exposure to an unfamiliar patient's history.

Without prior mental models, clinicians may struggle to distinguish rare but true details from model error and may find it difficult to trust these outputs [6,7]. The burden of verification in time-constrained environments associated with locating supporting evidence within long and redundant notes remains a central barrier to adoption [2,8].

Most deployed clinical summarization systems have focused on encounter-based summaries such as visit notes, discharge

XSL•FO
RenderX

summaries, and emergency department documentation, which are generated immediately after a clinical interaction [4,5,9,10]. In these settings, clinicians already possess a mental model of the patient from direct participation in care, and summaries primarily support recall, documentation, and communication [11]. In contrast, longitudinal medical record summaries synthesize years of fragmented documentation across multiple encounters and specialties into a single narrative [3,12]. This creates a distinct cognitive challenge because clinicians must determine whether individual summarized statements are supported by the underlying medical record while simultaneously constructing an understanding of the patient's history. As a result, longitudinal summarization requires not only accurate summaries but also efficient mechanisms for verifying individual clinical claims during first-pass review [2,8].

Prior Work

Existing provenance approaches commonly rely on document-level citations, section references, or phrase-level highlights [9-12]. While familiar from academic writing, these mechanisms often require manual search within cited documents. In longitudinal clinical documentation, relevant evidence may be embedded within multipage notes, making targeted verification inefficient.

Recent AI-assisted clinical information retrieval and summarization systems, including Perplexity, OpenEvidence, and Microsoft Copilot, have incorporated provenance through document-level citations, section references, or highlighted supporting snippets to improve transparency [13-15]. Similarly, human-centered explainable AI research has emphasized that explanations should be designed to support user decision-making and integrate naturally into existing workflows rather than simply increasing model transparency [16,17]. However, even when provenance is available, clinicians must still navigate lengthy clinical notes and determine whether the cited evidence adequately supports individual summarized claims, a process that can interrupt reading flow and increase cognitive burden during time-constrained chart review [18-21].

Although these approaches improve transparency, little work has specifically examined provenance interfaces designed to support rapid verification of individual clinical statements during longitudinal chart review. This represents an important gap in the literature because clinicians reviewing unfamiliar patients must efficiently distinguish supported clinical information from potential model errors while simultaneously building an understanding of the patient's history, yet few provenance interfaces have been designed specifically to support this verification workflow.

Study Objectives

We designed and evaluated a sentence-level provenance interaction model ("click to inspect") that makes every summary sentence directly inspectable in its source context. We conducted formative usability testing to assess whether this interaction reduces friction during verification and supports calibrated trust.

The objective of this study was to evaluate the usability of a sentence-level provenance interface for AI-generated longitudinal medical record summaries. Specifically, we aimed to (1) evaluate the perceived usability of the interface using the System Usability Scale (SUS); (2) assess clinicians' overall experience using the net promoter score (NPS); and (3) characterize clinician perceptions of verification workflow, verification burden, and trust through qualitative usability interviews. Collectively, these aims sought to determine whether sentence-level provenance represents a usable and practical approach for supporting rapid verification of AI-generated longitudinal medical record summaries during clinical chart review.

Methods

Overview of Study Design

This study was a formative usability evaluation of a web-based sentence-level provenance interface for AI-generated longitudinal medical record summaries. The system was evaluated using synthetic patient charts designed to simulate common longitudinal documentation patterns encountered in clinical practice.

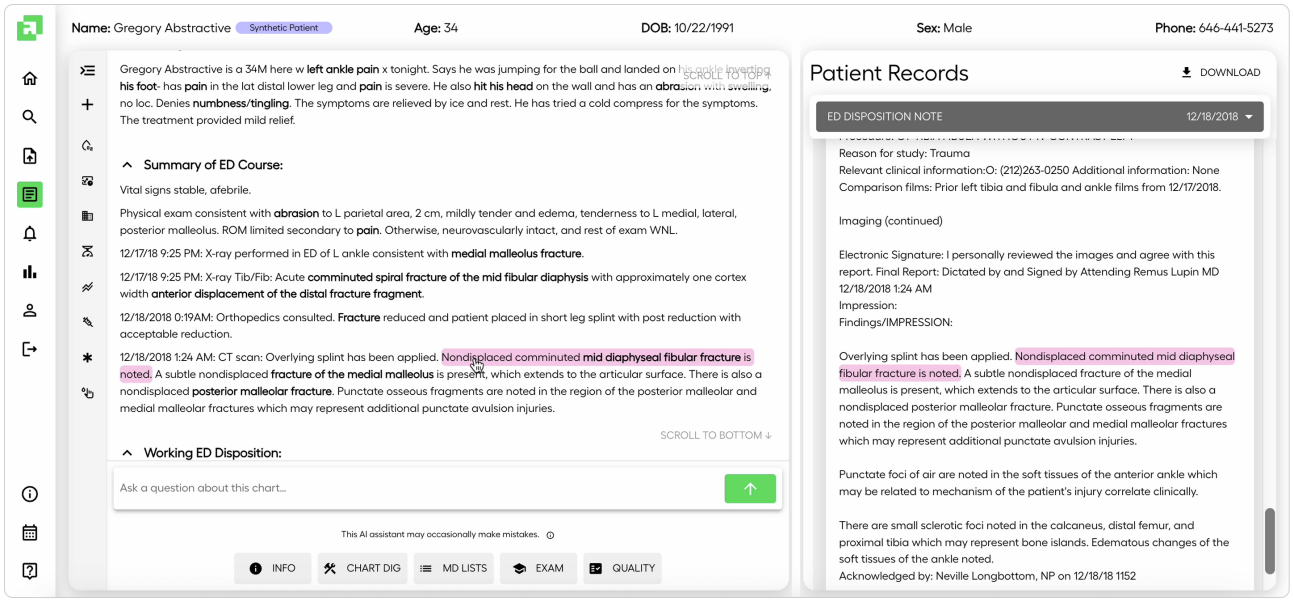
The purpose of this study was to evaluate the usability of the sentence-level provenance interface rather than the accuracy or clinical performance of the underlying summarization system. The AI-generated summaries used during testing were iteratively refined through structured clinician feedback to ensure that they reflected realistic longitudinal clinical documentation and supported evaluation of the verification workflow. Accordingly, the summaries served as a vehicle for evaluating the provenance interface and were not used to assess the performance of a specific language model or summarization approach.

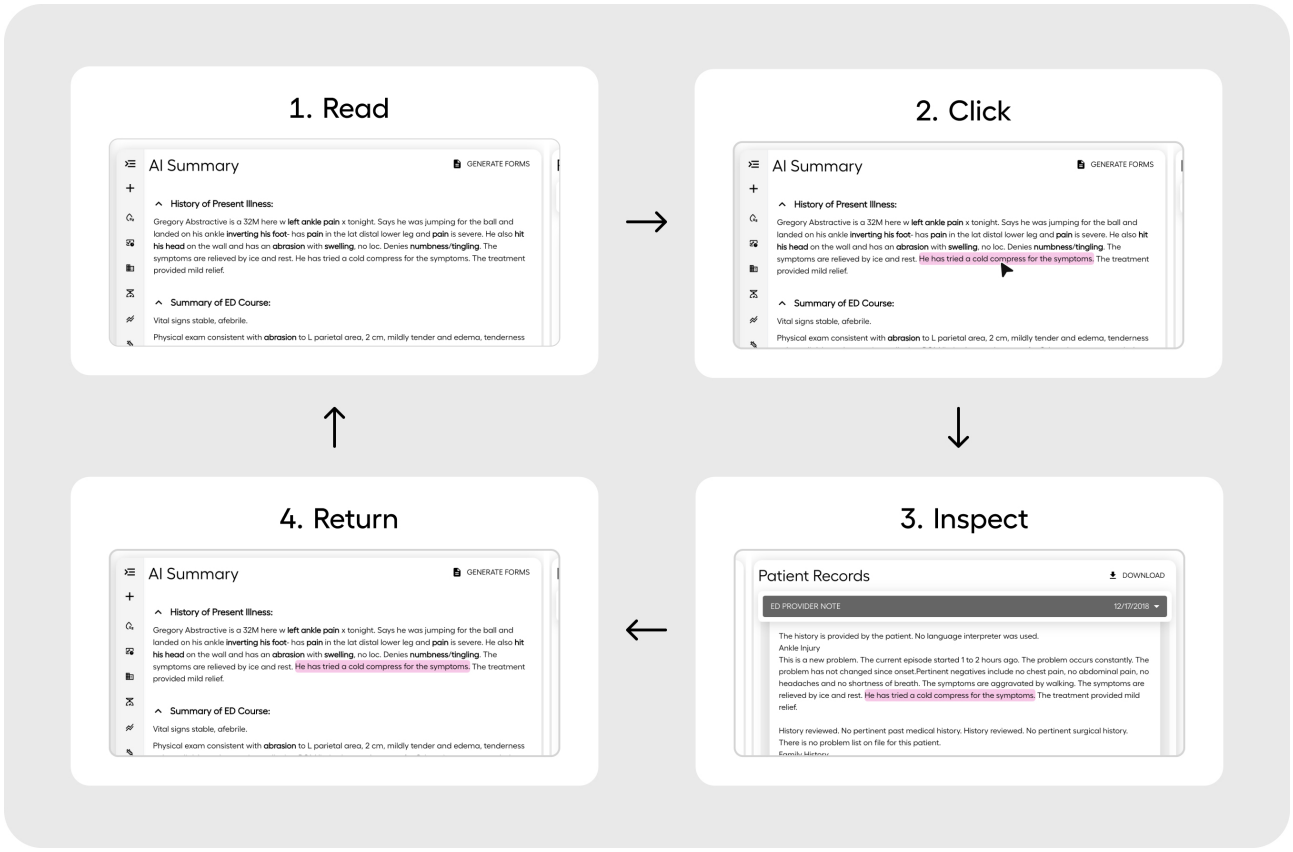
The Tool and Interface

Participants interacted with a web-based sentence-level provenance interface presenting AI-generated longitudinal medical record summaries alongside a source note viewer. Every sentence within the summary was interactive. When a participant selected a summary sentence, the interface opened the originating clinical note in a side-by-side view, automatically scrolled to the corresponding source sentence, and highlighted the matched text in context. This interaction was designed to support a rapid verification workflow by allowing clinicians to inspect supporting evidence without manually searching through source documentation (Figures 1-3).

XSL•FO
RenderX

Figure 1. Click-to-inspect summaries in use. A clinician clicks on a sentence in the longitudinal AI summary (left), and the system opens the originating note (right), automatically scrolling to and highlighting the matched supporting sentence in context.





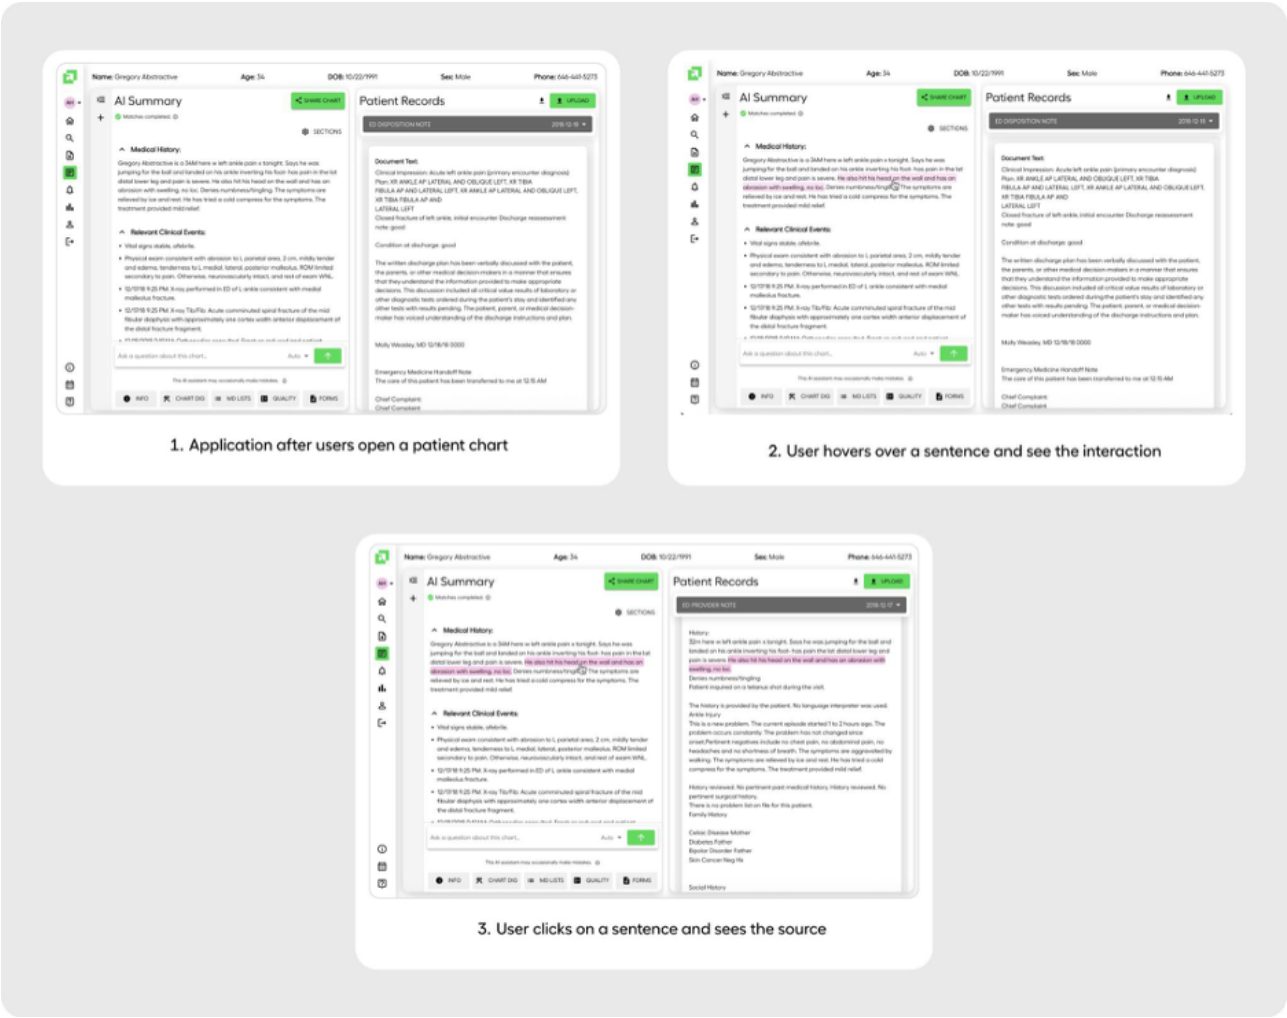


Figure 2. The click-to-inspect loop, where selecting a summary sentence opens the originating note, scrolls to the matched supporting sentence, and highlights it in context for rapid verification and return to reading.

XSL•FO
RenderX

Figure 3. The general overview of the workflow that a user would go through when navigating the application.

Two synthetic patient charts were developed for this study. The first represented an acute emergency department encounter involving an ankle injury, diagnostic imaging, and specialty consultation. The second represented a longitudinal outpatient history spanning multiple years of multispecialty documentation. Both charts were designed to reflect common longitudinal documentation patterns encountered in clinical practice, including fragmented histories, cross-specialty documentation, and varying levels of clinical complexity. Synthetic charts were authored and reviewed by board-certified clinicians to ensure clinical realism while avoiding the use of real patient information.

Sentence-level provenance links were generated using embedding-based semantic similarity between summary sentences and candidate source note sentences. Sentence embeddings were generated using the transformer-based sentence embedding model all-mpnet-base-v2 (Hugging Face). Before embedding, source clinical notes were converted from their structured representation into plain text and segmented into sentence-level units. Text was initially partitioned using line breaks, runs of 2 or more white space characters, bullet symbols, and dash space separators. Each resulting text segment was trimmed of surrounding white space and further segmented into individual sentences using the Natural Language Toolkit (Team NLTK) Punkt sentence tokenizer. Empty segments were discarded. No abbreviation expansion, spelling correction, or clinical terminology normalization was performed before embedding.

Cosine similarity was calculated between each summary sentence and all candidate sentences within the originating clinical note. For each summary sentence, the highest-scoring source sentence was selected as the provenance reference. A cosine similarity threshold of 0.70 was used to categorize provenance matches. Summary sentences whose highest similarity score was 0.70 or more were categorized as verified, whereas those with scores below 0.70 were categorized as unverified while remaining clickable within the interface. The threshold was established during iterative internal clinical review of provenance quality to identify a value that consistently distinguished clinically meaningful sentence matches from weaker semantic associations. This represented a clinician-informed calibration process rather than a formally validated statistical threshold.

The provenance interface used a one-to-one sentence mapping. Each summary sentence was linked to a single originating clinical note and a single highest-scoring source sentence within that note. The underlying summarization pipeline preserved the originating note associated with each generated summary sentence and did not generate individual summary sentences by combining information across multiple source notes.

XSL•FO
RenderX

Although a summary sentence could synthesize information from multiple sentences within the same note, the interface intentionally displayed only the highest-scoring supporting sentence. This design was selected to provide a single, consistent point of verification while minimizing visual complexity during chart review. Findings from the usability evaluation supported this approach as participants consistently described a single salient provenance location as intuitive and sufficient for verification during longitudinal chart review.

Participant Sampling and Recruiting

Clinicians were recruited between November 2023 and January 2024 through email outreach to medical students, resident physicians, and attending physicians using academic institutional mailing lists, residency program listservs, and professional networks across multiple health systems in the United States. Recruitment emails described the study as a usability evaluation of a clinical summarization interface and invited interested participants to complete a brief interest form. Participation was voluntary. Eligible participants were required to be actively engaged in clinical training or practice. No additional exclusion criteria were applied.

Usability Testing Procedures

Moderated usability sessions were conducted remotely via Zoom (Zoom Video Communications) between November 2023 and January 2024. Each session lasted approximately 30 minutes and followed a semistructured usability interview guide to ensure consistency across participants (Multimedia Appendix 1). The guide consisted of standardized clinical scenarios; predefined task-based usability assessments; and open-ended interview questions designed to evaluate clinician workflow, verification behavior, and overall usability of the sentence-level provenance interface.

During each session, participants interacted with the web-based interface while reviewing AI-generated longitudinal patient summaries. Participants were encouraged to use a think-aloud protocol, verbalizing their reasoning as they reviewed summaries and selectively inspected supporting source material. Moderators used nondirective follow-up prompts to clarify why participants chose to verify particular statements and how the interface influenced their verification process while allowing for flexibility to explore emerging usability issues. Participants were not required to inspect a predetermined number of statements, allowing for observation of natural verification behavior during clinical chart review. All sessions were audio and video recorded and transcribed for subsequent qualitative analysis.

Data Collection and Analysis

Following interaction with the interface, participants completed the SUS and an NPS questionnaire. The SUS is a validated 10-item instrument measuring perceived usability on a scale from 0 to 100. The NPS was assessed using the standard likelihood to recommend question (0-10), with respondents categorized as promoters (9-10), passives (7-8), and detractors (0-6).

In addition to quantitative usability measures, qualitative data were collected during these remotely moderated usability testing sessions via Zoom using a think-aloud session, in which participants described their verification strategies, perceived workflow friction, trust in AI-generated summaries, and overall experience using the interface during the Zoom session.

Descriptive statistics were calculated for quantitative usability outcomes. Mean SUS scores, SDs, and 95% CIs were calculated across participants. The NPS was calculated using the standard formula of the percentage of promoters minus the percentage of detractors.

Audio recordings were transcribed and independently reviewed by 2 researchers. Qualitative data were analyzed using an inductive thematic analysis approach to identify recurring themes related to verification workflow, verification burden, trust calibration, and integration into clinical practice. Themes were iteratively refined through discussion until consensus was achieved.

Ethical Considerations

This study was reviewed and approved by Pearl IRB (Indianapolis, Indiana, United States; 2025-0079) under an expedited review process and was determined to involve minimal risk. All study procedures were conducted in accordance with the approved protocol. Participants provided verbal informed consent before taking part. To protect participant privacy and confidentiality, all usability sessions were audio and video recorded solely for research purposes, securely stored in accordance with the approved study protocol, and analyzed by authorized study personnel. Synthetic patient charts were used throughout the study to ensure that no real patient information or protected health information was accessed or disclosed during usability testing. Participants received a US $25 electronic gift card upon completion of the usability session.

Results

Recruitment invitations were distributed through multiple overlapping institutional mailing lists, residency program listservs, and professional networks. As a result, the exact number of clinicians who received the invitation could not be determined because individual recipients may have received invitations through more than one distribution channel. During the recruitment period, 107 clinicians expressed interest in participating in the study, of whom 46 (43%) completed a moderated usability session and were included in the final analysis (Table 1).

XSL•FO
RenderX

Table . Characteristics of study participants (N=46).

Characteristics	Values
Age range (y)	20 - 60
Clinical specialty groups represented, n (%)	
Internal medicine	11 (23.9)
Surgical specialties	10 (21.7)
Radiology	4 (8.7)
Dermatology	3 (6.5)
Neurology	3 (6.5)
Ophthalmology	3 (6.5)
Emergency medicine	2 (4.3)
Family medicine	2 (4.3)
Obstetrics and gynecology	2 (4.3)
Pediatrics	2 (4.3)
Hematology and oncology	2 (4.3)
Anesthesiology	1 (2.2)
Psychiatry	1 (2.2)

Recruitment concluded when participant feedback demonstrated recurring and consistent observations regarding workflow, verification behavior, and overall usability. At that point, the sample size was considered sufficient for the formative usability evaluation because additional recruitment was unlikely to yield substantially new usability insights.

The mean SUS score was 86.25 (SD 7.77; 95% CI 83.96 - 88.54), indicating high perceived usability of the click-to-inspect interface.

The NPS was 35, calculated using the standard method (percentage of promoters minus percentage of detractors on the 0 - 10 NPS scale). Of the 46 participants, 22 (47.8%) were classified as promoters (scores of 9 - 10), 18 (39.1%) were classified as passives (scores of 7 - 8), and 6 (13%) were classified as detractors (scores of 0 - 6).

During the moderated think-aloud sessions, participants frequently described rapid access to supporting evidence as critical to their willingness to rely on the summary during initial review. Clinicians reported that being able to verify individual statements with a single click reduced cognitive load compared with document-level citation systems that require manual searching within lengthy notes. Participants noted that traditional provenance mechanisms often identify the source document but do not eliminate the effort required to locate the exact supporting passage within that document.

Sentence-level inspectability was consistently described as predictable and low friction. Participants reported that the absence of persistent citation markers or confidence indicators preserved reading flow while maintaining immediate access to supporting evidence when needed. Participants also emphasized that the ability to selectively verify clinically important or unexpected statements aligned well with real-world chart review workflows.

Representative participant comments included the following:

> *Being able to click directly on the sentence and see the exact line in the note makes it much easier to trust the summary.*
>
> *Normally I have to scroll through the whole note to find where something came from. This saves a lot of time.*
>
> *I like that I can verify the statements that matter without breaking my reading flow.*

Discussion

Principal Findings

This formative usability evaluation found that a sentence-level provenance interface for AI-generated longitudinal medical record summaries demonstrated high perceived usability among clinicians, with a mean SUS score of 86.25 (SD 7.77) and an NPS of 35. Consistent with the objectives of this study, clinicians reported that the click-to-inspect interaction reduced the effort required to verify AI-generated clinical statements while preserving reading flow during longitudinal chart review. Participants consistently described rapid access to supporting source material as enabling selective verification of clinically important statements without interrupting their workflow. These findings support the usability of sentence-level provenance as a verification interface independent of the underlying summarization model and suggest that embedding provenance directly within individual summary statements may reduce verification burden while supporting calibrated trust in AI-generated longitudinal summaries.

Our findings suggest that the value of provenance extends beyond simply identifying the source of summarized information. Participants reported that the interface made it easier to verify individual clinical statements while maintaining

XSL•FO
RenderX

focus on understanding the patient's history. Instead of navigating through lengthy clinical notes to locate supporting evidence, clinicians could inspect the source material only when they felt that additional verification was necessary. This workflow appeared to reduce the effort associated with verification and allowed clinicians to remain focused on interpreting the summary rather than searching for supporting documentation.

These findings are consistent with those of prior work in explainable AI showing that transparency mechanisms are most effective when they support user decision-making within existing workflows rather than simply exposing model outputs [16,17]. Existing AI-assisted clinical summarization and information retrieval systems commonly provide document-level citations, section references, or highlighted supporting snippets [13-15,22-25]. Although these approaches improve transparency, clinicians must still determine whether the cited material adequately supports the summarized clinical claim while navigating lengthy and fragmented documentation. Our findings suggest that sentence-level provenance may reduce this burden by making supporting evidence immediately accessible at the point where verification is needed.

The findings are also consistent with principles from human factors research. Clinical reasoning is typically performed at the level of individual findings, diagnoses, medication changes, and clinical events rather than entire documents. Participants consistently reported that they wanted the ability to verify only selected statements rather than every sentence within a summary. Clinicians naturally focused on information that was clinically important, unexpected, or likely to influence decision-making. The interface supported this workflow by allowing participants to selectively inspect supporting evidence without interrupting their review of the remainder of the summary. Participants also noted that the absence of persistent citation markers or confidence scores preserved reading flow while maintaining immediate access to supporting evidence when desired. Together, these observations suggest that minimizing visual complexity while preserving rapid inspectability may represent an important design principle for future AI-assisted clinical documentation systems.

Several limitations should be considered when interpreting these findings. First, this was a formative usability evaluation conducted using synthetic patient charts. Although synthetic data enable controlled testing without privacy concerns, they may not fully capture the variability, ambiguity, and complexity of real-world longitudinal clinical documentation. Second, although participants represented a broad range of clinical specialties, recruitment took place through academic institutional mailing lists, residency program listservs, and professional networks, which may limit the generalizability of these findings to other clinical settings. Third, this study evaluated perceived usability rather than objective performance. Outcomes such as time to verification, verification accuracy, detection of hallucinated or unsupported statements, and downstream effects on clinical decision-making were not measured. Accordingly, this study cannot determine whether sentence-level provenance improves clinicians' ability to identify summarization errors or unsupported clinical claims. Finally, provenance mapping relied on embedding-based semantic similarity, and its robustness across heterogeneous clinical documentation warrants further evaluation.

Future studies should evaluate sentence-level provenance in real-world clinical environments using production electronic health record data and AI-generated longitudinal summaries. Important outcome measures include verification time, verification accuracy, detection of unsupported or hallucinated statements, changes in information-seeking behavior, and downstream effects on clinical decision-making. Comparative studies should also evaluate sentence-level provenance against conventional document navigation and document-level citation interfaces to determine whether it improves verification efficiency, clinical reasoning, and trust calibration. Additional work is needed to understand how alternative provenance presentation strategies, including confidence scores and prioritization cues, influence verification behavior and clinician reliance on AI-generated summaries.

This study suggests that sentence-level provenance is a feasible and well-accepted approach for supporting verification of AI-generated longitudinal medical record summaries. As generative AI becomes increasingly integrated into electronic health record workflows, the design of verification interfaces may become as important as improvements in model performance. Supporting efficient, low-friction verification has the potential to improve clinician confidence, promote appropriately calibrated trust, and facilitate the safe integration of AI-generated longitudinal summaries into routine clinical practice.

Conclusions

Sentence-level provenance represents a human-centered approach to improving verifiability in AI-generated longitudinal medical record summaries. By making every summary sentence directly inspectable within its source context, the click-to-inspect interaction embeds verification into the act of reading rather than positioning it as an external search task. In formative usability testing, clinicians described the interface as intuitive and compatible with time-constrained workflows and reported high perceived usability. Although further empirical validation is needed, these findings suggest that designing provenance at the level of individual clinical statements may better align AI summarization tools with real-world clinical practice and support calibrated reliance in high-risk settings.

Abstract

Background: Adherence to chronic obstructive pulmonary disease (COPD) self-management plans can improve health outcomes, yet access to pulmonary rehabilitation remains limited. Digital self-management interventions, such as *myCOPD*, offer a potential means to extend support across care pathways. However, little is known about how these tools are delivered in routine practice or how delivery influences patient engagement across different clinical settings.

Objective: This study explored perceived barriers and facilitators to the delivery of and engagement with *myCOPD* by examining the perspectives of both patients and health care professionals (HCPs) across 2 National Health Service settings.

Methods: This qualitative study was conducted between November 2023 and April 2024 across 2 contrasting clinical pathways: community pulmonary rehabilitation and a hospital discharge service following acute exacerbation of COPD. Semistructured interviews were conducted with patients using *myCOPD* and HCPs involved in its delivery. Topic guides covered health background, digital technology use, and experiences of engaging with the intervention. A convenience sampling approach, with elements of purposive sampling, ensured representation across settings. Clinical data were obtained from health records with consent, and usage data were provided by my mhealth Ltd. Data were analyzed using abductive thematic analysis informed by the Medical Research Council's process evaluation framework.

Results: Thirty interviews were completed (16 patients and 14 HCPs). Patients described how multimorbidity, perceived digital ability, and socioeconomic context shaped their engagement with *myCOPD*, operating as "layers of vulnerability" that influenced whether COPD self-management could be prioritized. HCPs highlighted organizational and workflow constraints that shaped how the intervention was introduced and supported. Delivery approaches differed markedly between settings: community teams adopted proactive, relationship-based support that enabled iterative discussion, tailored recommendations, and continuity, whereas hospital teams described passive, onboarding-focused delivery shaped by time pressures, staffing constraints, and discharge priorities. These contrasting delivery models influenced engagement patterns, with proactive support associated with more *multifaceted engagement* (characterized as routine and sustained) and passive onboarding associated with *single-aspect engagement* (characterized as short-term and transactional). Participants also identified perceived barriers (eg, usability concerns, limited integration with in-person care) and perceived benefits (eg, improved inhaler technique, increased confidence, lifestyle adjustments).

Conclusions: Delivery context and local workflows play a central role in shaping how patients engage with digital self-management tools. Proactive, relational support appears to facilitate deeper and more sustained engagement, whereas passive onboarding may limit the intervention's potential. Implementation strategies should align digital tools with local capacities,

XSL•FO
RenderX

staffing structures, and patient characteristics, attending to layered vulnerabilities such as multimorbidity and digital confidence. Further work is needed to understand how proactive delivery models can be resourced and integrated within routine COPD care.

Introduction

Chronic obstructive pulmonary disease (COPD) affects an estimated 3 million people in the United Kingdom and contributes to approximately 30,000 deaths annually, many of which are preventable [1,2]. Exacerbations are clinically significant events that increase the risk of subsequent exacerbations and hospital readmissions, particularly within the first 3 months [3,4]. Effective self-management, including symptom recognition, inhaler technique, and timely action, can reduce exacerbations and improve quality of life [5,6]. However, access to pulmonary rehabilitation (PR), a core component of COPD self-management, remains limited, with fewer than one-third of eligible patients accessing PR within 90 days of referral [7]. These persistent gaps highlight the need for scalable approaches to support self-management across care pathways.

Digital self-management interventions offer a potential means to extend PR and provide ongoing support, yet evidence for their effectiveness remains mixed [8-10]. While some studies report improvements in inhaler technique, symptom monitoring, and exercise adherence, others highlight challenges related to uptake, sustained engagement, and integration into routine care. A recurring issue is that digital interventions are often implemented without sufficient understanding of how they fit within existing clinical workflows or how frontline teams introduce and support their use [11]. Implementation research emphasizes that digital tools are not inherently effective; their impact depends on how they are delivered, supported, and embedded within organizational contexts. Factors such as staffing capacity, digital readiness, professional roles, and local service priorities can shape adoption, fidelity, and engagement [12].

Engagement with digital interventions is increasingly conceptualized as an implementation outcome influenced by both individual and structural determinants. COPD disproportionately affects older adults and people experiencing socioeconomic disadvantage, who may also face barriers related to digital access, confidence, and multimorbidity [13,14]. These overlapping factors can shape how individuals navigate digital tools and the extent to which they are able, or supported, to engage with them [15,16]. Understanding how patient characteristics intersect with service-level contexts is therefore essential for ensuring equitable benefit. An intersectional approach, attending to how multiple characteristics combine to produce advantage or disadvantage, can illuminate how patients navigate digital tools within the constraints of multimorbidity, digital ability, and socioeconomic context [11,17,18]. The concept of "layers of vulnerability" proposed by Luna [19,20] is particularly relevant for understanding how vulnerabilities emerge from the interaction between individuals and their health care environments, rather than from individual characteristics alone.

myCOPD is a widely adopted digital self-management intervention recommended by the NICE Early Value Assessments for PR and COPD self-management [21]. Despite its deployment across National Health Services (NHSs), limited evidence exists on how *myCOPD* is implemented in real-world settings, how delivery varies across clinical pathways, or whether these variations influence patient engagement. Existing evaluations have focused primarily on clinical outcomes or usability, with less attention to the organizational and relational processes that shape engagement in practice [22-25].

To address this gap, we examined the implementation of *myCOPD* across 2 contrasting NHS settings: community PR and a hospital discharge pathway following an acute exacerbation of COPD. Guided by the Medical Research Council's (MRC's) process evaluation framework [26], we explored how contextual factors, delivery approaches, and patient characteristics interact to shape engagement trajectories. This study aimed to identify implementation factors influencing the delivery of and engagement with *myCOPD* across 2 NHS clinical settings and explore how patient characteristics and structural factors interact to shape engagement trajectories, informed by the concept of "layers of vulnerability."

By analyzing implementation processes across settings, this study contributes to our understanding of how digital self-management interventions can be more effectively and equitably integrated into routine COPD care. These aims informed the sampling strategy, interview topic guides, and abductive analytic approach.

Methods

Study Settings

The study was conducted across 2 contrasting NHS clinical settings:

First, the hospital discharge pathway (Bristol), where *myCOPD* was introduced as part of the acute exacerbation of COPD discharge bundle. Eligible patients were identified during follow-up clinics or virtual ward reviews within 6 weeks of hospital discharge. Delivery was primarily supported by digital health champions (DHCs) due to staffing pressures and workflow constraints.

Second, the community PR (Cornwall), where *myCOPD* was integrated into routine PR delivery. A digital health advisor (from my mhealth Ltd) and a respiratory care coordinator supported registration, activation, and ongoing use. Clinicians used the *myCOPD* dashboard to monitor progress and tailor self-management discussions.

XSL•FO
RenderX

These settings differed in purpose, workflow, and available resources, providing a natural comparison of delivery approaches.

Intervention: *myCOPD*

myCOPD is a digital self-management app providing educational modules, inhaler-technique videos, PR content, symptom tracking, and action-plan support. Clinicians can view patient-reported data through a dashboard to support remote monitoring and personalized care. The intervention content was identical across sites.

Participants, Recruitment, and Sampling

Patients were recruited from the PROPEL (A Pragmatic Real-World Multicenter Observational Research Study to Explore the Clinical and Health Economic Impact of *myCOPD*) study cohort. During their baseline PROPEL visit, all eligible participants were informed about the qualitative component and invited to opt in or out. Those who opted in were recontacted to arrange an interview after their scheduled 3-month follow-up visit, timed to ensure adequate exposure to the intervention. The eligibility criteria at each site are outlined in Textbox 1.

Textbox 1. Eligibility criteria across settings.

Setting 1 (Bristol)

- **Inclusion criteria**
  - Adult patients aged >18 years and able to provide informed consent
  - Clinical diagnosis of chronic obstructive pulmonary disease (COPD)
  - Admitted to hospital with a primary diagnosis of acute exacerbation of COPD (AECOPD)
  - Assessed in a follow-up clinic or a virtual ward within 6 weeks of an AECOPD
- **Exclusion criteria**
  - Patients aged <18 years
  - No clinical diagnosis of COPD
  - End-of-life care or palliative care
  - Unable to provide informed consent

Setting 2 (Cornwall)

- **Inclusion criteria**
  - Adult patients aged >18 years and able to provide informed consent
  - Clinical diagnosis of COPD, deemed suitable for referral to pulmonary rehabilitation by the local clinical team
  - Motivated or willing to take part
- **Exclusion criteria**
  - Unstable angina
  - Myocardial infarction within 6 weeks
  - Uncontrolled cardiac arrhythmias
  - Unstable hypertension
  - Severe cognitive impairment
  - Locomotor or other severe medical conditions preventing the patient from safe participation in group activities
  - Unable to provide informed consent
  - Any condition deemed by the principal investigator to make the participant unsuitable for the study

A convenience sampling approach was used, with elements of purposive sampling to ensure representation across both clinical settings. Health care professionals (HCPs) involved in delivering *myCOPD* were identified by site leads and approached via email. A purposive sampling strategy ensured variation in professional role (DHCs, nurses, and physiotherapists) and setting (community vs hospital).

Data Collection

Semistructured interviews were conducted via Microsoft Teams (audio or video, depending on the technological accessibility of participants). Topic guides were tailored for patients and HCPs and refined iteratively by experienced qualitative researchers. Interview topics included experience of COPD, use of digital technology, engagement with *myCOPD*, and perceived

XSL•FO
RenderX

barriers and facilitators. Example questions are presented in the full topic guides in Multimedia Appendix 1.

With informed consent, clinical data (eg, COPD severity, years since diagnosis, long-term conditions) were obtained from participants' health records held by NHS clinical teams. Similarly, with consent, *myCOPD* usage data (eg, logins, module completion, and PR access) were obtained directly from my mhealth Ltd, which provided anonymized usage summaries for participants enrolled in the PROPEL study.

Procedure

At the start of each interview, participants received a verbal recap of study aims, confidentiality, and their right to withdraw. One interviewer was present at each interview (MR conducted all patient interviews, and HCP interviews were split between BC and MR). MR (a PhD researcher in health psychology with training in qualitative interviewing and prior experience as a patient and public involvement [PPI] officer) conducted all patient interviews and facilitated PPI sessions. BC (an experienced qualitative researcher) conducted HCP interviews. Their positionalities—MR's long-standing ties to the local community and BC's research background—were acknowledged and reflexively considered throughout the analysis. Interviews were recorded, transcribed verbatim, checked for accuracy, and imported into NVivo 14 (Lumivero) for analysis. All participants received financial compensation (payments of £75 [US $100] for HCPs; vouchers of £25 [US $30] for patients). Finally, the data presented here include CAT scores that were taken at baseline by clinical research staff.

Analysis

Coding was conducted by 2 researchers (BC and MR) for HCP interviews and by a researcher (MR) for patient interviews. HCP and patient transcripts were coded independently. During theme development, we compared the coded data to identify shared patterns, at which point the analytical process merged into a unified set of themes. Analyzing the transcripts together captured the relational aspects of self-management and reflected an overlap in coding and candidate themes across groups. While both groups discussed a particular theme, typically one group described the theme in more detail; for example, HCPs and patients both described the importance of multimorbidity, but patients described in greater detail how it shaped engagement.

Researcher positionalities were addressed through structured reflexive practices. BC and MR kept journals during data collection and coding, revisiting these reflections during theme development to check for assumptions and bias. MR also held regular debrief meetings with senior qualitative researchers (BA, KB, and LY) to discuss how background experiences might shape interpretation. These discussions helped mitigate potential limitations of single coding and promoted consistency and rigor. MR also used analytic memos and diagramming to track decision-making and consider alternative interpretations. Together, these practices provided a systematic reflexive process that helped ensure interpretations remained grounded in the data.

Coding followed an abductive thematic analysis [27] workflow that combined the MRC process evaluation framework [26] with inductive code generation. Transcripts were first read repeatedly to support familiarization. A deductive coding structure based on MRC domains (context, implementation, engagement, mechanisms of impact) [26] served as the overarching structure, and data were coded line-by-line according to the relevant categories. Alongside this, inductive codes were generated to capture participant-led insights that did not fit the MRC framework. The coding framework was refined iteratively, with codes merged, repositioned, or expanded as patterns became clearer. Coded data were then reviewed within and across domains to identify candidate themes, with the MRC structure providing the overarching scaffold and inductive codes supplying the detailed content. Themes were developed through team discussion, diagramming, and matrix mapping to examine relationships across settings and between patient and HCP accounts. Reporting of qualitative methods and findings was informed by the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist (Checklist 1). This iterative movement between empirical data and implementation theory supported the identification of mechanisms, such as how delivery approaches shape engagement trajectories, that are central to understanding implementation and align with calls for qualitative methods [28].

PPI

PPI activities were integrated throughout the PROPEL study and used to refine qualitative findings. The PPI group for the work outlined here consisted of Windrush Generation Elders (pioneering individuals who immigrated to the United Kingdom from Caribbean countries and other Commonwealth nations between 1948 and 1971). They all had experience of living with or caring for someone with asthma or COPD. This group highlighted the importance of intersectionality before data collection and therefore supported this focus. One-to-one sessions were held with stakeholders (professionals based in the NHS and at the digital provider) who were experienced in delivering *myCOPD*. Work with the community-based group adopted a participatory approach to activities (facilitated by MR). These activities were designed to assess the relevance, clarity, and real-world applicability of emerging themes. Feedback informed the refinement and interpretation of themes.

The PPI group was not told the results at the beginning of the workshop (Multimedia Appendix 2 provides further detail using GRIPP2 [Guidance for Reporting Involvement of Patients and the Public, version 2] form); they were asked to individually draw journey maps of their experiences with COPD (in some cases, asthma). We then discussed their maps, with the chance for them to respond to each other and adapt their own maps. Finally, the results were introduced, and we discussed factors that overlapped with the results and those that were different, reasons for differences, and the importance of each factor. Consent was not obtained for PPI activities, and therefore these do not feature as a facet in the "Results" section. PPI highlighted that the results were relevant, how they related to lived experience, and a few aspects that were missing from the results (eg, the role of carers).

XSL•FO
RenderX

Ethical Considerations

Ethical approval was granted by the NHS Research Ethics Committee (REC reference: 23/SC/0155) and the University of Southampton (ERGO: 84797). All participants provided informed consent. Clinical and usage data were anonymized or deidentified before analysis. Confidentiality was maintained throughout, and participants received financial compensation for their time.

The qualitative interview data generated and analyzed during this study are not publicly available due to confidentiality agreements and the absence of participant consent for data sharing.

Results

Descriptive Data

Thirty interviews were conducted, 16 with patients and 14 with HCPs. Patient interviews lasted 14 to 35 (mean 23.7, SD 6.3) minutes, and HCP interviews lasted 23 to 57 (mean 36.8, SD 7.9) minutes. Sixteen of the 37 patients who initially agreed completed interviews; there was a range of reasons for nonparticipation: no response to invitations (n=15), unavailable contact details (n=2), technical failures (n=2), or withdrawal (n=2). Patient characteristics are provided in Table 1, and HCP characteristics are provided in Table 2. Participant usage data (Table 3) indicated higher engagement among Cornwall patients, who had a longer period since activation (107 - 148 days) and more frequent logins. Across both sites, 81.25% (13/16) accessed educational modules and 68.75% (11/16) accessed PR content.

Overview of Thematic Analysis

Five themes were developed, each with subthemes (Table 4). Read sequentially, the themes describe a pathway from patient characteristics to delivery context, engagement patterns, perceived barriers, and perceived benefits. This structure highlights how individual and structural factors interact to shape engagement with *myCOPD*. As mentioned in the "Methods" section, the analysis of the transcripts was often complementary between HCPs and patients. For example, both HCPs and patients could describe the health care setting as affecting engagement with *myCOPD*, though HCPs typically provided more detail.

Table . Summary of themes and subthemes.

Theme	Subthemes	Interplay between HCP[a] and patient accounts
Patient characteristics related to engagement	• Perceived digital ability • Negotiating multimorbidity • Socioeconomic status	• Complementary accounts, patients provided more detail
Important differences in health care setting	• Perceived purpose of health service • Organizational-structural factors • Approaches to delivery of *myCOPD*	• Complementary accounts, HCPs provided more detail
Engagement with *myCOPD*	• Single-aspect engagement • Multifaceted engagement	• Complementary accounts, patients provided more detail

Perceived barriers to engagement	• User perceptions of *myCOPD*
	• External barriers
		• Complementary accounts
		  • Users provided more detail
		  • HCPs provided more detail

Perceived benefits of engagement	• Targeted behavior change • Wider lifestyle adjustments	• Complementary accounts, patients provided more detail

[a]HCP: health care professional.

Patient Characteristics Related to Engagement

Three characteristics (multimorbidity, perceived digital ability, and socioeconomic context) operated as "layers of vulnerability" influencing engagement. Importantly, it was not the presence of a characteristic alone but how patients interpreted and negotiated that characteristic that shaped their engagement trajectory.

Negotiating Multimorbidity

The impact of living with multiple long-term conditions was commonly discussed. HCPs and patients often recognized the uncertainty caused by negotiating multimorbidity.

> *It's very difficult, when you've got another illness, you can't really put it all on one thing.* [PAT06, hospital patient]

Other health conditions potentially inhibit engagement with *myCOPD*. For example, positive management of another condition could affect quality of life to such an extent that COPD was not currently prioritized (eg, weight loss). In other instances, the presentation of other health conditions seemed to compete for prioritization.

> *I've got asthma, COPD, the heart problem, and I'm being treated for bladder cancer. Unfortunately, it's [COPD is] like number three [in terms of priorities].* [PAT03, hospital patient]

These accounts illustrate how multimorbidity among patients formed a core layer of vulnerability, shaping whether COPD self-management could be prioritized and how patients navigated competing health demands.

Perceived Digital Ability

Patients' perceptions of their own digital ability also impacted engagement with *myCOPD*. Some participants expressed a level of digital inhibition that prevented engagement. Patients with conditions such as dyslexia could also perceive engagement as overwhelming.

> *I'm afraid of it...I don't know what I'm doing half the time. I'll get confused. I don't want to put the wrong answer...it worries me.* [PAT05, community patient]

A common contradiction was observed among patients between their perceived digital abilities and their reported digital capabilities. The following quote is from a patient who described their use of digital technology as "not good" and "very limited."

> *[I have] an iPhone 13 mini...I go on Internet, social media occasionally...check football scores...I use Google quite a lot. I'll check the weather and watch videos...Occasionally I'll check the news. [And I use] WhatsApp...I use the NHS app to order prescriptions...I find that easier to do [with] the NHS app, probably easier than trying to get to see someone.* [PAT08, hospital patient]

Perceived digital ability operated as another layer of vulnerability, influencing not only whether patients felt able to use *myCOPD* but also how confidently they interpreted and acted on its content.

Socioeconomic Status

Socioeconomic status (SES) was rarely discussed directly, and a marker of SES was not collected as part of the PROPEL study,

XSL•FO
RenderX

but there were instances where economic resources appeared to influence engagement with *myCOPD*. The following extract highlights a participant of high SES who was less invested in the app because they were able to access support for self-management from a private health care team.

> *I couldn't keep waiting for NHS responses, so I went privately to see a respiratory consultant, and he put me onto an ENT consultant who is very good. And they also put me onto a respiratory physio, and she was very good. And I've obviously taken hints from them of what to do. And yeah, I think I've got most things under control fairly well.* [PAT09, community patient]

Socioeconomic context, specifically having the financial ability to seek private health services, presents a potential layer of vulnerability. Such differences in financial resources may influence the perceived value of engaging with *myCOPD*.

Important Differences in the Health Care Setting

Approaches to Delivering myCOPD

This theme highlights factors relevant to how HCPs approached the delivery of *myCOPD*. Two subthemes (the perceived purpose of the health service and organizational-structural factors) appeared to influence the third subtheme (approaches to the delivery of *myCOPD*). Given the distinct approaches to delivering *myCOPD*, the health care setting is conceptualized as a layer of vulnerability that can hinder or promote engagement with *myCOPD*. These approaches also influenced how clinical teams used DHCs.

Community Setting

Among community professionals, the general perception was that the purpose of their service was to provide and improve COPD self-management regimens over several weeks. Community professionals often described discussing relevant self-management strategies with patients and using *myCOPD* as an initial step toward engagement.

> *[We] try and find out which is the best route initially [for the patient to] start engaging with the app...I suggest looking at chest clearance, or if they're not taking inhalers properly then we'd look at the inhaler technique...trying to find something that they engage with well and get them to concentrate on that initially.* [HCP12, community-based HCP]

Between contacts, community professionals described checking patient usage reports in *myCOPD*. At in-person visits, professionals would check patient responses to, and understanding of, accessed content and then develop self-management strategies by signposting patients to further relevant content. In this context, DHCs were used for brief check-ins with patients and to address technical issues. This proactive approach was often described as a clear and purposeful process that used *myCOPD* as a medium to demonstrate and discuss tailored self-management techniques.

> *I do like [myCOPD] because you can see how well the patients are doing with that symptom tracker...you can have a look at your patients and say "oh, he's not good today. It might be worth giving him a phone call," [to ask the patient] "have you spoken to a GP, have you taken action on this?"* [HCP11, community-based HCP]

Hospital Setting

In contrast, hospital professionals often described a service that focused on recovery from exacerbation in preparation for discharge. Organizational-structural factors appeared to influence the approach to delivering *myCOPD*. For example, hospital-based professionals perceived internet connectivity, understaffing, and patient expectations (of being discharged) as adversely affecting how *myCOPD* was delivered.

> *There's quite a big workload for my colleagues, [it's] quite a big hospital. If there was maybe more employees to go through the app...but I don't know if we've got enough resources...to thoroughly implement it.* [HCP7, hospital-based HCP]

These contextual issues induced an approach to delivery that was passive, fundamentally reducing engagement to onboarding. This was commonly expressed as "selling" *myCOPD*. This passive approach seemed to be an embedded process in which clinical professionals avoided discussing the app with patients; anything related to the app was deemed the work of the DHC.

> *We ask the Band 4 [DHC] to see the patients for the myCOPD app, you know introduce [it and] phone them again afterwards.* [HCP1, hospital-based HCP]

Engagement With *myCOPD*

This theme describes how patients perceived engagement with *myCOPD*, a perception seemingly affected by contextual factors described in previous themes. Two subthemes are used to describe different types of engagement. The contrast in engagement across the 2 sites highlights that engagement itself is a layer of vulnerability rather than a neutral process, one that does not rely solely on design and individual capacity.

Single-Aspect Engagement

Single-aspect engagement describes a focused type of engagement, characterized by accessing specific parts of the app, as if they were stand-alone components (eg, breathing exercises, inhaler technique, and physical activity). Single-aspect engagement was often described in terms that were transactional and short-term, patients expected to achieve clear benefits from use. Both sets of patients, community and hospital, described single-aspect engagement.

> *[Regarding inhaler technique] I didn't realize I was doing so much wrong, and it does make a difference if you do it properly...[also] some of the techniques for getting your breath back [I] didn't know anything about that. Again, that's something new that I've learnt.* [PAT06, hospital patient]

Multifaceted Engagement

Multifaceted engagement describes a more comprehensive use of *myCOPD*, often characterized by a sense of purpose and routine. Single-aspect engagement remains present, but usage does not need to fulfill a specific function.

XSL•FO
RenderX

> *It's a normal daily thing. You know, I do it in the morning to record when I take my medicines and steps, and I do it in the evening to record any exercise I've done.* [PAT04, community patient]

Multifaceted engagement seemed to stem from proactive communication and management between patients and professionals. Hospital HCPs tended to check and prompt usage, whereas community HCPs tended to check and prompt meaningful engagement. Here, interviews with HCPs help to understand the different types of engagement described by patients.

> *I see if they're actually using it [myCOPD], and if not, I do tend to send them a little message...You know, "Please remember to use this" or "I have noticed you haven't activated it" or "I've noticed you haven't used it in a couple of weeks."* [HCP13, hospital HCP]

> *I'll use the app to check how the patients doing and then motivate them on these follow up calls, to motivate them how to continuously use [myCOPD] because the whole point is to make sure they're getting that PR support after an exacerbation. So, to ensure they don't get unwell and really focus.* [HCP2, community-based HCP]

Perceived Barriers to Engagement

Overview

Perceived barriers to engagement seem to be affected by the previous themes and are categorized into 2 subthemes. User perceptions of *myCOPD* describe gaps between the actual provision of *myCOPD* and users' understanding of that provision. External barriers are perceived issues that are beyond the direct remit of *myCOPD* (eg, fit with in-person care and the degree to which *myCOPD* is embedded within services). Misunderstandings about app functionality and uncertainty about data fidelity interact with existing layers of vulnerability, shaping how confidently patients and clinicians rely on the tool.

User Perceptions of myCOPD: App Functionality

While many participants (both patients and HCPs) described *myCOPD* as easy to use, some participants made initial judgments based on whether they perceived the app as intuitive. For example, some participants passed judgment based on their understanding of a specific function being absent (eg, accessibility functions) and not realizing that the desired functionality was offered.

> *Patients who cannot read, [there is a] low reading age in Cornwall, or [have] eyesight problems, or have dyslexia may struggle as the questionnaires and tabs are all word-based. Perhaps a speaker icon with the questions and tabs narrated would benefit patients.* [HCP11, community HCP]

This perceived functionality was described by some participants when navigating *myCOPD*. These perceptions could have been overcome through discussion with technical support. Similarly, some patients described burdensome expectations to complete "lengthy" physical exercise sessions, even though *myCOPD* typically builds tolerance, ranging from 8 to 40 minutes, depending on user preferences.

> *I've just been through the exercises and it's an hour's worth of exercises...the whole bundle of exercises and watching all the videos and doing the exercise is close on an hour.* [PAT09, community patient]

User Perceptions of myCOPD: Trust in Patient Usage Reports

Community-based patients and professionals articulated the importance of building trust in patient self-reports provided in *myCOPD*. This trust would encourage professionals to tailor treatment effectively. Simply providing reports without an explanation of their underlying fidelity left room for suspicion. For example, the Activity Diary in *myCOPD* has a calendar option that reports the number of minutes and the Rating of Perceived Exertion achieved during exercise, a design aimed at increasing fidelity.

> *[Usage reports] tell you that patients have done their PR, but actually they opened the tile, looked at the first page and then ticked that they've done all the exercise. You get that clinician's sixth sense, that they might not have actually done the exercise.* [HCP9, community-based HCP]

External Barriers: Contrasting Perceptions of Fit With In-Person Care

Patients did not expect HCPs to check their *myCOPD* activity but also felt unable to increase their engagement in conversations during face-to-face consultations. As outlined above, community professionals frequently described using *myCOPD* to better target their professional expertise. In contrast, hospital professionals often preferred in-person care to using *myCOPD*.

> *We see them after the acute phase, they've had an exacerbation, and they're in hospital and I suppose generally that's always gonna be better...It's better to see anyone face-to-face.* [HCP7, hospital-based HCP]

External Barriers: Embedding myCOPD Into Routine Practice

Professionals frequently mentioned that *myCOPD* was not embedded enough within services. Embedding sometimes meant having a critical mass of users to be seen as routine practice; at other times, it meant buy-in from frontline staff and managers.

> *I think it needs to be enforced by the whole team whereby we say [to patients], "look, when you're going home, we need to see this information and it's gonna be used in the clinic." I think then...adherence would be better.* [HCP6, hospital-based HCP]

Community HCPs were proactively using *myCOPD* but also highlighted the need to provide a dedicated space to support patients with engagement during existing face-to-face consultations.

> *If it [myCOPD] was part of pulmonary rehab and we did make it more approachable, [it would] make them*

XSL•FO
RenderX

> *[patients] feel like they're all doing it together, they're all in the same boat [as COPD patients]...a bit of support over the next few weeks, then you'll be good to run with it.* [HCP3, community-based HCP]

Where *myCOPD* was not well integrated into routine care, organizational constraints compounded existing layers of vulnerability, limiting opportunities for patients to develop sustained engagement.

Perceived Benefits of Engagement

The perceived benefits of engagement with *myCOPD* appear to be affected by the first 3 themes. The first subtheme captures direct benefits associated with *myCOPD*. For HCPs, this meant positive alignment with existing care guidelines; for patients, this meant that the app was a tangible resource for improving specific abilities. The second subtheme describes wider benefits of *myCOPD*.

Targeted Behavior Change

Targeted behavior change describes how *single-aspect engagement* was perceived to improve specific abilities (eg, breathing through an exacerbation, improved inhaler technique, and increased physical activity). This association often led to descriptions of improved self-confidence. Overall, patients described being able to use *myCOPD* to address and improve specific behaviors that concerned them.

> *It's [chest clearance on myCOPD] helped...that's one thing, you can hear it now. I'll get like a frog in the throat and in the chest...everybody thinks I've got cough or cold all the time, but hang on, just got to clean myself [performs chest clearance].* [PAT03, hospital patient]

> *[I've got] more confidence, really, confidence in managing my condition...When I used to walk uphill, to do the horses, [I] used to stop to take a breath or take my inhaler and now I just keep going but I slow down...I realise that I don't have to stop, and I don't have to rush...[I'm] kind of not worried about losing my breath because I can control it.* [PAT07, community patient]

Wider Lifestyle Adjustments

This subtheme describes benefits associated with *multifaceted engagement*. This seemed to be a longer-term type of engagement with benefits yet to materialize. This type of benefit was only associated with patients from community settings and was typically developed through a latent process of analysis. Short transcript extracts do not adequately explain this subtheme; however, there was one example that demonstrated the potential benefits of wider lifestyle adjustments.

One patient noticed increasing breathlessness over several weeks and did not understand why. The patient eventually accessed the reporting functions in *myCOPD* and, because they had been recording exercises and symptoms daily, were able to spot a pattern in their breathlessness. Consequently, they were able to deduce that the breathlessness was a result of chopping wood and adjusted their behavior to avoid symptoms by taking a preventative inhaler before chopping wood or delaying the activity until later in the day.

Discussion

Principal Findings

This study explored how *myCOPD* was delivered and used across 2 contrasting NHS settings and how contextual, organizational, and individual factors shaped engagement. Across both sites, patients described how multimorbidity, perceived digital ability, and socioeconomic context influenced their capacity to engage with the intervention. These characteristics did not operate in isolation; rather, they interacted with local delivery practices to shape engagement trajectories.

A key finding was the marked difference in delivery approaches between settings. Community PR HCPs adopted a proactive, iterative model of support using *myCOPD* to structure conversations, reinforce self-management strategies, and monitor progress. In contrast, hospital HCPs described a more passive, onboarding-focused approach shaped by workflow pressures, limited staffing, and the prioritization of discharge. These delivery styles appeared to influence whether patients engaged in single-aspect engagement (targeted, short-term usage) or multifaceted engagement (routine usage).

Both HCPs and patients identified barriers and facilitators to engagement. Barriers included usability concerns, competing health priorities, limited digital confidence, and challenges integrating the app within in-person care. Facilitators included personalized support from clinicians, clear explanations of app features, and opportunities to discuss content during follow-up contacts. PPI contributors confirmed the relevance of these findings, emphasizing the importance of timely support, clear communication about the purpose of the app, and recognition of the challenges posed by multimorbidity and limited digital confidence.

A key strength of this study is the inclusion of both patients and HCPs across 2 contrasting NHS pathways, enabling a nuanced understanding of how delivery context shapes engagement. The use of abductive thematic analysis allowed us to integrate theoretical insights with inductively generated themes, and PPI involvement strengthened the relevance and clarity of the findings. Collectively, these findings highlight that engagement with *myCOPD* is not simply a function of individual motivation or app design but emerges from the interaction between patient characteristics and the delivery environment, an insight that aligns with and extends implementation theories emphasizing context-mechanism interactions [27].

Comparison With Prior Work

Our findings align with implementation research demonstrating that digital interventions are not inherently effective; their impact depends on how they are introduced, supported, and embedded within clinical workflows [11,26]. Prior COPD digital evaluations [22-25] similarly reported high initial interest in inhaler videos and symptom tracking but noted rapid declines in use. Our findings extend this work by showing why this decline occurs, specifically, that passive onboarding in hospital settings limits opportunities for relational reinforcement.

XSL•FO
RenderX

More specifically, our observation that proactive, relationship-based support in community PR settings facilitated sustained engagement echoes the work of Pinnock et al [5,6] on supported self-management and aligns with the theorization of implementation mechanisms by Lewis et al [28], which emphasizes the importance of relational reinforcement and iterative feedback loops. Our data provide concrete examples of how these mechanisms operate within COPD pathways, illustrating how clinicians used *myCOPD* to scaffold conversations, tailor recommendations, and maintain continuity, practices that have been theorized but rarely described empirically in COPD digital implementation studies.

Conversely, the passive onboarding approach observed in hospital settings reflects challenges documented in acute care environments, where digital tools are often introduced during periods of high patient burden and limited staff capacity [10,14]. This is consistent with the findings of O'Connor et al [29], which indicate that workflow pressures and resource constraints in acute care limit opportunities for relational support and follow-up. Our findings extend this literature by showing how these constraints shape not only uptake but also the depth and trajectory of digital engagement, with hospital patients more likely to adopt single-aspect, short-term use.

Our findings also contribute to emerging evidence on digital inequalities. Multimorbidity, perceived digital ability, and socioeconomic context shaped how participants navigated *myCOPD*, consistent with the literature highlighting the intersection of health and digital disparities [13-16]. Informed by the concept of "layers of vulnerability" proposed by Luna [19,20], our analysis suggests that these vulnerabilities are dynamic and relational, shaped not only by individual circumstances but also by the support available within clinical settings. This was evident in patients who described shifting their self-management priorities in response to exacerbations or competing long-term conditions, relying on family members or clinicians to navigate digital tasks when confidence fluctuated, and adjusting their engagement depending on whether services provided opportunities for discussion, troubleshooting, or reinforcement.

In doing so, our study provides empirical grounding for the conceptualization of vulnerability as layered rather than categorical, as proposed by Luna [19,20], demonstrating how multimorbidity, digital confidence, and socioeconomic constraints accumulate and interact within real-world COPD pathways. This complements the call for intersectional approaches to digital health disparity research made by Husain et al [11] and aligns with the argument of Veinot et al [30] that digital inequalities are structurally produced rather than individually determined. Our findings also resonate with the findings of Greenhalgh et al [31], specifically the finding that multimorbidity often complicates digital adoption, particularly when tools are not embedded within supportive relational contexts.

Limitations

Although this study offers important insights into how delivery context shapes engagement with *myCOPD*, several limitations should be acknowledged when interpreting the findings. First, participants were recruited from within the PROPEL study cohort, which may limit transferability to settings where *myCOPD* is introduced outside of a research context. Second, interviews were conducted remotely, which may have influenced participation among individuals with limited digital access. Third, while we examined differences across 2 settings, the sample size did not allow for detailed subgroup analysis (eg, by digital literacy, severity, or SES). Finally, usage data provided by my mhealth Ltd offered helpful context but did not capture qualitative nuances of engagement. These limitations underscore the need for future work that examines delivery models across a wider range of organizational contexts and includes more granular measures of digital literacy and multimorbidity burden, as recommended by Venoit et al [30].

Implications for Practice and Implementation

Our findings highlight the importance of aligning digital self-management interventions with local workflows and capacities. Proactive, iterative support (such as checking usage data, discussing content during follow-up, and tailoring recommendations) appears to facilitate more meaningful engagement. Services adopting *myCOPD* may benefit from clarifying roles (eg, between clinicians and DHCs), ensuring adequate staffing, and embedding digital support within routine contacts. These implications arise directly from the contrast observed in our study: PR clinicians were able to provide iterative support because roles were clear and time was protected, whereas hospital clinicians lacked these structural conditions. More specifically, our data suggest that proactive delivery models may require explicit resourcing, including protected time for clinicians to review usage data and integrate digital discussions into routine care. This aligns with the argument of Greenhalgh et al [32] that digital health implementation depends on relational work and organizational readiness. Hospital settings, where workflow pressures limit such opportunities, may benefit from dedicated DHCs or structured onboarding protocols that extend beyond discharge.

At the patient level, recognizing the influence of multimorbidity, digital confidence, and socioeconomic context is essential for equitable implementation. Tailored onboarding, opportunities for hands-on support, and clear communication about the purpose and benefits of the app may help address barriers. These findings reinforce the value of attending to layers of vulnerability when designing and delivering digital self-management support. In practice, this may involve prioritizing hands-on demonstrations for patients with low digital confidence, offering multimorbidity-sensitive guidance that helps patients identify which app features align with their immediate priorities and ensuring that digital support is available beyond initial onboarding. These approaches are consistent with the suggestions of Vorrink et al [33] to improve digital self-management interventions.

For policy and commissioning, these findings suggest that digital interventions should not be implemented as stand-alone tools but as components of broader self-management pathways that account for organizational readiness and patient diversity. Commissioners may therefore need to incorporate workflow assessments, staffing considerations, and digital literacy support

XSL•FO
RenderX

into procurement and implementation plans, ensuring that digital tools are embedded within coherent, adequately resourced pathways rather than added as isolated components. This aligns with Normalization Process Theory as outlined by Murray et al [34], which emphasizes the importance of integration within existing workflows.

Implications for Research

Future research should examine how different models of delivery influence long-term engagement and clinical outcomes, including whether proactive support can be feasibly scaled. Further work is also needed to explore how digital interventions can be tailored for individuals with multimorbidity, low digital confidence, or limited access to technology. Mixed methods evaluations that integrate qualitative insights with detailed usage analytics may help identify mechanisms of engagement and inform more equitable implementation strategies.

Our findings point to several specific avenues for investigation, including comparative studies of proactive versus passive delivery models, evaluations of DHC roles within COPD pathways, and intersectional analyses that examine how layers of vulnerability shape engagement trajectories over time. Integrating relational measures of support with usage analytics may be particularly valuable for identifying mechanisms that drive sustained engagement, as suggested by the work of Lewis et al [28] on implementation mechanisms.

Conclusions

Delivery context and local workflows play a central role in shaping how patients engage with *myCOPD*. Proactive, relationship-based support appears to facilitate more integrated and sustained engagement, whereas passive onboarding may limit the intervention's potential. Considering patient characteristics, particularly multimorbidity and perceived digital ability, alongside organizational capacities may support more equitable and effective implementation of digital self-management tools in COPD care. The concept of layers of vulnerability provides a useful lens for understanding how individual and structural factors combine to shape engagement trajectories.

By illustrating how delivery models interact with patient characteristics to shape engagement, this study contributes to a more nuanced understanding of digital self-management implementation and highlights the need for context-sensitive, equity-oriented approaches to digital health in COPD care.

Acknowledgments

We would like to thank all individuals who participated in patient and public involvement activities for this study. We would also like to thank the clinical and research support provided by Cornwall Partnership NHS Foundation Trust, North Bristol NHS Trust, and University Hospitals Bristol & Weston NHS Foundation Trust. No generative AI was used in the preparation of this manuscript. We would also like to acknowledge our research collaborator Unity Insights Limited for running statistical analysis.

Funding

MR is completing a PhD jointly funded by the National Institute for Health and Care Research Southampton Biomedical Research Centre and my mhealth Ltd. This work was commissioned and funded by SBRI Healthcare. SBRI Healthcare is an Accelerated Access Collaborative (AAC) initiative, in partnership with the Academic Health Science Networks (AHSNs). The views expressed in the publication are those of the author(s) and not necessarily those of SBRI Healthcare or its stakeholders.

Data Availability

The qualitative interview data generated and analyzed during this study are not publicly available due to confidentiality agreements and the lack of participant consent for data sharing.

Authors' Contributions

MR conceived and conducted the data analysis, collected the data, and drafted and revised the manuscript. BA conceptualized the overarching study, provided supervision, and commented on manuscript drafts. KB provided supervision and commented on manuscript drafts. TW secured funding for the project, conceptualized the overarching study, provided supervision, and commented on manuscript drafts. LY provided supervision and commented on manuscript drafts. AB commented on manuscript drafts and was responsible for delivering the wider PROPEL (A Pragmatic Real-World Multicenter Observational Research Study to Explore the Clinical and Health Economic Impact of *myCOPD*) study. BC conducted initial patient and public involvement work and contributed to data collection. JD and RW served as site leads and commented on manuscript drafts.

Conflicts of Interest

MR completed this work as part of a PhD jointly funded by the Southampton National Institute for Health and Care Research Biomedical Research Centre (NIHR BRC) and my mhealth Ltd. AB is employed by my mhealth Ltd. TW is the cofounder, shareholder, and director of my mhealth Ltd. The views expressed are those of the authors and not necessarily those of the Southampton NIHR BRC or my mhealth Ltd. BC was a research fellow on this study, based at University of Southampton, and moved to the University of Westminster. All other authors declared no conflicts of interest.

Abstract

Background: Health information technology (HIT), while designed to improve practice efficiency and patient care, can contribute to physician burnout when designed without clinical practice in mind. Administrative and clinical demands now require physicians to spend more time on HIT, a burden that contributes to burnout and affects time with patients.

Objective: This study had two objectives: (1) to examine how physician perceptions of specific HIT functions may alleviate or contribute to physician burnout within the differing health care landscapes of Ontario and Nova Scotia, with particular attention given to physician perceptions of HIT associated with administrative burdens, interoperability, and system integration, and (2) to explore physician experiences and perceptions of HIT as potential factors affecting physician burnout, with the goal of delivering findings (eg, a model) that could be applied to improve physicians' HIT experience.

Methods: We designed an exploratory mixed methods study that deployed a cross-sectional survey in 2 Canadian provinces: Ontario and Nova Scotia. Centralized clinician management software (Ontario) and medical association networks (Nova Scotia) were used to recruit from an estimated 35,341 (Ontario) and 2809 (Nova Scotia) physicians. The survey was distributed between February and April 2024. Nonphysician clinicians, clinic staff, and non-HIT users were excluded, resulting in 1245 Ontario and 136 Nova Scotia physician HIT-user respondents. For both the Ontario and Nova Scotia samples, descriptive analyses of quantitative survey items were compared, and open-text responses were subjected to qualitative coding for themes. Subgroup differences in HIT-related burnout were analyzed in the larger Ontario sample.

Results: Common experiences were apparent despite differences in the samples, provincial health systems, and available HIT. "Managing communications related to patient care" and "inputting data into your EMR" were among the top 3 administrative burdens. While "logging in and out of technology platforms" ranked higher in Nova Scotia as an administrative burden, the related theme of integration and interoperability was prominent in both samples. In the Ontario sample, perceptions of HIT, quality of support, and hours worked per week accounted for over half of the variation in self-reported burnout.

Conclusions: While physicians appreciate the advantages of HIT for patient care, they also experience an overwhelming administrative and documentation burden, as well as disjointedness across data platforms, which contributes to their burnout. Greater ongoing involvement by end users in the design and usability of these technologies, along with improved standardization and interoperability, would reduce these burdens while maintaining the benefits of digital health systems.

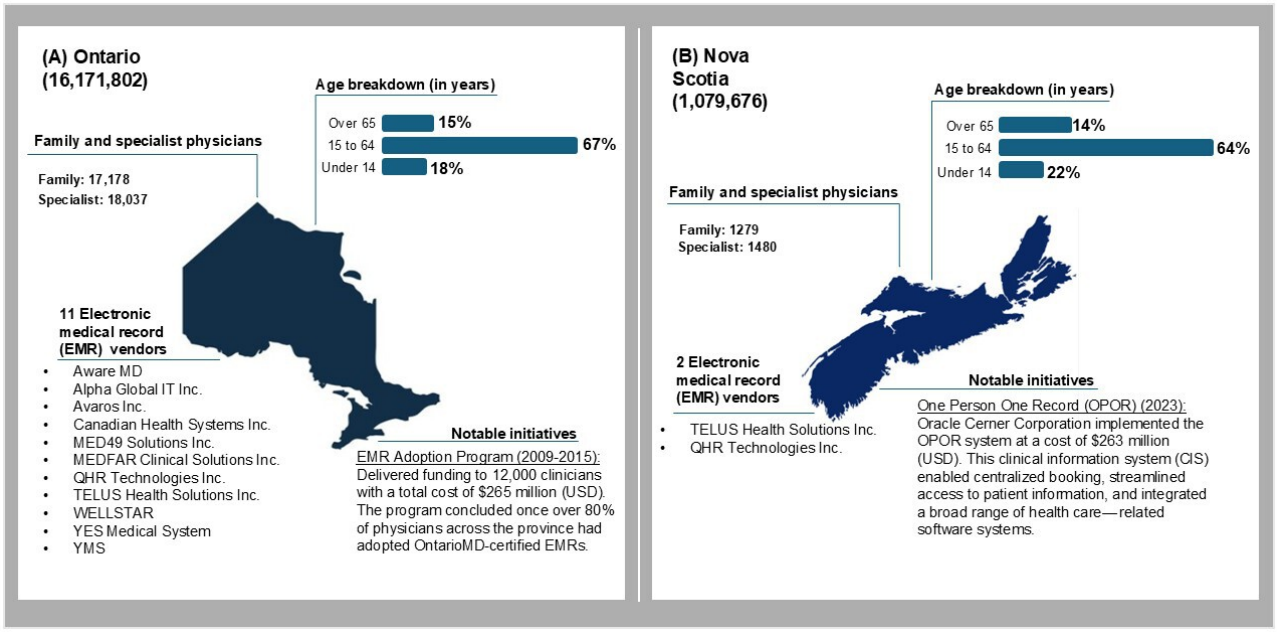
KEYWORDS

burnout; digital health; EMR; physician wellness; stress; health care workforce; administrative burden; electronic medical record

Introduction

Physician burnout remains a system-wide problem with consequences for physicians and health care delivery in Canada. The Canadian Medical Association's (CMA) 2025 National Physician Health Survey found that 46% of physicians (n=3310) reported symptoms of burnout [1] (high levels of at least one indicator of depersonalization or emotional exhaustion using the Maslach Burnout Inventory [2]). The CMA study connects burnout and related health outcomes to an escalation in administrative burden: over the 3 iterations of their survey—2017, 2021, and 2025—there has been a significant increase in the proportion of respondents reporting spending an excessive or moderately high amount of time on their electronic medical record (EMR) on administrative tasks outside of regular hours, from 36% to 49% in 2021 and 64% in 2025. Here and elsewhere, it has been found that the burden is particularly high in family medicine [3]. One study reported that this group spends



XSL•FO
RenderX

an average of 19 hours a week on administrative tasks [4]. This has an impact on access to primary care when family doctors experience administrative demands competing for patient-facing time and/or reduce (or leave) clinical practice due to burnout.

While workload, administrative burdens, and insufficient time with patients are neknown contributors to physician burnout [5,6], health information technology (HIT)—encompassing the electronic systems designed to collect, share, and manage patient information—has introduced new dynamics [7-9]. Paradoxically, the technological solutions intended to support a physician's daily work can also add to their workday burden, as they adapt to a tsunami of expensive, new, and largely unregulated HIT platforms while having a minimal role in their design and implementation [10,11].

In Canada, while federal initiatives shape the overall approach to health nationwide, provinces are responsible for (and fund) health care delivery. This leads to differences in models for care delivery that can affect physician workload—for example, in Ontario, a primary care physician in a Family Health Team may have access to more resources than a primary care physician working outside that model. Provinces are also responsible for decisions affecting the technologies clinicians use to manage patient data and to interact with others in the provincial health system, including the implementation of (provincial) system-wide initiatives. Our study focuses on 2 settings—the Canadian provinces of Ontario and Nova Scotia—to explore physicians' HIT experiences, including potential contributors to burnout in health care providers, their use of HIT, and notable HIT initiatives (Figure 1) [12-16].

Figure 1. Comparative context. (A) Ontario and (B) Nova Scotia.

While previously relying on 1 of 2 EMRs on the market in the province, Nova Scotia physicians only recently (December 6, 2025) began the implementation of One Person One Record (OPOR) [17], a clinical information system designed by Oracle Cerner to address centralized booking, access to patient information, and integration across institutions and software systems. In contrast, community-based Ontario physicians have had greater choices available to them via certification and adoption programs beginning in 2009 [18], allowing physicians to choose from a list of certified offerings meeting a minimum standard. Physicians working in both community and hospital settings rely on hospital information systems (commonly referred to as HIS) such as EPIC. Both provinces feature multiple platforms for transmitting reports from hospitals, laboratories, and diagnostic facilities to a patient's electronic record. In addition, physicians may have access to add-ons, only some of which may be integrated (ie, accessible directly from the EMR without having to log out and log in to a different platform with a different username and password).

The relative maturity of the HIT landscape in Ontario is a consequence of provincial government investment, which includes change management support via a team of field advisors and peer support (ie, physicians and other clinical staff) who connect physicians with resources, provide guidance, and offer other change management support for adopting and implementing new technologies (physicians are free to choose a noncertified EMR outside of this system). Government-funded programs are delivered by OntarioMD (OMD, a subsidiary of the Ontario Medical Association). The closest analog to OMD in Nova Scotia would be the E-Health division of the provincial medical association, Doctors Nova Scotia, which provides physician support, advice, and guidance on these technologies.

We designed a mixed methods study to explore physicians' perceptions of HIT and their relationship to their burnout. As described, Ontario and Nova Scotia are not directly comparable, given their differences in size, HIT infrastructure, and historical support for HIT adoption. We hypothesized that, despite these differences in maturity, we may see commonalities across Ontario and Nova Scotia physicians in terms of the benefit they derive from HIT, their expectations vs the reality of their experience, their usability challenges, and the ways in which the day-to-day world of clinical practice is affected by HIT.

XSL•FO
RenderX

Through this exploratory, contextual analysis, we sought to learn which aspects of HIT are perceived by physicians as valuable and which they perceive as contributing to their burnout; the balance between the 2 shapes their overall experience. Our secondary objective, given sufficient data, was to run tests of significance, which could contribute to a model for understanding the factors that contribute to tech-related burnout.

Methods

Survey Instrument

Between 2018 and 2024, OMD conducted an annual survey of clinicians as an evaluative mechanism (internal purposes only) to provide insight into the impact of physician-facing initiatives and to inform future priorities. Within this survey, there was a section on challenges, with optional open-text questions that were reviewed and coded for themes. The cumulative findings suggested that a focused interrogation of the impact of technology on physicians was warranted.

We designed and conducted a self-administered electronic questionnaire on HIT-related burnout, including potential factors, guided by (1) a literature review on HIT-related factors contributing to physician burnout, (2) a review of qualitative responses to annual OMD surveys on challenges with HIT, and (3) team discussions of evidence to date. The questionnaire was piloted by the Nova Scotia E-Health Committee, comprising 9 physicians and 2 medical learners, and then refined with support from OMD-affiliated physicians. The final 25-item instrument consisted of 23 mandatory closed-ended and 2 open-ended questions. The first question asked whether respondents were currently using HIT in their primary practice; those who responded "no" were excluded from subsequent questions on HIT. Three potentially sensitive questions in the "About You" section included "prefer not to answer" as an option. Two versions containing the same content specified regional consent and identification details (Multimedia Appendix 1). Microsoft Dynamics 365 Customer Voice was used to develop and distribute both questionnaires separately via links embedded in email and on social media. Respondents could complete the questionnaire at their own pace and edit previous responses, if necessary. No incentives were provided for survey completion. Survey design is reported according to the CHERRIES checklist [19].

Sampling and Distribution

The questionnaire was launched on February 14, 2024, with an in-field period until April 5, 2024. In Nova Scotia, distribution used nonprobability voluntary response sampling [20] via Dalhousie Faculty of Medicine (FoM) communications, the website, social media, and department newsletters. The Doctors Nova Scotia e-newsletter and discussion forum and the *Nova Scotia Health (NSH)* newsletter also distributed the e-questionnaire and reminders. In Ontario, the questionnaire was distributed using OMD's customer relationship management software to an estimated sampling frame of between 24,000 and 31,000 Ontario physicians and other clinical staff. Reminder emails to complete the questionnaire were sent at regular intervals. Additionally, social media posts were shared throughout the distribution period on behalf of both OMD and the Ontario Medical Association. Unique identifiers in the form of College of Physicians and Surgeons of Ontario registration numbers precluded duplicate responses. Eligibility criteria of "current use of HIT" and "family physician" or "specialist" were applied to ensure a valid sample of respondents according to study objectives.

Analysis

Quantitative

Using Microsoft Power Query and Power BI, Ontario and Nova Scotia data were cleaned and organized separately due to the qualitative and methodological distinctiveness of the 2 samples, thereby addressing potential methodological, statistical, and interpretive errors [21]. Structured data models and tables were derived using step-by-step queries for export into the R Studio environment (version 2024.04.2+764 [2024.04.2+764]; Posit Software, PBC). After consulting the relevant literature [22,23], we determined that there was insufficient power in the Nova Scotia sample for significance testing due to the bias inherent in small sample sizes. We then limited our comparative analysis to descriptive data. For numeric data, measures of central tendency (mean) and dispersion (SD and range) were calculated. For categorical data, frequency counts or percentages were calculated.

Statistical tests of reliability and internal item consistency were conducted on the Ontario perceptions scale data to evaluate psychometric properties, as well as the potential to calculate an overall score on perceptions. The perceptions scale data showed a standardized Cronbach α criterion of 0.854 and moderate intercorrelations (Table 1). A polychoric factor analysis with equamax rotation yielded a 2-factor solution, which could be described as *positive perceptions about HIT* (ie, "easier," "communication," "revolutionize," "access data," "quality care," and "patient coordination") and *negative perceptions about HIT* (ie, "negative impact," "reason for job stress," and "prevent patient care"). To derive an overall numeric score for perceptions as a proxy measure of attitude toward HIT, each item's Likert-scale categories were converted into numeric equivalents, with scores of 1 for "Strongly Disagree" and 5 for "Strongly Agree." The 3 *negative perceptions about HIT* items were reverse scored. The resulting overall perception score ranged from 9 to 45, with higher scores indicating more favorable attitudes toward HIT.

[a]$P<.0001$.

Ontario numeric data were assessed for evidence of normal distributions and outliers. Outliers were identified by examining boxplots and normal curves, as well as via statistical tests such as the Rosner test. Subject matter experts were consulted to determine plausible upper and lower limits for a range of values. These included the 3 physician coauthors and 2 OMD colleagues with decades of experience working with clinical practices on the use of HIT in its various forms. Outliers identified in the following variables were replaced with the median of the distribution: “hours per week” (6 values); “hours per week on admin” (10 values); “extra hours per week on admin” (8 values); “% of time spent on admin” (4 values); “% on patient care” (1 value); “% burnout from tech” (1 value); “age” (3 values); and “years of practice” (3 values).

Respondents assessed their level of tech-related burnout on a scale of 0 (no burnout) to 10 (extreme burnout). Respondents were asked to rank 10 administrative tasks (validated through a systematic literature review, consultation, and the results of internal qualitative research) in order from greatest to least burden. The percentage of respondents who selected a task as one of the top 3 most burdensome tasks was derived by summing the counts of first, second, and third place responses for each administrative task and then dividing the sums by the number of respondents. Using robust, brute-force, rank-aggregation statistical procedures, the final list of tasks from most to least burdensome was derived.

Due to the type of data and observed nonnormal distributions, nonparametric tests of group differences were selected to better understand tech-related burnout in relation to Ontario sample characteristics. Specifically, tests of group median differences were conducted using Kruskal-Wallis (KW) rank-sum tests for independent samples, as well as follow-up Mann-Whitney *U*-tests, where relevant. To determine statistical associations among numeric data, Pearson product-moment or point-biserial correlation tests were conducted.

Multiple regression analysis was used to identify potential factors associated with self-reported tech-related burnout. For this analysis, tech-related burnout was treated as a continuous numeric outcome variable [24,25]. First, potential factors and covariates were identified. Then, nonparametric tests were conducted systematically for each potential factor or covariate in relation to tech-related burnout to assess statistical significance and effect sizes. Monotonic effects of ordinal-scale variables were assessed using Bayesian generalized nonlinear multilevel modeling methods. Surviving factors were entered systematically into forward and backward stepwise regression tests until the best-fitting parsimonious model was yielded. Due to the large sample size, power, and potential clinical significance of the findings, a stringent alpha criterion of $P=.001$ was used to determine statistical significance.

Qualitative

We included open text questions (response required) to collect respondents’ reasoning behind their answers. The main open-text question was “How does health information technology contribute to or help alleviate your burnout?” We reviewed and coded categories and compared emerging themes in the quantitative data and from our literature review on physician burnout [26]. As the responses were in a long-answer format, it was possible to code multiple references within a single response. A total of 43 responses were omitted from the coding report for being either (1) uncodable (eg, a dash, a dot, a question mark, or random letters), (2) some version of “no idea,” or (3) difficult to determine what was meant by the respondent (eg, a phrase that appeared unrelated to the question), even following consultation with other members of the research team. Each team coded separately, led by a coder familiar with their jurisdiction to facilitate interpretation of context-specific references in the open text. Two coders were used for the Ontario sample and 1 for the Nova Scotia sample. While this meant that each team generated its own codebook, our intent

XSL•FO
RenderX

was to capture the perspectives of respondents within their regional contexts—given differences in population size, digital maturity, etc—to see whether any areas of commonality emerged despite those differences. After initial coding, codebooks were iteratively refined within the research team, and coding was revisited with discussion where ambiguity or disagreement emerged. Following completion of coding, salient codes were reviewed in detail for common themes across samples.

Ethical Considerations

The Nova Scotia questionnaire was approved by the Research Ethics Board at Dalhousie University (Halifax, Nova Scotia, Canada, file number: 2023 - 6993). As OMD operates under both a provincial government and professional association structure without an institutional ethics board, the Ontario survey was deployed with informed consent language (in consultation with the Dalhousie team and OMD's legal team) in the survey header, asking participants to read the consent text, which also cites OMD's privacy policy on information sharing [27]. Participants were asked to confirm they had read the text and that they agreed to participate. Emailed invitations to complete the survey also used language regarding the voluntary nature of participation.

Results

Quantitative Findings

Because the objective of the study was to explore *physician* experiences with HIT, 138 Ontario and 20 Nova Scotia nonphysician clinicians and clinic staff, as well as 24 Ontario and 4 Nova Scotia non-HIT physician users, were excluded, resulting in 1245 Ontario and 136 Nova Scotia physician HIT user respondents. Data on clinician and clinical characteristics are reported in Table 2. Significant differences in self-reported tech-related burnout by characteristic are noted for the Ontario sample only.

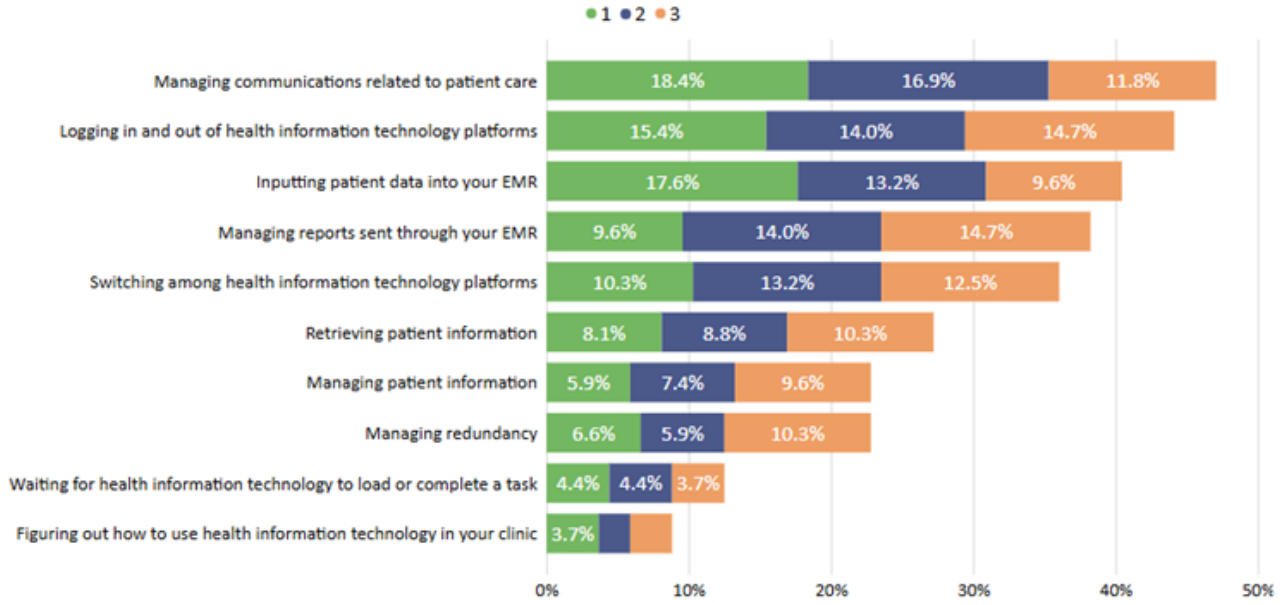
Top Burdensome Administrative Tasks



Figures 2 and 3 show the order from most to least burdensome administrative tasks, with bars representing the percentages of the top 3 burdens. Over half of the Ontario sample ranked the following administrative tasks as a top 3 burden: managing reports sent through your EMR (929/1245, 74.6%), managing communications related to patient care (810/1245, 65.1%), and inputting patient data into your EMR (675/1245, 54.2%). The top 3 burdens for the Nova Scotia sample were managing communications related to patient care (n=72, 47.1%), logging in and out of health information technology platforms (60/136, 44.1%), and inputting patient data into your EMR (55/136, 40.4%). For Ontario specialists, the top 3 most burdensome tasks were managing communications related to patient care, inputting patient data into your EMR, and managing reports sent through your EMR. For Nova Scotia specialists, the top 3 most burdensome tasks were logging in and out of HIT platforms, managing communications related to patient care, and retrieving patient information. For both Ontario and Nova Scotia family physicians, the top 3 most burdensome tasks were managing reports sent through your EMR, managing communications related to patient care, and inputting patient data into your EMR.

Figure 2. Top 3 most burdensome tasks among Ontario physicians (N=1245).

XSL•FO
RenderX

Figure 3. Top 3 most burdensome tasks among Nova Scotia physicians (N=136).

Perceptions and Motivations of HIT

Table 3 provides data on perceptions of HIT, as well as motivations for using HIT. For the Ontario sample, significant differences in burnout levels across the agreement categories for certain perception and motivation items are noted. Most Ontario and Nova Scotia physicians agreed with the following beliefs regarding HIT: HIT facilitates coordination of patient care (978/1245, 78.6% in Ontario; 82/136, 60.3% in Nova Scotia) and HIT improves the quality of patient care (819/1245, 65.8% in Ontario; 76/136, 55.9% in Nova Scotia). Most Ontario physicians agreed that HIT makes it convenient for me to access data (861/1245, 69.2%), while over half of Nova Scotia physicians agreed that HIT will revolutionize the future of medicine (82/136, 60.3%). In terms of motivations for using HIT, the most frequently cited reason for using HIT among Ontario physicians was that they either believed HIT would help them provide better patient care or believed HIT would be of value to them, both internally driven sources of motivation. Among Nova Scotia physicians, the most frequently cited reason for using HIT was that they were required to use it, an externally driven source of motivation.

Physicians' Typical Work Week

Table 4 shows descriptive statistics on physicians' work week. Significant associations with technology-related burnout were noted for the Ontario sample. Ontario and Nova Scotia physicians in our sample reported an average work week of 37.4 (SD 14.0) and 39.1 (SD 14.5) hours, respectively, about half of which was spent on direct patient care (50.2%, SD 16.4) in the Ontario sample. Around 26% and 20% of Ontario and Nova Scotia physicians' time was spent on administration related to patient care. Ontario and Nova Scotia physicians worked an average of 8.6 (SD 7.1) and 4.8 (SD 5.7) additional hours per week, respectively, offsite on administration related to patient care.

Table . Physicians' typical work week.

Survey item and category	Ontario (N=1245), mean (SD; range)	Nova Scotia (N=136), mean (SD; range)
Hours worked per week at the practice[a]	37.4 (14.0; 0-90)	39.1 (14.5; 8-80)
Hours worked per week on administration related to patient care[a]	14.0 (9.1; 0-50)	10.5 (9.4; 0-60)
Hours worked per week outside the practice on administration related to patient care[a]	8.6 (7.1; 0-35)	4.8 (5.7; 0-30)
% of time at practice spent on direct patient care	50.2 (16.4; 0-100)	53.0 (28.6; 0-100)

Quality of HIT Support

In terms of HIT support, over 40% in Ontario (539/1245, 43.3%) received support from their technology vendor; over half in Nova Scotia (69/136, 50.7%) reported support from their on-site technical support. In both cases, these forms of support were deemed at least acceptable (75.4% for Ontario and 79.7% for Nova Scotia; Table 5). For the Ontario sample, significant differences by tech-related burnout are noted.

Table . Sources and quality of support among physicians.

Source of support and quality of support[a]	Ontario, n (%)	Nova Scotia, n (%)
On-site tech support	445 (35.7)	69 (50.7)
Excellent	43 (9.7)	6 (8.7)
Very good	157 (35.3)	14 (20.3)
Acceptable	158 (35.5)	35 (50.7)
Fair	61 (13.7)	11 (15.9)
Poor	26 (5.8)	3 (4.3)

Poor	51 (9.5)	2 (7.7)
Other	261 (21.0)	41 (30.1)

[a]P<.001.

Tech-Related Burnout Levels

In the Ontario and Nova Scotia samples, the median level of self-reported tech-related burnout was 7 and 6, respectively; levels with the highest frequency counts were 7 or 8 in the Ontario sample and 5, 6, or 7 in the Nova Scotia sample. A little over half of the Ontario sample reported a tech-related burnout level of at least 7, while almost two-thirds reported a tech-related burnout level of at least 6. In the Nova Scotia sample, most respondents reported a tech-related burnout level of at least 5. Table 6 shows the findings from an additional question on tech-related burnout.

Table . Percentage of overall work-related burnout due to HIT.

Province	Work-related burnout score, mean (SD; range)
Ontario (N=1245)	42.9 (26.0; 0-100)
Nova Scotia (N=136)	37.0 (25.6; 0-99)

A series of KW rank sum tests on the Ontario data, given its larger sample size, yielded significant results for support quality (KW χ_4^2=90.6; P<.001), proficiency (KW χ_4^2=25.0; P<.001), and clinician type (KW χ_1^2=21.8; P<.001). In this sample, higher quality support and greater proficiency yielded lower levels of self-reported tech-related burnout, whereas lower-quality support and greater (less) proficiency yielded lower (higher) levels of self-reported tech-related burnout. Specialists also tended to report lower tech-related burnout. More unfavorable or favorable perceptions of HIT yielded higher or lower levels of self-reported tech-related burnout. Specifically, agreeing that HIT is the reason for job stress (KW χ_4^2=523.98; P<.001), prevents patient care (KW χ_4^2=305.6; P<.001), or negatively impacts their practice (KW χ_4^2=360.8; P<.001) yielded significantly higher levels of self-reported tech-related burnout. Conversely, all other items yielded statistically significant differences in median self-reported tech-related burnout, with more favorable views of perception linked to lower levels of self-reported tech-related burnout. Pearson product moment correlation tests also yielded a significant correlation between the overall score on perceptions and tech-related burnout (r=−0.56; P<.001). Hours per week at practice (r=0.19; P<.001), hours per week (r=0.33; P<.001) or percent of time (r=0.21; P<.001) spent on administration related to patient care, and extra hours per week spent on administration related to patient care (r=0.34; P<.001) yielded weak-to-moderate positive correlations with self-reported tech-related burnout.

Systematic stepwise regression tests yielded a robust, well-fitting model explaining about 60% of the variation in self-reported tech-related burnout (R^2=0.60; F(7,1237)=266.515; P<.001). Table 7 shows the performance of individual factors in the regression model. Percentage burnout tech (ie, the respondent's estimated percentage that technology contributes to their burnout) was subsequently removed due to difficulties in interpretation, which resulted in a model accounting for about

XSL•FO
RenderX

half of the variation in self-reported tech-related burnout, with 6 stable, meaningful, and potentially actionable factors. All ordinal factors evidenced monotonic, near-linear trends. Follow-up statistical tests were conducted to confirm the regression model. Neither multicollinearity (ie, through examination of variance inflation factors) nor autocorrelation among residuals (ie, through the Durbin-Watson test) was observed. A Bonferroni test for outliers indicated no studentized outliers (P<.05).

Table . Regression factor coefficients.

Predictor	Coefficients (SE)	*t* test (*df*)[a]	*P* value
Intercept	1.841 (0.333)	5.534 (138)	<.001

Prevent patient care	0.227 (0.048)	4.695 (138)	<.001
Reason job stress	0.661 (0.059)	11.277 (138)	<.001
Support quality	–0.194 (0.046)	–4.186 (138)	<.001
Hours per week	0.017 (0.003)	4.903 (138)	<.001
Hours per week extra	0.052 (0.007)	7.529 (138)	<.001

[a]Two-tailed *t* test.

Qualitative Findings

Both coding teams began by assigning responses to the main qualitative question, “How does health information technology contribute to or help to alleviate your burnout?” into 2 themes: negative (corresponding to “contributes to”) and positive (corresponding to “alleviates”). With the larger Ontario sample, QSR NVivo software was used to facilitate coding, and automated sentiment analysis was attempted but was found to be inaccurate upon review—with frequent misattributions of sentiment due to expressive ambiguity or sarcasm, for example. As described in the “Methods” section, blank or difficult-to-interpret responses were excluded from coding.

Using this approach, 146 references were coded as negative and 31 as positive in the Nova Scotia sample, with 864 coded as negative and 657 as positive in the Ontario sample. Each coding team then proceeded with open coding for themes that emerged under each of the 2 larger categories. Codebooks were developed for each province’s sample with codenames and definitions. Once this step was completed, the 2 coding teams compared codebooks to identify similarities across themes—with a focus on aligning code definitions rather than codenames.

From this we discovered that the 2 most common positive themes in both groups were aligned, although in reverse order. The first of these in the Ontario sample dealt with HIT’s capacity to facilitate data management and accessibility (coded as “data management”—168 references; in the Nova Scotia sample coded as “accessibility”—7 references, the second most common). The second refers to administrative efficiency (coded as “regular task completion”—112 references; in the Nova Scotia sample coded as “efficiency”—11 references, the most common).

The considerably larger set of references for the negative statements also offered greater complexity and some differences between the samples. The highest frequency of negative statements in the Ontario sample referred to report management. The second most common theme in the Ontario sample and the most common in the Nova Scotia sample were aligned: the challenges of systems that “don’t talk to each other,” that is, do not interact easily (some variation of which we saw frequently), so that accessing all the necessary patient data requires logging in and out of multiple unconnected platforms. These responses often cited the interruptive nature of recalling different login information and completing dual-factor authentication. These types of references were initially coded as “interoperability and integration” in the Ontario sample and “fragmented” in the Nova Scotia sample.

Otherwise, there were additional differences in the remaining negative codes. Table 8 shows the 4 most common negative subthemes coded in each sample, including the codename, definition, number of references for each code, and a sample quote.

XSL•FO
RenderX

Table . Qualitative coding and sample responses: negative experiences.

Code	Definition	Count, n	Sample quote
Ontario (n=684)			
Managing reports	Duplicate, redundant, irrelevant, too long, labeled incorrectly, or poorly formatted reports.	177	“I have to read all reports that come in, even the useless ones. Waste of my time.”
Interoperability and integration	Systems don’t speak to one another; cognitive overload from switching between platforms and authentication modes.	120	“Lots of platforms promising to improve my workflow, but each requires a unique login and password.”
Work-life balance	EMR availability 24/7 leads to expectation to access beyond work hours.	111	"Never get a break from checking, even when on vacation.”
Referrals	Too many different forms, and specialists reject if forms are not filled correctly; no centralized system to pull information.	102	"Different institutions have different referral platforms and logins.”
Nova Scotia (n=146)			
Interoperability and integration	Fragmented systems require logging in and out of each system and systems do not communicate between one another.	30	"You need to search multiple different techs to find all the data needed.”
Accessibility	Data cannot be found; uploading delays; stored in the wrong place; difficulty navigating.	17	“Limited access to some information locations or difficulty finding specific documentation.”
Time	Time-consuming, slower to use HIT than paper.	17	“Extra hours for admin tasks leave me tired and use up brain energy.”
Usability	HIT systems are not user-friendly, not intuitive, too difficult to use, and technologically challenging.	17	“Implementation with our EMR was so non-user-friendly that we had to deimplement it and revert to phone calls.”

Discussion

Interpretation

Despite notable differences between the provinces in HIT maturity, complexity, adoption rates, practice models, and physician characteristics, common themes emerged surrounding HIT involvement in burnout. While physicians identified many positive aspects of HIT, our findings show that most physicians self-assessed their tech-related burnout level as high: 6 out of 10 in Nova Scotia and 7 out of 10 in Ontario. On average, Ontario respondents reported that 43% of their overall burnout is tech-related, while Nova Scotia respondents reported 37%. Ontario respondents reported greater tech-related burnout and attributed a higher percentage of their overall burnout to technology. Over a third of burnout in our respondents’ self-reports is attributable to HIT.

The top-ranked administrative burdens share commonalities across provinces. Nova Scotia respondents identified managing communications as their primary burden; in Ontario, this ranked second after managing reports due to the effects of nonstandardized implementation of Health Report Manager (HRM) in hospitals (a long-standing issue, which is in the process of being addressed in the province). Both samples ranked inputting patient data into their EMR in third place and logging in and out of technology platforms in their top 5 (second in Nova Scotia and fifth in Ontario). This issue emerged strongly in the qualitative material, which revealed frustrations with logging in and out of non-EMR-integrated platforms for referrals, data portals, etc, which all require unique logins, passwords, and dual-factor authentication. Responses suggest that physicians experience these as both adding to cognitive burden and taking time away from patient care. In both samples, ongoing change initiatives—the provincial rollout of OPOR in Nova Scotia and both HRM improvement initiatives [28] and the Primary Care Action Plan in Ontario [29]—are likely to have an impact on the future experience of administrative burdens and perhaps shift these rankings. Other initiatives at the national level to improve vendor attention to interoperability and standards for HIT solutions brought to market may also have an impact on the physician experience. Bill S-5, the *Connected Care for Canadians Act*, would require HIT vendors to make the technology they sell to clinics interoperable, with penalties for “data blocking.” [30-32] Further, a national effort to standardize data content nationwide is underway with the Pan-Canadian Health Data Content Framework [33]. In the meantime, expensive HIT tools are outpacing our health system’s capacity to adapt. For example, auto-population of forms, patient data integration, and AI assistance are not uniformly regulated or implemented across Canadian practices and provinces [34].

XSL•FO
RenderX

One of the strengths of our approach is the elicitation of candid physician comments via the open text survey questions and our subsequent analysis. This has allowed us to see more layers of the physician experience, especially the complex "love/hate" relationship physicians have with their HIT. In the qualitative material, we found commonality across the Ontario and Nova Scotia samples in terms of the expressed positives of HIT, particularly for data management and administrative efficiency. These align with the reasons HIT was developed and implemented, particularly where government investment is involved. We note with interest that while both samples showed common issues with interoperability and integration (in line with the quantitative results), there were differences in how respondents expressed their other challenges with HIT. In the Ontario sample, we found high counts of references to specific issues, for example, incoming document management and referrals; this was not the case in the Nova Scotia sample, where "usability" was a common theme. This may be due to differences in the samples (ie, higher counts of specific mentions in the larger Ontario sample). We also suggest that the sample from Ontario's more mature HIT environment may have progressed beyond general usability concerns to complaints about more specific challenges.

Perceptions about HIT showed some agreement with positive statements about technology. This tended to be stronger in Ontario, perhaps due to that province being a more seasoned HIT landscape than Nova Scotia and some anticipatory concern in Nova Scotia about the province's upcoming move from a largely paper-based system to OPOR. In both samples, more than half of respondents agreed with positive statements about the impact of HIT on patient care and data access. However, about half of each sample also strongly agreed that HIT prevents spending more time with patients. Indeed, both samples reported spending about half their time on direct patient care, with a notable proportion on administration (approximately 20% in Nova Scotia and 25% in Ontario). These particular (types of) perceptions are conceptually similar to tech-related burnout; therefore, one would expect robust associations. However, findings were moderate and somewhat unclear, which may indicate that perceptions are mediated or moderated by other yet unstudied attributes. Many open text responses contained some version of "I spend more time with the computer than with my patients" related to documentation and accountability expectations that increase screen-related tasks and dominate the patient encounter. These negative perceptions associated with administrative burdens compete with the perceived benefits to patient care. This aligns with findings elsewhere regarding the contribution of daily frustrations, task, and workload burden to burnout [4,7] and underscores many physicians' complex relationships with HIT.

HIT is (or should be) a highly modifiable contributor to burnout; improving physicians' experience of HIT could decrease some burnout overall. Physicians may see the benefits of HIT for patient care in principle; however, a physician's ability to yield optimal value from HIT depends on usability, ease of switching between platforms and nonstandardized forms and referrals, and lessening administrative burden, all of which influence time spent on patient care. HIT co-designed with physicians [35] could lead to interoperability and usability standards that better address the needs of a variety of different practice types, physician characteristics, and proficiency levels—with positive effects system-wide. A focus on human factors in the design of HIT can offset the usability challenges that may be unintentionally introduced by technology vendors in disregarding the realities of clinical practice [36-38]. An example of co-design supporting interoperability exists in the Belize Health Information System implementation, where Canadian and Belizean health professionals worked with community input for design and deployment [39,40]. The result was a system that was easy to use and reduced administrative tasks, including searches and redundancies—while also generating low development and maintenance costs and improving patient outcomes. Successful implementation of HIT relies on the involvement of end-user health care professionals at the outset to better translate the realities of clinical practice workflow to technological solutions.

Future Directions

The OPOR initiative presents an opportunity for a prestudy and poststudy in the Nova Scotia context, similar to other preimplementation or postimplementation studies in this area—particularly to investigate the impact on dedicated patient care time [41]. In Ontario, government-led initiatives such as the Primary Care Action Plan [29] intend to address several areas of HIT that contribute to administrative burden; plans to standardize implementation of HRM in hospitals will also address a large contributor to unwieldy inboxes [28]. A follow-up questionnaire pursuant to implemented changes could explore whether these have had an impact on administrative burden and burnout. There is also an opportunity to further investigate differences between specialists and primary care physicians. While the Nova Scotia sample had a higher representation of specialists than the Ontario sample, the area of specialty was primarily pediatrics, where physicians often act as de facto family physicians, providing incremental care over years to the same families. As we did find lower levels of self-reported tech burnout among specialists compared to family physicians, capturing the difference between "true" specialists (those who provide secondary rather than primary care) and family physicians may provide insights from the greater contrast in practice style. Although there are similarities across specialists and family physicians in terms of most burdensome tasks, the qualitative analysis in our study suggests that the reality of administrative burden in clinical practice may differ between the 2 groups. In turn, this may be contributing to tensions (eg, primary care physicians express frustration with nonstandardized referral forms and the extra administrative burden these forms generate).

Limitations

These findings are preliminary and exploratory and provide a foundation on which to further explore tech-related burnout. We recognize as a limitation that our measure is subjective, based on self-report, and not a validated objective measure. These findings are based on perceptions and associations between self-reported items. Because we used multiple avenues to promote the questionnaire, respondents were not prevented

XSL•FO
RenderX

from accessing the questionnaire more than once; however, we controlled for duplicate responses via unique identifiers. Because we used various sampling methods and exclusion criteria, it is difficult to discern the sampling frame and calculate response rates. The sample is unlikely to be representative. There are limitations to generalizability associated with the small Nova Scotia sample and lack of variability in characteristics that preclude certain statistical tests, hinder precision, and potentially introduce bias, including overestimation of effect sizes. Certain response biases (eg, respondents with higher levels of burnout may have been more motivated to participate), common in this type of research, may have influenced the analysis. We attempted to address related biases in our analysis and reporting. Because findings primarily reflect physician experiences within 2 Canadian provincial health systems, they may not reflect or represent experiences in other health care settings. Although measured on a scale following best practices and adapted from similar scales noted in the literature, our tech-related burnout scale has not yet been validated and is subject to interpretation. Although yielding a significant predictive model, it is difficult to ascertain what an increase of a burnout level of "5" to "6" entails clinically. Qualitative research may help to describe these types of scales. The inductive qualitative coding approach, in which we created separate codebooks for Ontario and Nova Scotia, posed limitations to the comparability of that coding. Further, thematic coding may be subject to bias due to the small number of coders involved (2 for Ontario, 1 for Nova Scotia). Furthermore, this analysis should be viewed as exploratory as we continue to understand tech-related burnout and further refine our approach. We note evidence of validity via the strong correlation yielded between our burnout scale and "Percent burnout from technology." Furthermore, some of the regression factors were measured on scales despite evidencing monotonic, near-linear trends from Bayesian generalized nonlinear multilevel modeling tests. Finally, self-report questionnaires are subjective, so we did not secure objective measures of either burnout or time usage. We followed best practice approaches such as item checks of respondents' attention and piloted ease of questionnaire completion. Our findings are best interpreted as reflecting respondent perceptions and experiences.

Conclusion

Our study provides a broad picture of the physician experience of HIT in the 2 settings we studied. Physician needs may change depending on their location, practice type, specialty, scope of practice, and day-to-day schedule. HIT should have the flexibility to accommodate these needs and be tailored to the people it serves. For this to happen, physicians need to be deeply involved, including in the design of programs to simplify clinical workflows, for example, the use of AI in clinical decision support. Physicians expressed a need to spend more time with patients than with HIT. The current plethora of largely unregulated vendors for an increasingly diverse set of platforms to address the needs of clinical practice, and the lack of full patient-centered integration, may result in high costs for less user-friendly systems. This study reinforces the complexity of HIT systems and their impact on administrative burden. Ongoing involvement of physicians—who actively use these systems—in HIT design and implementation is essential.

This study contributes practical relevance to the growing literature examining the relationship between technology and burnout [7,8,42-45] with analysis and interpretation of physician perspectives on their complex relationships with HIT. HIT may facilitate patient data collection, management, and use, but it can also add cognitive and administrative burdens to physicians' everyday work life. HIT is not inherently protective or harmful; rather, physician experience depends heavily on usability, interoperability, workflow alignment, and meaningful physician involvement in design and implementation to address their clinical realities.

Acknowledgments

The authors thank Christina Jones for her support in the analysis and production of this paper. The authors would also like to thank the physicians who participated in this study for their time and candid responses. No GenAI tools were used in the preparation of the manuscript.

Funding

This study was supported by the Canadian Institutes of Health Research (WI2 179934) and the Dalhousie Faculty of Medicine Osman Fund for Research in Medicine. Abstract

Background: Hepato-pancreato-biliary (HPB) oncology involves complex surgical planning and multidisciplinary decision-making that present significant cognitive, spatial, and communicative challenges. While augmented reality (AR) technologies are emerging as valuable tools in surgical planning, most existing systems are developed in a technologically deterministic manner, often without consideration of patients' lived experiences or the collaborative needs of multidisciplinary clinical teams. This limits their integration into complex workflows and their potential for meaningful clinical impact.

Objective: This study aimed to co-design and evaluate a human-centered AR system that supports spatial understanding, emotional sensitivity, and collaborative decision-making in HPB surgical oncology.

Methods: This mixed methods human-centered design study was conducted between February 2024 and September 2025 and comprised 2 phases. In Phase 1, convenience sampling was used to recruit 14 oncology health care professionals (surgeons, oncologists, and psycho-oncology specialists) and 10 patients with cancer from multidisciplinary oncology care settings to participate in co-design workshops and semistructured interviews exploring the cognitive, communicative, emotional, and workflow requirements for an AR system supporting HPB surgical oncology. Qualitative data were analyzed using reflexive thematic analysis and informed iterative prototype development. In Phase 2, the resulting AR prototype was evaluated through usability testing with 10 hepatobiliary clinicians using simulated multidisciplinary tumor board planning scenarios. Usability was assessed using the System Usability Scale (SUS), supplemented by observational data and qualitative feedback.

Results: The co-design process identified intersecting spatial, cognitive, emotional, and communicative challenges in HPB surgical oncology. These findings informed the iterative development of an AR prototype that functioned as a shared cognitive and communicative workspace. The system enabled collaborative manipulation of 3D anatomical models, emotionally calibrated visualizations, and seamless integration with existing planning workflows. The prototype achieved a mean SUS score of 67.25 (SD 7.95), indicating acceptable usability. In simulated multidisciplinary tumor board scenarios, clinicians reported improved spatial understanding, reduced cognitive load, and enhanced interdisciplinary communication. Patients with cancer participating in the co-design phase valued the ability to engage with their own anatomy in an emotionally manageable way and reported that interactive visualization improved their understanding and sense of agency. Overall, the findings suggest that AR systems designed with human-centered methods can function not only as visualization tools but also as boundary objects that support communication and distributed cognition in complex cancer care settings.

Conclusions: A human-centered co-design process can guide the development of AR systems that extend beyond technical novelty to become emotionally attuned, cognitively supportive, and workflow-compatible tools in surgical oncology. By foregrounding the needs of both patients and professionals, AR can function as a boundary object that facilitates collaborative decision-making, empathetic communication, and multidisciplinary coordination in complex oncology care. This study provides

XSL•FO
RenderX

actionable design recommendations for developing AR technologies that are meaningfully integrated into complex clinical contexts.

KEYWORDS

augmented reality; human-centered design; surgical oncology; co-design; multidisciplinary care; patient-clinician communication

Introduction

Augmented reality (AR) overlays digital information onto the real-world environment, enabling users to interact with patient-specific 3D anatomical information while maintaining awareness of their physical surroundings [1-3]. In surgery, AR has emerged as a promising technology for improving visualization, spatial understanding, and interpretation of complex medical imaging, allowing clinicians to manipulate and explore 3D reconstructions derived from computed tomography (CT) and magnetic resonance imaging (MRI) scans more intuitively than conventional 2D image review [4-6].

This capability is particularly relevant in hepato-pancreato-biliary (HPB) surgery, a specialty focused on diseases of the liver, pancreas, and biliary system, where intricate anatomy and close relationships between tumors, vascular structures, and bile ducts present significant challenges for surgical planning [7]. Although contrast-enhanced CT and MRI provide detailed anatomical information, surgeons must mentally reconstruct 3D spatial relationships from 2D images, making preoperative planning cognitively demanding and increasing the risk of anatomical localization and trajectory planning errors [8,9].

These challenges have driven growing interest in AR to improve surgical planning and intraoperative navigation. Achieving clear resection margins is fundamental in surgical oncology, yet accurate intraoperative tumor localization remains challenging, particularly in anatomically complex and deformable organs such as the liver [10-12]. Conventional image-guided techniques often provide limited real-time spatial guidance. AR addresses this limitation by superimposing 3D anatomical and pathological information directly onto the surgical field, improving spatial awareness and supporting tumor localization, resection planning, and intraoperative navigation [13,14].

In HPB surgery, AR has improved visualization of tumors in relation to vascular and biliary anatomy, enhancing spatial perception during complex liver resections and supporting intraoperative decision-making through real-time anatomical overlays [13,15,16]. In colorectal liver metastasis surgery, AR-assisted navigation enabled rapid registration and successful resection of previously undetectable lesions while achieving clear surgical margins [16]. AR has also improved anatomical orientation during transthoracic minimally invasive liver resections, supporting greater surgical precision [17,18].

Despite these advances, AR remains limited by tissue deformation and organ movement, which can reduce registration accuracy during liver and pancreatic surgery [16]. Broader challenges include integration with existing imaging systems, interoperability across platforms, and incorporation into surgical workflows. Addressing these issues through robust registration methods and user-centered system design will be essential for wider clinical adoption [19].

Within the field of human-computer interaction (HCI), there is increasing recognition that the effective integration of AR into health care requires more than technical sophistication; it must also address the pragmatic needs, cognitive constraints, and interaction preferences of diverse user groups. Successful adoption of AR in clinical practice hinges on understanding how technology interacts with human behavior and complex health care environments [20]. Clinical technologies that are poorly integrated into health care workflows can increase cognitive workload, disrupt clinical processes, and reduce operational efficiency, highlighting the importance of designing systems that align with routine clinical practice [19,21].

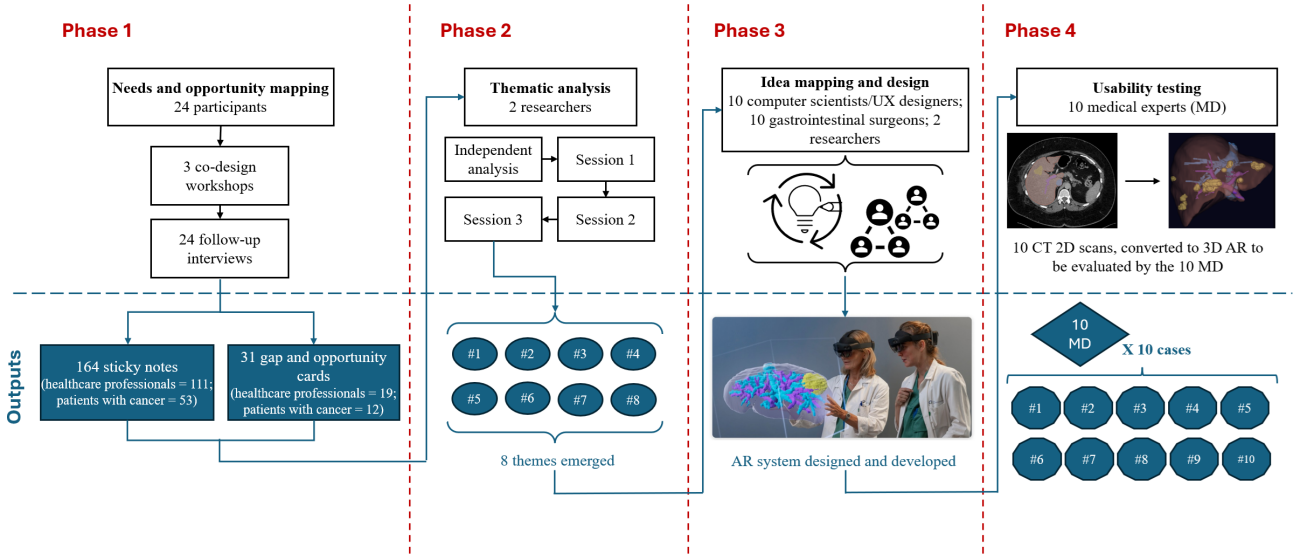
Human-centered design approaches, particularly participatory and co-design methods, have therefore become increasingly important in the development of clinical AR systems. These approaches emphasize iterative development, contextual evaluation, and continuous involvement of end users, ensuring that systems reflect the perspectives of both health care professionals and patients [22]. In oncology, where clinical decision-making is complex and communication is central to patient care, co-design helps identify workflow requirements, usability barriers, and communication needs that may otherwise remain overlooked [23,24]. Furthermore, involving patients throughout the design process can improve usability, trust, and acceptance while supporting shared decision-making and more patient-centered care [25].

Designing AR systems for surgical oncology also requires careful consideration of the clinical environment. Interfaces must support intuitive interaction in sterile, time-critical settings while minimizing cognitive load and physical discomfort [26]. Persistent challenges, including gesture occlusion, lighting interference, and fatigue associated with head-mounted displays, continue to affect usability, although multimodal interaction combining gesture, voice, and gaze offers opportunities to improve user control and workflow integration [27].

Despite the growing application of AR in HPB surgery, the systematic incorporation of both health care professionals' and patients' perspectives throughout the design and evaluation of AR systems remains limited. Consequently, important workflow, communication, and usability requirements may not be fully addressed during system development. To address this gap, this study used a structured, iterative human-centered design approach to develop and evaluate an AR platform for preoperative planning and patient communication in HPB surgery. The aims of this study are to investigate how participatory co-design with health care professionals and

XSL•FO
RenderX

patients can inform the development of clinically relevant AR technologies, evaluate the platform's usability and integration within realistic clinical workflows, and derive design principles to support the future development and implementation of human-centered AR systems for surgical oncology.



Methods

Study Design

This study integrates participatory design, immersive visualization, and clinical cocreation to explore how AR can support surgical oncology workflows, particularly in liver and pancreatic care. Grounded in principles of human-centered design [28] and participatory co-design [21], it investigates how interactive 3D anatomical models can enhance spatial understanding, interdisciplinary coordination, and communication in high-stakes surgical environments. The AR system was developed through a collaborative, iterative process within a complex sociotechnical health care ecosystem. Consistent with sociotechnical frameworks for health IT [29] and ergonomics-informed design [30], health care professionals and patients were engaged as active partners throughout the research process.

The study comprised 2 interconnected phases. Phase 1 focused on participatory co-design and iterative prototype development, while Phase 2 evaluated the usability of the resulting AR prototype in simulated multidisciplinary planning scenarios. The qualitative component of Phase 1 was guided by an interpretivist paradigm, recognizing that technology use and clinical decision-making are shaped by users' experiences and the contexts in which they occur. Semistructured interviews and co-design activities were therefore used to explore the cognitive, emotional, communicative, and workflow needs of health care professionals and patients with cancer. Figure 1 summarizes the overall study workflow.

Figure 1. To generate the catalog of ideas and guide the design of the augmented reality surgical oncology system, we followed 4 phases. In Phase 1, human-centered designers gathered data through co-design workshops and follow-up interviews. In Phase 2, we analyzed all collected materials and identified key cognitive, emotional, and communicative needs, as well as systemic gaps and opportunities in current practice. In Phase 3, we used these findings and participant-generated ideas to design and develop the augmented reality system. In Phase 4, we conducted usability testing with 10 medical experts specializing in hepatobiliary cancer treatment. AR: augmented reality; CT: computed tomography; MD: doctor of medicine; UX: user experience.

Phase 1: Co-Design and Development

Recruitment and Sampling

Phase 1 used convenience sampling to recruit participants with direct experience relevant to HPB oncology care, surgical planning, psychosocial cancer support, and patient communication. Recruitment was iterative, with participants recruited until the research team determined that the dataset provided sufficient breadth and depth of perspectives to inform the co-design process and no substantially new design requirements or experiential insights were emerging from successive workshops and interviews.

Recruitment for Phase 1 commenced in February 2024 through the project partner organizations, Leeds Teaching Hospitals NHS Trust, and the Cyprus Association of Cancer Patients and Friends. Separate invitation emails tailored to the respective participant groups were distributed via the organizations' professional mailing lists for health care professionals and patient mailing lists for patients with cancer. Health care professionals, including surgeons, oncologists, and clinical or counseling psychologists, as well as patients with cancer with relevant experience of surgical oncology care, who met the study eligibility criteria were invited to participate. Individuals who expressed interest by responding to the invitation email were subsequently contacted by the research team, provided with detailed information about the study, and invited to participate in the co-design workshops and semistructured interviews. Participation was entirely voluntary and initiated by individuals who responded to the invitation.

A total of 24 participants were enrolled in Phase 1, including oncology patients and a diverse cohort of clinical professionals specialized in oncology who were involved in the design and preliminary prototyping of the AR system. The clinical cohort (n=14) represented a wide range of roles across the oncology

XSL•FO
RenderX

care spectrum, including medical doctors specializing in oncology and/or general surgery, including cancer surgery (n=9), as well as clinical or counseling psychologists with specific expertise in cancer-related psychological support (n=5). Participants in this group ranged in age from 29 to 46 (mean 36.2, SD 5.6) years, and the gender distribution included 8 male and 6 female professionals. Their perspectives were considered particularly valuable in identifying cognitive, emotional, communicative, and workflow-related challenges associated with current cancer care practices.

The patient cohort (n=10) was previously treated for hepatobiliary, pancreatic, or other types of cancer surgery, including 4 who had specifically undergone hepatobiliary or pancreatic procedures within the previous 6 to 18 months. Their ages ranged from 35 to 55 (mean 49.8, SD 8.6) years and included male (n=7) and female (n=3) participants. All had direct experience with surgical consultations, preoperative imaging, and multidisciplinary cancer care pathways, positioning them to reflect on the clarity, accessibility, and emotional impact of both conventional and AR-enhanced communication approaches.

Procedure

The co-design activities were conducted across multidisciplinary oncology settings in Cyprus and the United Kingdom as part of the HoloSurge project. The workshops were facilitated by MM and M Krini, researchers with expertise in human-centered design, qualitative research, and stakeholder engagement. Recruitment commenced in February 2024, and the co-design workshops were conducted between March and May 2024. A total of 5 workshops were held, comprising 2 face-to-face workshops (with 4 and 5 participants, respectively) and 3 online workshops (5 participants per workshop). Participants were allocated to either the face-to-face or online workshops according to their geographical location, availability, and personal preference. This approach maximized participation while ensuring that discussions reflected authentic clinical and patient experiences across diverse health care contexts.

The co-design activities followed a structured design thinking approach [31] consisting of 4 sequential activities (refer to Multimedia Appendix 1 for the cocreative workshop materials). First, participants completed empathy mapping exercises to reflect on the thoughts, emotions, concerns, communication needs, and challenges experienced during surgical oncology care and multidisciplinary decision-making. Second, facilitated group reflection sessions encouraged participants to discuss and compare their experiences, identify shortcomings of current clinical workflows, and highlight unmet needs. Third, collaborative ideation activities enabled participants to propose and refine ideas for AR-supported functionalities, interfaces, and interaction techniques that could address the identified challenges. Finally, feature prioritization exercises required participants to evaluate the proposed ideas, discuss their feasibility and clinical value, and collectively identify the features considered most important for inclusion in the prototype.

Participants were encouraged to discuss challenges associated with current surgical planning workflows, communication practices, emotional support, multidisciplinary collaboration, and patient understanding of imaging data and treatment plans. Throughout the sessions, facilitators documented structured observational notes capturing participant interactions, nonverbal responses, group dynamics, and emergent discussion points. Workshop activities were supported by structured facilitation guides, including empathy mapping templates, collaborative ideation exercises, and feature prioritization matrices, while facilitators used a standardized observation template to document interactions and contextual observations. Workshop discussions were not audio-recorded. Instead, detailed facilitator field notes, structured observation templates, and participant-generated artifacts (eg, empathy maps and feature prioritization matrices) were collected during each workshop and used as qualitative data sources during analysis.

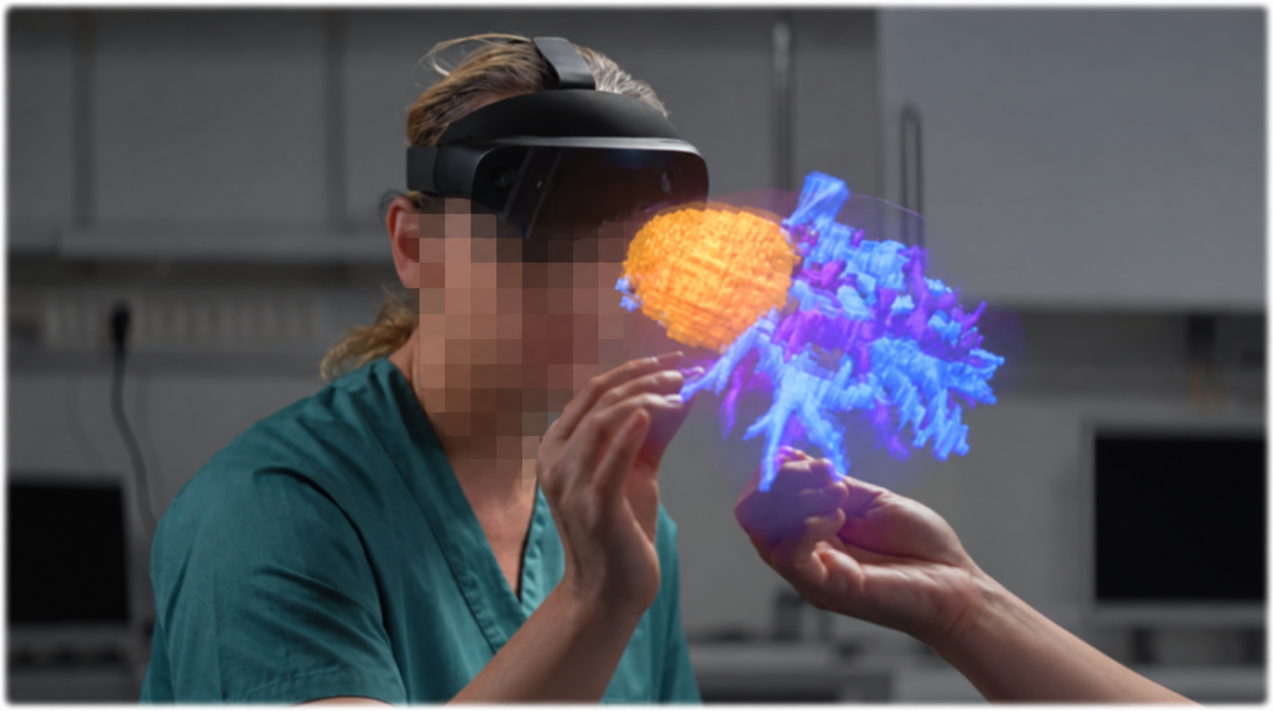
Following the workshops, MM and M Krini conducted semistructured interviews to explore participants' reflections and experiences in greater depth. The interviews were conducted between March and May 2024, following completion of each workshop, and were held either face-to-face or via Microsoft Teams, according to participants' geographical location and preference. Interviews were guided by a semistructured interview schedule comprising open-ended questions exploring participants' experiences of current communication challenges, expectations regarding AR integration into oncology workflows, emotional responses to anatomical visualization, and desired system functionalities (refer to Multimedia Appendix 1 for the interview guides). As expected within an iterative human-centered design process, the emphasis of the interview questions was refined between successive sessions to explore emerging themes and design requirements identified during earlier workshops while maintaining consistency with the overall study objectives. All interviews were audio-recorded with participants' consent and transcribed verbatim prior to analysis.

Data Analysis

Qualitative data sources included workshop discussions, semistructured interviews, facilitator observational notes, and participant-generated artifacts, including empathy maps and feature prioritization matrices. Qualitative data were analyzed using reflexive thematic analysis (RTA) [32]. This analytic approach was selected because of its suitability for examining experiential, emotional, and interpretive dimensions across diverse stakeholder groups while acknowledging the active role of researchers in knowledge generation. Two members of the multidisciplinary research team (MM and M Krini) independently coded the qualitative data, drawing on their complementary expertise in HCI, oncology care, psychology, and clinical communication. The analysis involved iterative familiarization with the dataset, generation of initial codes, development and refinement of themes, and interpretive synthesis. Following independent coding, the researchers engaged in reflexive discussions to compare interpretations, explore alternative explanations, and iteratively refine the developing themes. Any differences in interpretation were resolved through discussion, with themes further reviewed by the wider multidisciplinary research team to ensure that they reflected the breadth and depth of participants' perspectives rather than to achieve coding agreement.

XSL•FO
RenderX

The critical incident technique [33] was additionally used to identify moments of heightened salience during workshops and interviews, including expressions of cognitive burden, emotional distress, uncertainty, communication breakdowns, or shifts in group consensus. These incidents were used to support interpretation of key experiential and interactional challenges relevant to AR system design.



The multidisciplinary research team comprised researchers with expertise in HCI, oncology care, psychology, and clinical communication. As researchers involved in the co-design and evaluation of the AR system, we acknowledge that our disciplinary backgrounds and prior experience could influence data collection and interpretation. Reflexive discussions were therefore conducted throughout the analytical process to critically examine assumptions, identify potential disciplinary or experiential biases, and consider alternative interpretations. Credibility was enhanced through triangulation across multiple stakeholder groups (health care professionals and patients with cancer) and complementary data sources, including co-design workshops, semistructured interviews, facilitator observational notes, and participant-generated artifacts. Confirmability was supported through iterative refinement of themes and regular multidisciplinary team discussions throughout the analytical process.

Phase 2: Usability Evaluation

System Design and Development

The AR prototype was developed using a human-centered design approach informed by the findings of the co-design workshops (Phase 1). The design prioritized accurate spatial visualization, intuitive sterile-compatible interaction, and clear anatomical representation to support HPB surgical planning and multidisciplinary collaboration. Figure 2 illustrates the AR system in use during a simulated surgical planning session.

Figure 2. Depicts the augmented reality system in use during surgical planning.

The system was developed in Unity 3D using the Microsoft Mixed Reality Toolkit and deployed on the Microsoft HoloLens 2, an optical see-through head-mounted display featuring spatial mapping, hand tracking, gaze tracking, voice commands, and 6 degrees-of-freedom tracking. Patient-specific 3D anatomical models were generated from contrast-enhanced CT (portal venous phase) DICOM datasets using the HoloCare Studio 2 segmentation pipeline and integrated into the Unity-based HoloSurge application.

The prototype enabled health care professionals to inspect holographic anatomical reconstructions from multiple viewpoints, manipulate models through midair hand gestures (rotation, scaling, and repositioning), isolate anatomical structures (eg, tumors and vessels), and use contextual annotations and anatomical labels during collaborative surgical planning. Color coding, visual hierarchy, and gesture-based interaction were incorporated to improve interpretability and reduce cognitive workload.

The interface was iteratively refined through design walkthroughs with surgeons and radiologists, leading to improvements in interaction stability, anatomical labeling, and overall usability. During the second phase, participants individually used a single HoloLens 2 while other participants observed the mirrored headset view on an external display. Although the prototype was designed primarily for health care professionals in multidisciplinary planning, its architecture supports future multiuser and patient-facing collaborative visualization. To ensure consistent evaluation conditions, all sessions were conducted offline, with pilot testing confirming smooth real-time rendering and interaction performance.

XSL•FO
RenderX

Recruitment and Sampling

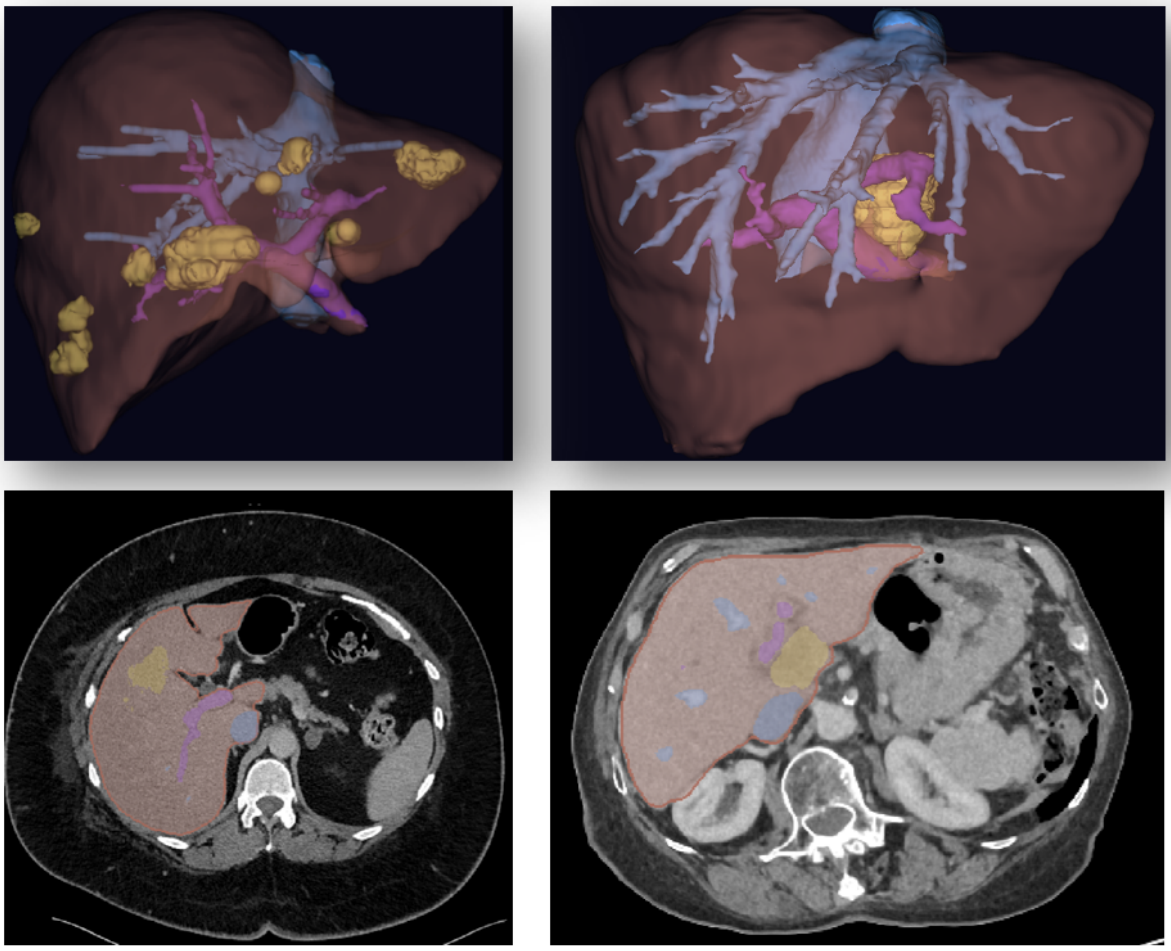
Phase 2 focused on evaluating the usability of the AR system within simulated multidisciplinary preoperative planning scenarios involving colorectal liver metastasis (CRLM) cases, a condition in which colorectal cancer spreads to the liver. Convenience sampling was used to recruit health care professionals with direct expertise in hepatobiliary cancer treatment and multidisciplinary tumor board decision-making, as these participants represented the intended end users of the system and were best positioned to evaluate its clinical usability and perceived utility within realistic preoperative planning scenarios. Recruitment continued until a multidisciplinary sample representing the key clinical roles involved in hepatobiliary surgical planning had been achieved, and the usability evaluation generated sufficient feedback to inform iterative refinement of the prototype.

Eligible clinicians were recruited through Leeds Teaching Hospitals NHS Trust using professional and institutional mailing lists. Invitation emails describing the study were circulated to health care professionals involved in hepatobiliary cancer care and multidisciplinary tumor board meetings. Clinicians who expressed interest were subsequently contacted by the research team, provided with detailed study information, and invited to participate in the usability evaluation. Participation was voluntary, and all participants provided informed consent prior to enrollment.

Ten medical experts participated in this evaluation, each with a professional background directly related to hepatobiliary cancer treatment. This included consultant surgeons (n=5), 2 with fewer than 5 years of consultant experience and 3 with more than 5 years in senior roles, surgical trainees (n=3), a radiology trainee (n=1), and one consultant radiologist (n=1) with more than 5 years of specialization in hepatobiliary imaging.

Participants were male (9/10, 90%) and female (1/10, 10%) clinicians. All were affiliated with high-volume surgical centers and regularly contributed to tumor board discussions and operative planning sessions. While all participants were highly experienced in their respective domains, none had previous exposure to head-mounted AR systems prior to the evaluation, which allowed for a neutral assessment of usability and perceived utility. Sessions were conducted over a 4-week period and held in person at Leeds Teaching Hospitals NHS Trust, Leeds, United Kingdom, with one session held each week.

Procedure



The usability evaluation was conducted in person at the Leeds Teaching Hospitals NHS Trust, United Kingdom, within a clinical simulation environment designed to closely reflect multidisciplinary tumor board planning and preoperative decision-making in hepatobiliary oncology. This setting was selected to maximize ecological validity by enabling participants to interact with the AR system under conditions representative of routine clinical practice while maintaining a controlled environment for usability evaluation.

Participants first received a brief orientation to the AR hardware, interface, and interaction techniques prior to beginning the evaluation tasks. During each session, participants reviewed approximately 2 - 3 clinical cases derived from portal venous phase CT datasets and explored interactive 3D holographic anatomical reconstructions using gesture-based interaction.

Each clinician was introduced to 2 or more patient cases selected from a total dataset of 10 CRLM cases that had been processed into interactive 3D anatomical models. Using the Microsoft HoloLens 2 headset, participants manipulated holographic structures through midair gestures, including rotation, scaling, repositioning, and spatial exploration of tumors, vascular anatomy, and surrounding liver structures to support clinical interpretation and surgical planning. These evaluations occurred in settings that closely mirrored multidisciplinary planning meetings, also known as tumor board meetings, where specialists collaboratively discuss cancer treatment decisions and clinical simulation environments. Examples of the cases are displayed in Figure 3.

XSL•FO
RenderX

Figure 3. Images from liver surgery planning, 2D images of computed tomography (CT) scans with anatomical annotations and 3D reconstructions of colorectal liver metastases (CRLMs) using portal venous phase CT images (blue: hepatic veins; purple: portal veins; yellow: CRLM). (A) Ten small CRLMs threatening future liver remnant; (B) segment 1 CRLM in close proximity to hepatic veins and portal veins.

Sessions lasted up to 20 minutes and were facilitated by members of the research team with expertise in surgical devices and technology assessment. A standardized usability evaluation protocol was followed for all participants. Facilitators documented interaction behaviors, usability challenges, technical issues, and emergent feedback using structured observational notes. The usability protocol, observational procedures, and System Usability Scale (SUS) questionnaire remained unchanged throughout the study to ensure consistency across all evaluation sessions.

SUS Administration and Analysis

Following completion of the AR interaction tasks, participants completed the SUS [34], a validated 10-item questionnaire widely used to assess perceived usability of digital systems and health care technologies. The questionnaire was administered in paper format immediately following each usability evaluation session and was completed independently by participants in the presence of a member of the research team, who was available to clarify procedural questions but did not influence participants' responses. Participants rated each statement on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree). SUS scores were calculated according to the standard scoring procedure, producing a total usability score ranging from 0 to 100, with higher scores indicating greater perceived usability. Scores for early-stage prototypes often range between 60 and 70 [35].

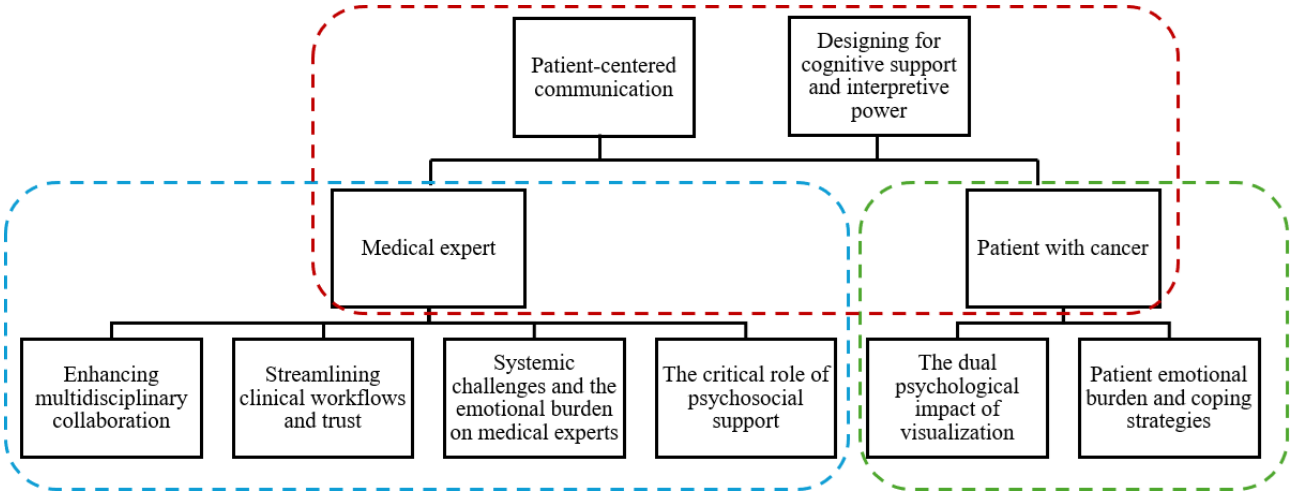
Ethical Considerations

Ethical approval was obtained from the National Bioethics Committee (reference number: EEBK EP 2024/56) for Phase 1. All participants provided written informed consent prior to participation. Participation was voluntary, and participants could withdraw at any time without consequence. The Information Governance Team of the Leeds Teaching Hospitals NHS Trust, Leeds, United Kingdom, approved the service evaluation in Phase 2. The AR system used existing imaging data that had been acquired as part of routine clinical care. Clinician participation in Phase 2 was voluntary, and participants could withdraw at any time without consequence.

All collected data were anonymized and deidentified prior to analysis. Participant information was securely stored on password-protected institutional systems accessible only to the research team. No personally identifiable information was included in the analysis or reporting of findings. Participants

XSL•FO
RenderX

did not receive financial compensation for participation in either study.



Results

Phase 1: Co-Design and Development

Overview

Through a structured co-design process involving 14 oncology professionals and 10 patients with cancer, a thematic analysis of qualitative insights identified 8 core themes that informed the development of the AR system. These themes reflect diverse yet intersecting perspectives and needs, shaping a user-centered framework for AR in cancer care. Two themes—(1) patient-centered communication and (2) designing for cognitive support and interpretive power—emerged from both groups, reflecting shared priorities in improving communication and understanding within cancer care. From the medical professionals' side, four additional themes emerged: (3) enhancing multidisciplinary collaboration**,** (4) streamlining clinical workflows and trust, (5) systemic challenges and the emotional burden on medical experts**,** and (6) the critical role of psychosocial support. These themes reflect health care professionals' core needs for efficiency, clarity, emotional sustainability, and seamless teamwork in high-pressure clinical environments. On the patient side, two unique themes were identified: (7) the dual psychological impact of visualization and (8) patient emotional burden and coping strategies. These capture patients' fundamental needs for emotional safety, autonomy, and accessible understanding throughout their cancer journey. Figure 4 visually summarizes these 8 themes and clearly indicates their sources, whether from health care professionals, patients, or both, highlighting the integrative and human-centered foundation of the AR system's design.

Figure 4. Schematic representation of the 8 core themes, illustrating the unique and shared needs of oncology professionals and patients with cancer that informed the human-centered design of the augmented reality system.

Patient-Centered Communication

Our findings reveal significant communicative and emotional challenges that patients face when trying to understand their diagnoses and proposed surgical plans. Many reported difficulties translating 2D imaging data, such as CT and MRI scans, into a meaningful spatial understanding of their anatomy, an issue well-documented in the literature as a cognitively demanding task for nonexperts [8]. One (patient 2, interview) patient reflected, "The doctor would show me the scans, and I'd nod along, but I really had no idea what I was looking at."

Patients frequently described pretending to understand explanations despite remaining uncertain, while clinicians similarly acknowledged that patients often avoid asking questions or admitting confusion (patient 5, workshop; surgeon 4, workshop). These accounts reveal an epistemic asymmetry within clinical encounters that limits genuine shared decision-making.

Patients also described frustration with existing communication practices, reporting that explanations were often unclear, inconsistent, or lacked sufficient emotional support (patient 8, workshop). These findings are consistent with previous research demonstrating that health care professionals and patients with cancer frequently fail to discuss treatment goals and clinical end points in sufficient depth, leaving many patients uncertain about the purpose and expected outcomes of treatment [36,37]. Psychologists further emphasized that effective communication extends beyond providing technical information and should also foster psychological safety and confidence throughout the decision-making process (counseling psychologist 2, workshop).

The co-design workshops identified AR as a potential solution for bridging this communication gap by providing a shared visual reference that supports both understanding and dialogue. Patients explained that unclear explanations often discouraged them from asking follow-up questions because of embarrassment or uncertainty. This aligns with evidence that many patients with cancer continue to have unanswered questions following clinical consultations [38], while psychological distress can further reduce comprehension, particularly during discussions of difficult prognoses [39]. Integrating such insights into prognostic discussions could not only improve mental well-being, but also empower patients to make informed, value-aligned decisions [39].

During the workshop, both patients and clinicians strongly endorsed the use of AR to facilitate clearer, more equitable communication. All medical experts in the study (14/14) agreed

XSL•FO
RenderX

that 3D models would enhance patient understanding, and nearly all patients (9/10) said such visual explanations would be "very useful" (patients 1 - 5 and 7 - 10, workshop) for explaining procedures. This is consistent with previous studies highlighting AR's promise in improving physician-patient communication [3]. As one surgeon (surgeon 6, workshop) stated, "Simple diagrams aren't enough, we need better visuals to explain surgical procedures."

Our findings extend this evidence by showing how AR can redistribute interpretive power, transforming patients from passive recipients into active participants in their care. One patient (patient 9, workshop) expressed this desire plainly, "I want to be treated like a person, not just a case."

These preferences align with human-centered design principles that advocate for patient-focused communication tools [25]. By enabling patients and health care professionals to manipulate and explore the same holographic model together, the AR system transforms 1-way explanations into active, collaborative dialogues.

Designing for Cognitive Support and Interpretive Power

Across both patient and health care professional groups, participants consistently emphasized the need for tools that reduce cognitive load in complex, high-pressure situations. Consistent with previous research [13], they viewed AR as having strong potential to support spatial reasoning and scenario planning, provided that the system is intuitive, modular, and context-aware. As one surgeon (surgeon 3, interview) explained, "In the operating room, I don't have time to figure things out. If it's not immediate and obvious, I won't use it, no matter how impressive it looks."

These findings highlight that usability and cognitive efficiency are prerequisites for successful clinical adoption.

Patients expressed similar expectations from a nonexpert perspective, emphasizing that technology should simplify rather than complicate their understanding of their condition and treatment (patient 6, workshop). Participants described becoming overwhelmed by overly technical explanations and stressed the importance of clear, accessible communication supported by appropriate guidance (patient 6, workshop). One patient (patient 2, interview) summarized this need by stating, "I want to understand what's going on, but if it's too technical or overwhelming, I just shut down."

These findings suggest that cognitive accessibility should be a fundamental design principle, supporting both patient understanding and clinical decision-making [26].

Rather than functioning solely as a visualizer, the AR system should act as an interpretive companion, one that helps users assess options, understand implications, and engage in meaningful deliberation. Based on this finding, AR systems should be developed with this in mind, incorporating interactive features that enable comparative reasoning, gesture-driven spatial manipulation, and adjustable interface layers that reveal or hide detail according to cognitive demand [27]. This approach supports a broader reconceptualization of AR, positioning it not just as a tool for seeing, but as a platform for thinking and communicating within complex clinical ecosystems. In this way, the system becomes a cognitive framework that enhances both clinical reasoning and patient understanding [26].

Enhancing Multidisciplinary Collaboration

While individual understanding is essential, as highlighted in the previous theme, this cognitive support becomes even more critical in team-based care environments. Clinical professionals, including surgeons, oncologists, and mental health specialists, identified significant cognitive load and communication barriers in existing multidisciplinary team meetings. They described the mental challenge of reconstructing anatomical relationships from 2D imaging, a well-recognized difficulty in hepatobiliary surgery [7]. As one surgeon (surgeon 1, interview) explained, "Current meetings are often a series of people looking at a flat screen and trying to mentally reconstruct the anatomy. It's time-consuming and leaves room for miscommunication." As an oncologist (oncologist 3, workshop) explained, "Overall, participants viewed multidisciplinary collaboration as fundamental for improving communication, reducing ambiguity, and supporting coordinated clinical decision-making."

These communication challenges extended beyond surgical teams. Psychologists described difficulties understanding treatment plans and surgical pathways, limiting their ability to respond to patients' concerns or provide individualized psychosocial support. One counseling psychologist (counseling psychologist 1, interview) noted, "Patients sometimes want to talk about the procedure and express fears about whether the tumor was completely removed. I want to support them in that moment, but I often don't understand the surgical pathway well enough to respond meaningfully."

Participants further explained that organizational barriers, including bureaucracy and limited integration into clinical discussions (surgeon 1 and 2, workshop; oncologist 2, workshop), frequently restricted psychologists' involvement (patient 4 and 9, workshops; clinical psychologist 2, workshop), despite evidence psychological support is essential for addressing anxiety, uncertainty, and fear of recurrence, all of which influence treatment adherence and quality of life [40,41].

Across professional groups, participants identified the need for tools that facilitate shared understanding rather than discipline-specific communication. Rather than simply visualizing anatomy, they envisioned AR as a collaborative platform capable of making complex surgical information accessible to all members of the care team, including psychosocial professionals. As one psychologist (clinical psychologist 1, interview) explained, "We're often the ones patients turn to after the medical explanation, and it's difficult to offer meaningful reassurance when we ourselves don't fully understand the treatment plan or the rationale behind it."

Consistent with previous research demonstrating AR's value in improving spatial understanding during oncologic surgery [13], participants suggested that shared interactive 3D visualizations could enhance multidisciplinary communication, strengthen collaborative decision-making, and improve continuity of patient care.

XSL•FO
RenderX

These user-driven insights informed the AR system's core functionalities, including collaborative viewing and gesture-based interaction. Given that fragmented communication is a known contributor to medical error, AR has the potential to serve as a safety-enhancing platform for aligning interprofessional perspectives. This extends existing research on AR in surgical planning [16] by positioning it not only as a technical tool, but as a collaborative artifact for real-time interdisciplinary dialogue, where all team members can simultaneously view and interact with the same 3D model.

Streamlining Clinical Workflows and Building Trust

Medical experts emphasized that successful adoption of AR depends on its seamless integration into existing clinical workflows. Participants consistently highlighted the need for systems that are intuitive, efficient, and compatible with sterile surgical environments, where time pressure and cognitive demands are high (oncologist 1, workshop; surgeon 5, workshop). These findings align with previous research demonstrating that AR adoption is facilitated by technologies that accommodate the realities of health care practice, support intuitive interaction under sterile conditions, and minimize cognitive load [19,26]. Beyond efficient visualization, participants envisioned AR as an intelligent workflow assistant capable of providing context-sensitive support throughout surgical procedures. As one surgeon (surgeon 4, interview) explained, "A helpful system should track where I am in the procedure and respond intelligently, not just display anatomy."

This perspective reflects growing interest in adaptive AR systems that interpret procedural context and deliver tailored guidance to support clinical decision-making during surgery [19].

Trust emerged as another critical requirement for clinical adoption. Participants emphasized that confidence in AR depends not only on the accuracy of anatomical visualizations but also on transparency regarding the system's limitations. Concerns regarding model registration errors and false precision, particularly when operating on deformable tissues [16], highlighted the need for interfaces that clearly communicate uncertainty. As one oncologist (oncologist 2, interview) stated, "If I don't know where the model stops being accurate, I won't use it to make a decision."

These findings directly informed the inclusion of confidence overlays and provenance panels that communicate source data, precision limits, and uncertainty, consistent with recommendations for improving clinician trust in AR-based surgical systems [19].

Participants also emphasized that technological trust should complement, rather than replace, interpersonal trust between clinicians and patients. As one surgeon (surgeon 3, workshop) noted, "The patient's trust must be earned. No technology can replace that."

This underscores that AR should be viewed as a support tool rather than a substitute for the expertise, empathy, and interpersonal connection provided by health care professionals. The success of AR in surgical contexts therefore depends not only on its technical accuracy, but also on its seamless integration into existing workflows, its ability to adapt to procedural stages, and its role in reinforcing, rather than replacing, the clinician-patient relationship.

Systemic Challenges and the Emotional Burden on Medical Experts

Medical professionals consistently described systemic inefficiencies and ethical pressures as significant challenges affecting both patient care and professional well-being. Participants highlighted concerns related to rising costs, administrative burden, resource limitations, and broader health care structures that constrained the delivery of patient-centered care (oncologist 2, workshop; surgeon 1, workshop). As one participant (surgeon 6, workshop) remarked, "Care is top notch, but it's expensive and riddled with systemic inefficiencies."

These challenges extend beyond the clinical setting into the structural realities of the health care system.

Similar concerns were expressed across professional groups, including psychologists (counseling psychologist 2, workshop), indicating that emotional fatigue and fear of error are shared experiences throughout multidisciplinary cancer care (oncologist 1, 2, and 3, workshop; surgeon 3, workshop). These findings extend existing usability literature by demonstrating that technologies intended for clinical practice should address not only functional and cognitive demands but also the emotional context in which decisions are made [21]. Participants therefore envisioned AR as more than a technical visualization tool, suggesting features such as reflective checkpoints, private annotations, and postoperative debriefing functions that could support clinical reflection and psychological resilience following complex decisions.

Participants also emphasized that future technologies should help alleviate systemic challenges while preserving the human aspects of care. They envisioned intelligent systems capable of supporting personalized treatment planning, anticipating complications, improving workflow efficiency, and assessing patient understanding without replacing clinician judgment or interpersonal relationships (surgeon 5, workshop; oncologist 2, workshop). As one surgeon (surgeon 3, workshop) explained, "...an AI for personalizing treatment and predicting complications, but not for replacing human connection."

Such perspectives position AR and AI as supportive partners in care that can reduce workload, facilitate communication, and strengthen decision-making while maintaining the central role of human expertise and compassion [19].

The Critical Role of Psychosocial Support

Psychologists consistently emphasized that effective cancer care extends beyond medical treatment, requiring a holistic approach that actively addresses patients' psychological and emotional needs. Participants viewed psychosocial support as a core component of cancer care rather than an adjunct to clinical treatment, highlighting that emotional processing, individualized care, and psychoeducation are fundamental to helping patients navigate their illness (clinical psychologist 2, workshop). As one psychologist (counseling psychologist 1, workshop) explained, "It's about creating space for emotional processing."

XSL•FO
RenderX

This perspective aligns with previous research demonstrating that successful implementation of clinical technologies requires careful consideration of users' cognitive needs, emotional state, and interaction preferences [20].

Participants further stressed that psychosocial care should be tailored to each patient's emotional readiness and should evolve throughout the cancer journey, from diagnosis to rehabilitation (clinical psychologist 2, workshop). Rather than adopting standardized approaches, psychologists described adjusting communication and therapeutic support according to patients' knowledge, concerns, and capacity to process information (clinical psychologist 3, workshop). This patient-centered perspective reflects broader human-centered design principles that promote shared decision-making by recognizing individual needs and preferences [25].

Psychologists also described the considerable emotional burden associated with their professional role. Participants reported experiencing guilt, frustration, and fear when time pressures, organizational barriers, or limited involvement in clinical decision-making prevented them from providing the level of support they considered necessary (clinical psychologist 2 and 3, workshop; counseling psychologist 2, workshop). One participant (counseling psychologist 1, workshop) reflected, "It's hard to handle emotionally when patients pass away without understanding their situation."

These concerns suggest that emotional strain is influenced not only by patient distress but also by systemic barriers that limit meaningful psychosocial engagement, consistent with evidence showing that poorly designed clinical systems can amplify professional workload and emotional fatigue [21].

Consequently, participants viewed technology as a means of strengthening rather than replacing the human aspects of cancer care. They emphasized the need for tools that facilitate communication, improve patient understanding, and create more opportunities for meaningful clinician-patient interactions. As one psychologist stated, "enhance, not replace, the human side of care" (counseling psychologist 2, workshop). Participants also highlighted the value of patient-facing communication tools that promote understanding and engagement throughout the care pathway (clinical psychologist 1; counseling psychologist 1 and 2, workshop). These insights reinforce the importance of designing technologies that support collaborative, empathetic, and patient-centered care while preserving the central role of human relationships in clinical practice [23].

In the context of the proposed AR system, these findings informed the inclusion of features that support psychosocial care, including shared visualizations for patient-clinician discussions, accessible explanations of procedures, and communication tools that adapt to patients' emotional readiness. Rather than functioning solely as a cognitive aid for clinical decision-making, the proposed AR system was envisioned as a platform that also strengthens trust, communication, and empathetic engagement throughout the cancer journey.

The Dual Psychological Impact of Visualization

Patient participants expressed markedly different emotional responses to visualizing their internal anatomy. For some, gaining visual clarity fostered a sense of empowerment; for others, confronting the graphic reality of their condition was distressing. As one participant (patient 6, workshop) explained, "I wouldn't want to see much detail; sometimes ignorance is bliss."

In contrast, another (patient 4, interview) reflected, "If I had seen the tumor and where they would cut, I would've asked more questions. I was scared because I didn't know."

These contrasting perspectives demonstrate that patients differ not in whether they value visual information, but in the amount, timing, and manner in which it is presented.

These perspectives highlight the need for visualizations to be optional, personalized, and emotionally calibrated. The contrasting views informed our design principle of optionality and personalization. AR interfaces for patients must enable modulation of exposure, staged delivery of information, and support for diverse communication preferences (eg, visual, verbal, or simplified icon-based formats). This approach aligns with best practices in inclusive interaction design, which emphasize supporting collaborative and equitable decision-making [22,23].

Participants also highlighted the importance of being able to explore holographic visualizations at their own pace within a psychologically supportive environment (patient 1, interview), a concept reflected in affective scaffolding [42]. These findings informed several key design elements, including step-by-step walkthroughs, interactive annotation tools, adjustable levels of visual detail, and customizable emotional tone settings. Addressing emotional alongside informational needs is essential, as successful implementation of AR depends not only on technical sophistication but also on accommodating users' cognitive constraints and interaction preferences [20]. By embedding emotional sensitivity into the interface, the proposed AR system supports trust, understanding, and patient autonomy while reducing the risk of emotional overload.

Patient Emotional Burden and Coping Strategies

Patient participants described cancer as a profound disruption to their daily lives and personal identities, creating an ongoing struggle to regain a sense of normalcy while adapting to life after diagnosis. Many expressed a desire to return to life before cancer, free from fear and uncertainty. As one participant (patient 2, interview) explained, "...to feel normal again, like before. To be healthy, and not afraid."

This aspiration is consistent with previous literature, which shows that many patients seek to "get back to normal" following treatment, although the meaning of normality varies between individuals, ranging from restoring previous routines to adapting to a "new normal" shaped by their cancer experience [43,44].

Fear of recurrence emerged as a persistent but often privately managed concern. Participants described coping by suppressing these fears, accepting cancer as part of their identity, or prioritizing the emotional well-being of their families over their own. One patient reflected, "I need to be strong for my family" (patient 6, interview). These findings suggest that many patients rely on self-management and informal support networks while

XSL•FO
RenderX

avoiding open discussion of their emotional struggles. Such coping strategies are consistent with literature describing self-reliance, fear of stigma, and concerns about burdening others as barriers to seeking psychological support [45-47].

These experiences reflect the concept of biographical disruption, where a cancer diagnosis threatens an individual's identity, mortality, and assumptions about the future, creating an existential rupture [48]. Addressing such disruption requires systems that recognize not only the clinical aspects of care but also the emotional and psychological burdens patients carry. Involving patients in the design process is essential to surface these often-unspoken needs and to ensure that technology acknowledges the full scope of their lived experience [25].

Patients also highlighted the importance of technologies that provide emotional support without increasing distress. Rather than replacing human care, they envisioned systems that improve understanding, facilitate communication, and connect patients with appropriate support when needed. As one participant (patient 8, workshop) stated, "Technology could help, especially if it connects me to care when needed."

Alongside these challenges, some participants also expressed gratitude for surviving cancer and for the care they had received, illustrating that resilience and appreciation coexisted with ongoing uncertainty (patient 10, interview). Participants emphasized that visual explanations, clearer communication, peer support, and access to psychological services could all contribute to reducing anxiety and improving understanding throughout the treatment journey.

These findings support a human-centered approach in which technology complements, rather than replaces, existing models of care by facilitating collaborative and equitable decision-making [23]. They also reinforce evidence that identity- and existence-related concerns remain insufficiently addressed during routine cancer care [49]. Consequently, participants identified several design priorities for the proposed AR system, including adjustable levels of visual detail, patient-paced interactions, and integrated access to psychosocial resources. Together, these features position AR as part of a broader support ecosystem that addresses both the informational and emotional challenges associated with living with and beyond cancer.

Phase 2: Usability Evaluation

The average SUS score across participants was 67.25 (SD 7.95; n=10), indicating moderate perceived usability. Qualitative feedback provided further context for these findings. Participants consistently identified the AR system as valuable for improving spatial understanding during complex surgical planning and facilitating shared understanding among multidisciplinary teams. As one surgeon (surgeon 2, interview) explained, "Being able to rotate and inspect the anatomy in 3D makes it much easier to understand the tumor's relationship to the vessels compared to looking at flat CT images."

These findings suggest that the system's principal strength lies in supporting visualization and collaborative clinical reasoning. Participants also identified several opportunities for improvement, including clearer anatomical labeling, more streamlined interaction workflows, and faster navigation between patient cases to better support high-volume multidisciplinary meetings.

Discussion

Principal Findings

This study investigated how participatory co-design with health care professionals and patients with cancer can inform the development of a human-centered AR platform for HPB surgical oncology, evaluated its usability within simulated multidisciplinary planning scenarios, and derived design principles to support the future development of AR systems for surgical oncology. The co-design process identified key cognitive, communicative, emotional, and workflow-related requirements that directly informed prototype development. The resulting AR platform demonstrated encouraging usability for an early-stage prototype while identifying key priorities for further refinement, including gesture recognition stability, anatomical labeling clarity, and workflow responsiveness. These findings provide evidence that participatory co-design can support the development of clinically relevant AR technologies that are better aligned with multidisciplinary workflows and patient-centered communication.

Our findings reinforce previous evidence demonstrating that AR can improve spatial understanding, facilitate surgical planning, and support intraoperative navigation through interactive 3D visualization of patient-specific anatomy [13]. However, unlike much of the existing literature, which has primarily focused on technical feasibility, our study adopted a human-centered approach that positioned health care professionals and patients as active contributors throughout the design process. The co-design process demonstrated that clinically relevant AR systems must address not only technical requirements but also cognitive, communicative, and psychosocial considerations that influence successful implementation within routine multidisciplinary oncology care. It is worth mentioning that, although conducted within HPB oncology, many of the design principles identified, including shared visualization, collaborative decision-making, workflow integration, and patient-centered communication, may also be transferable to other image-guided surgical specialties.

Health care professionals reported that immersive 3D models reduced the cognitive effort required to mentally reconstruct anatomy from conventional CT images, thereby supporting multidisciplinary tumor board discussions and surgical planning. Similarly, patients described improved understanding of their anatomy and planned procedures through intuitive spatial visualization. These findings are consistent with previous research showing that interpreting complex anatomical relationships from 2D imaging places considerable cognitive demands on clinicians, particularly in time-pressured environments [7,8]. Our findings suggest that AR may function as a shared cognitive workspace that facilitates communication, promotes shared understanding, and supports collaborative clinical decision-making, consistent with theories of distributed cognition in health care [50].

XSL•FO
RenderX

Importantly, our findings also suggest that AR may function as a boundary object within multidisciplinary oncology care. A shared holographic model provided a common point of reference that enabled different professional groups, including surgeons, radiologists, and psychologists, to interpret the same patient-specific anatomy according to their respective clinical perspectives while maintaining a shared understanding of the case. Participants emphasized that an AR shared visualization could improve multidisciplinary discussions, facilitate communication with patients, and better integrate psychosocial considerations into treatment planning. These findings extend the role of AR beyond a visualization tool, positioning it as a collaborative platform capable of supporting both technical decision-making and patient-centered cancer care.

The co-design process further highlighted the importance of emotional adaptation in patient-facing AR systems. While many participants viewed anatomical visualization as reassuring and empowering, others described feelings of anxiety or discomfort when confronted with detailed representations of their disease. These findings are consistent with previous studies of visual risk communication in oncology, which emphasize that the presentation of medical information can influence emotional responses and patient understanding [51]. Our findings therefore suggest that successful implementation of AR in oncology requires not only accurate anatomical visualization but also flexible approaches that allow information to be tailored according to patient preferences, emotional readiness, and clinical context.

Finally, to address the second aim of this study, the usability evaluation demonstrated acceptable usability (SUS score=67.25), providing encouraging evidence that the prototype can support clinically representative multidisciplinary planning workflows while identifying priorities for further refinement [52]. Qualitative feedback identified gesture recognition stability, clearer anatomical labeling, reduced loading times, and improved workflow responsiveness as the principal priorities for future refinement. These findings align with previous evidence demonstrating that workflow compatibility and intuitive interaction are critical determinants of successful implementation of surgical technologies in routine clinical practice [27].

Limitations and Future Directions

Several limitations should be considered when interpreting these findings. First, the study focused specifically on HPB oncology, and although many of the identified design requirements may be transferable to other image-guided surgical specialties, additional validation across broader clinical contexts is required. Second, the relatively small participant sample, particularly during the usability evaluation phase, may limit the generalizability of the findings. In addition, the prototype was evaluated within simulated multidisciplinary planning environments rather than routine clinical workflows, and the evaluation focused primarily on usability and user perceptions rather than objective measures of clinical performance. Consequently, future studies should examine the impact of AR on surgical planning accuracy, multidisciplinary decision-making, workflow efficiency, and patient outcomes in real-world clinical settings.

Future research should evaluate the platform in larger and more diverse clinical populations while continuing to refine interaction stability, workflow responsiveness, adaptive visualization, and integration with hospital information systems to support routine clinical adoption. Although the co-design process involved health care professionals and patients, future work should also include additional stakeholders, such as family caregivers, specialist nurses, allied health professionals, and health care administrators, to better capture the wider multidisciplinary cancer care ecosystem. Finally, future research should investigate emotionally adaptive visualization strategies that tailor information according to patient readiness, preferences, and clinical context while addressing broader implementation challenges, including privacy, data governance, and secure integration within health care systems.

Conclusions

This study demonstrates that the successful implementation of AR in surgical oncology depends not only on accurate anatomical visualization but also on effective integration within clinical workflows, multidisciplinary collaboration, and patient-centered communication. Through participatory co-design involving health care professionals and patients with cancer, we developed and evaluated a human-centered AR platform while deriving design principles to guide the future development and implementation of clinically relevant AR systems. These findings suggest that immersive AR technologies can function as collaborative cognitive tools that support shared understanding, improve communication, and facilitate multidisciplinary decision-making. Although further real-world clinical validation is required, this work provides a strong foundation for the future development and implementation of human-centered AR systems capable of supporting more collaborative, efficient, and patient-centered cancer care.

Abstract

Background: The German electronic health record (EHR) aims to enhance patient care and reduce costs, but users often worry about data privacy and security. To mitigate disease-related privacy concerns, for instance, surrounding stigmatized diseases, we test the effect of privacy fact sheets (PFSs)—a concise but comprehensive transparency feature designed to increase users' perceived control over their data—on increasing EHR use in a simulated online study.

Objective: The study aimed to investigate whether displaying a PFS shortly before upload decisions must be made mitigates disease-related privacy concerns and makes uploads more likely.

Methods: In an online survey study, 393 German participants from the recruitment platform Prolific were asked to interact with a randomly assigned medical report that varied systematically in terms of disease-related stigma (high vs low) and time course (TC; acute vs chronic). They were then asked to decide whether to upload the report to an EHR click dummy, while we systematically varied the presentation of privacy information (PFS vs no PFS). Participants were randomly (single-blinded) assigned to one of the 2×2×2 conditions (stigma, TC, privacy information).

Results: All 393 participants were randomly assigned to one of the following groups: low, acute, no PFS (n=52, 13.2%); low, chronic, no PFS (n=45, 11.5%); high, acute, no PFS (n=46, 11.7%); high, chronic, no PFS (n=55, 14%); low, acute, PFS (n=44, 11.2%); low, chronic, PFS (n=41, 10.4%); high, acute, PFS (n=56, 14.2%); and high, chronic, PFS (n=54, 13.7%). The results show that, in general, upload behavior is negatively influenced by disease-related stigma (odds ratio [OR] 0.130; $P<.001$) and positively influenced when a PFS is given (OR 4.527; $P<.001$). This increase was particularly pronounced for stigmatized diseases (OR 5.952; $P=.006$), but independent of the TC of the diseases.

Conclusions: Our results demonstrate that PFSs may help to increase EHR uploads in people interacting with a realistic EHR click dummy, by mitigating privacy concerns in scenarios involving stigmatized diseases. Results further indicate that a PFS is mainly relevant and effective for people with increased privacy risk perceptions, whereas they neither benefit nor hurt others. Thus, implementing PFSs may increase the likelihood that users who perceive high privacy risks when confronted with sensitive or stigmatized health information decide to upload their data to the EHR, ultimately increasing digital health equity.

Introduction

Background

The electronic health record (EHR) is one key element in the digital transformation of health care systems because it allows patients' health data (eg, diagnoses, therapies, vaccinations, and medication plans) to be readily documented, exchanged, and viewed by various stakeholders [1-6]. The resulting network of care providers can make patient treatment more effective, safer, and faster across institutions [7]. For instance, preexisting conditions, intolerances, and medication plans can be taken into account during diagnosis and treatment to prevent adverse medication interactions, duplicate diagnoses, overtreatment, and undertreatment [5]. Also, it is hoped that physicians will spend less time on obtaining patients' medical history thanks to the EHR, which they could devote to actual patient treatment [8]. In Germany, approximately 90% of residents are covered

XSL•FO
RenderX

by statutory health insurance and thus received an EHR account by default in January 2025, unless they opted out [9-11]. From October 1, 2025, health care providers are required to use the EHR infrastructure for documentation and data exchange [11]. A prerequisite for the potential of EHRs to realize is user engagement. Specifically, the Patient Data Protection Act mandates that patients maintain sole control of their data, allowing them to decide which information is stored in the EHR, who has access to it, and which data are to be deleted [5]. Consequently, the success of the EHR hinges on patients' actual use of the technology. But national and international studies indicate that many patients remain skeptical toward the EHR, mainly due to concerns arising from limited trust in both data security (ie, the technical and organizational measures that protect personal data) and data privacy (ie, the rights and rules governing how personal data is collected, used, and shared) [8,12-15]. In Germany, these concerns were intensified due to reported security issues, which were addressed and resolved during the rollout [16,17]. However, concerns about EHR use are not static in nature. Our previous studies suggest that participants adapt their attitudes toward EHR dynamically. For instance, we could show that the perceived risks and benefits of using EHR are related to disease-specific privacy concerns, such as the stigma and the time course (TC) of diseases, that is, the more permanent and risky nature of data associated with chronic conditions [18-20]. Previous studies have also shown that existing communication strategies, for instance, by health insurers or the Federal Ministry of Health, have not been sufficient to effectively convey the core functions and data protection mechanisms of the German EHR [13,14,21]. Against this background, there is a need for concise and comprehensible communication strategies that can transparently explain data privacy and data security measures, thereby strengthening user trust in the EHR. In this study, we investigate the effect of a privacy fact sheet (PFS)—a concise but comprehensive transparency feature—on increasing EHR use and, specifically, to what extent the PFS can mitigate disease-related privacy concerns and increase the upload of medical reports to the EHR.

Prior Work

"Notice and choice" is the most widely used framework for ensuring data privacy worldwide [22,23]. As its name suggests, it consists of 2 components: privacy notices and privacy choices. Whereas *privacy notices* explain how personal data are collected, processed, and shared with third parties, *privacy choices* give users control over various aspects of these practices, including the decision to start and terminate them [22]. Various studies indicate that, if informed by privacy notices, users are empowered to choose IT systems that match their preferences, typically those with high data security and privacy standards, and avoid less secure ones [24,25]. But the current formats used for privacy notices, most commonly *privacy policies*, tend to provide rather detailed information and often use legal jargon [26-30], which aims to maximize legal protection of IT providers rather than to transparently inform users [31]. Research has shown that overly lengthy and complex privacy policies may ultimately serve as a "red flag," leading users to lose trust in the provider, if not to discontinue technology use altogether [32,33]. Consequently, concise, easy-to-understand privacy notices are a prerequisite for users to adopt digital health technologies such as the EHR [33-35].

In contrast to full-blown privacy policies, the shorter *transparency features* have been shown to be an effective type of privacy notice, because they provide a brief and easy-to-understand overview of data privacy and data security measures and are meant to inform rather than to provide legal assurance [36,37]. Recent work also shows that such transparency features can decrease privacy concerns and increase EHR acceptance by strengthening users' perceived control over personal data—a construct that describes the extent to which users feel able to understand, oversee, and control how their personal data are handled and that plays a central role in privacy calculus models [7,38-40]. Stronger perceptions of control are known to reduce privacy concerns and foster trust in digital health and online technologies [7,38,39,41].

Empirical studies across domains suggest that transparency features may influence user behavior. For instance, a study in the eCommerce domain demonstrated that displaying a transparency feature positively influences purchase numbers [37]. But increased use does not (only) depend on the format of the privacy notice; it is also influenced by the contents it provides, including the efficacy of the mentioned data protection measures and privacy choices, and its timing, that is, when the privacy notice is given to users [42]. At the same time, studies in other digital contexts have reported mixed results regarding the behavioral impact of privacy notices and transparency features, suggesting that their effectiveness may depend on contextual factors such as perceived privacy risk or data sensitivity [36,43]. Our previous studies have shown that a transparency feature with a concise but comprehensive summary of all relevant contents—which we refer to as a PFS—positively influences EHR use when given shortly before the upload process [40,44]. In addition, we could show that a patient-centered framing of these contents that specifies what users can do to control the EHR and emphasizes their perceived control over personal data (eg, you can control all of your data) has the biggest effect on EHR adoption [44].

As stated at the outset, in another line of studies, we have shown that privacy concerns, intention to use the EHR, and upload behavior are influenced by the characteristics of diseases, in particular by disease-related stigma and TC [18-20]. Disease-specific stigma has been shown to have an inhibiting influence on upload behavior and to increase the risks people perceive when they are asked to upload information related to these diseases to the EHR [18,19]. Conversely, the TC of diseases (ie, whether diseases are chronic rather than acute) tends to increase both privacy concerns and intention to use the EHR. That is, patients with chronic conditions recognize a greater value in using the EHR but have heightened privacy concerns when it comes to uploading chronic conditions to the EHR [20]. In this study, we aim to merge these two lines of studies to validate and extend the positive effect of a patient-framed PFS on users' decision to upload diseases to the EHR click dummy when disease-specific privacy concerns are systematically varied.

XSL•FO
RenderX

Aim of This Research and Approach

In this study, we test whether displaying a patient-framed PFS, developed in our previous studies [40,44], shortly before the decision to upload a medical report must be made increases the likelihood that users upload medical reports to the EHR for diseases that vary along 2 dimensions: TC and disease-specific stigma. After describing the methods and results, we discuss the implications, reflect on the study's limitations, and conclude with a reflection on the objective of this study.

Methods

Ethical Considerations

This study was approved by the Ethics Committee of the Department of Psychology and Ergonomics at Technische Universität Berlin (tracking number: AWB_KAL_1_230206_Erweiterungsantrag). The study is registered as a randomized controlled trial at Deutsches Register Klinischer Studien (DRKS00033652). Participants volunteered to participate in the survey, and written informed consent was required to participate. On the first page of the survey, participants were told about the experimenter, the study purpose, what data were to be collected during the study, and where and for how long they would be stored. Also, participants had the possibility to download a PDF with the study information. Hence, participants were informed about the duration of the survey (approximately 8 min) as well as the compensation for participation. All data were collected and stored in an anonymized form. No directly identifying personal information was collected. Data were processed confidentially and used exclusively for research purposes.

Participants

The online study was conducted between April 15, 2024, and May 16, 2024. Based on an a priori power analysis for a logistic regression using G*Power (version 3.1.9.7) with disease-related stigma (high vs low), TC (acute vs chronic), and privacy information (PFS vs no PFS) as binomial distributed predictors, a false positive rate α of .05, a power β of .80, an estimated odds ratio (OR) for the predictor with the smallest expected effect size (TC) of 1.7 (derived from the prestudy with n=80 participants), and a probability of the outcome (upload decision) under the null hypothesis of 0.5, reflecting a conservative assumption, we aimed for a sample size of 363 participants. To ensure this target was met, we oversampled participants by 30%, resulting in a total sample of 471 individuals. Oversampling accounted for potential exclusions due to failed attention checks, study dropouts, self-reported invalid data (approximately 20%), as indicated in preliminary studies [40,44], and prior medical histories with the diseases used in the study (approximately 10%, based on prior findings) [18]. Individuals 18 years and older residing in Germany were allowed to participate in the study, as the content and questions of the study were designed to fit the context of the German EHR. Another prerequisite was that participants had no personal previous experience (own illness) with the diseases mentioned in the medical reports we used for this study, as the handling of stigmatized diseases by affected persons is different from that of unaffected persons [45]. Sampling was conducted through Prolific, a crowdsourcing platform used to recruit participants for online surveys and experiments, known for its diverse participant pool and high data quality [46]. Participation was compensated with 1.78€ (US $2.09) for 8 minutes, which corresponds to the German minimum wage. The mean value of the processing time was 8:47 minutes (SD 3:57 min), and the median was 8 minutes. A total of 471 individuals participated in the study.

Design

The experimental design replicates the disease-related manipulations from our previous study [18] and extends them by testing whether transparent privacy information can reduce disease-related privacy concerns and influence upload behavior. This approach also extends prior privacy calculus–based work by focusing on actual behavior rather than intentions, as behavioral measures provide stronger ecological validity and better capture situational influences on privacy decisions [47,48]. We used a 2×2×2 between-subject study design with the 3 independent variables (IVs): stigmatization potential (SP), TC, and privacy information. Each participant was assigned to one unique combination of these conditions. As in preliminary studies, SP (high vs low) and TC (acute vs chronic) were manipulated by displaying the diagnoses of a disease with the respective characteristics [18,19]. Additionally, privacy information (PFS vs no PFS) was manipulated by either displaying a PFS during the upload process or not. In preliminary studies, participants associate disease-related stigma with high risks [18,19], and consequences could arise in areas related to personal lifestyle, occupation, and social life if medical findings became known [19,45,49,50]. Furthermore, previous studies show that participants perceive the upload of diseases with a chronic TC as more beneficial than the upload of acute diseases [8,19,20]. Participants were randomly (single-blinded) assigned to one of the conditions in parallel (simple randomization, ratio: 1:1:1:1:1:1:1:1) using LimeSurvey's built-in "rand" function. The randomization process was fully automated within LimeSurvey, ensuring allocation concealment throughout data collection. Neither the participants nor the researchers conducting the data collection were aware of the assigned condition at any point prior to or during data collection. The dependent variable was the decision to upload the medical report, that is, whether participants were willing to upload the medical findings to the EHR [18,19,40]. Reporting of this randomized controlled trial followed the CONSORT-eHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) guidelines; a completed CONSORT-eHEALTH checklist is provided in Checklist 1.

Materials

Following a common practice in technology acceptance studies [51,52], we used a case vignette to represent a typical situation in which an EHR app may be used. In particular, the case vignette depicted a situation where the participant has recently started using an EHR app and is now faced with the decision to upload a medical finding to their EHR (see Multimedia Appendix 1). Additionally, the disease/injury was described in lay terms with 1 to 3 sentences (see Multimedia Appendix 2). The stimuli used in the study were realistic but specially created

XSL•FO
RenderX

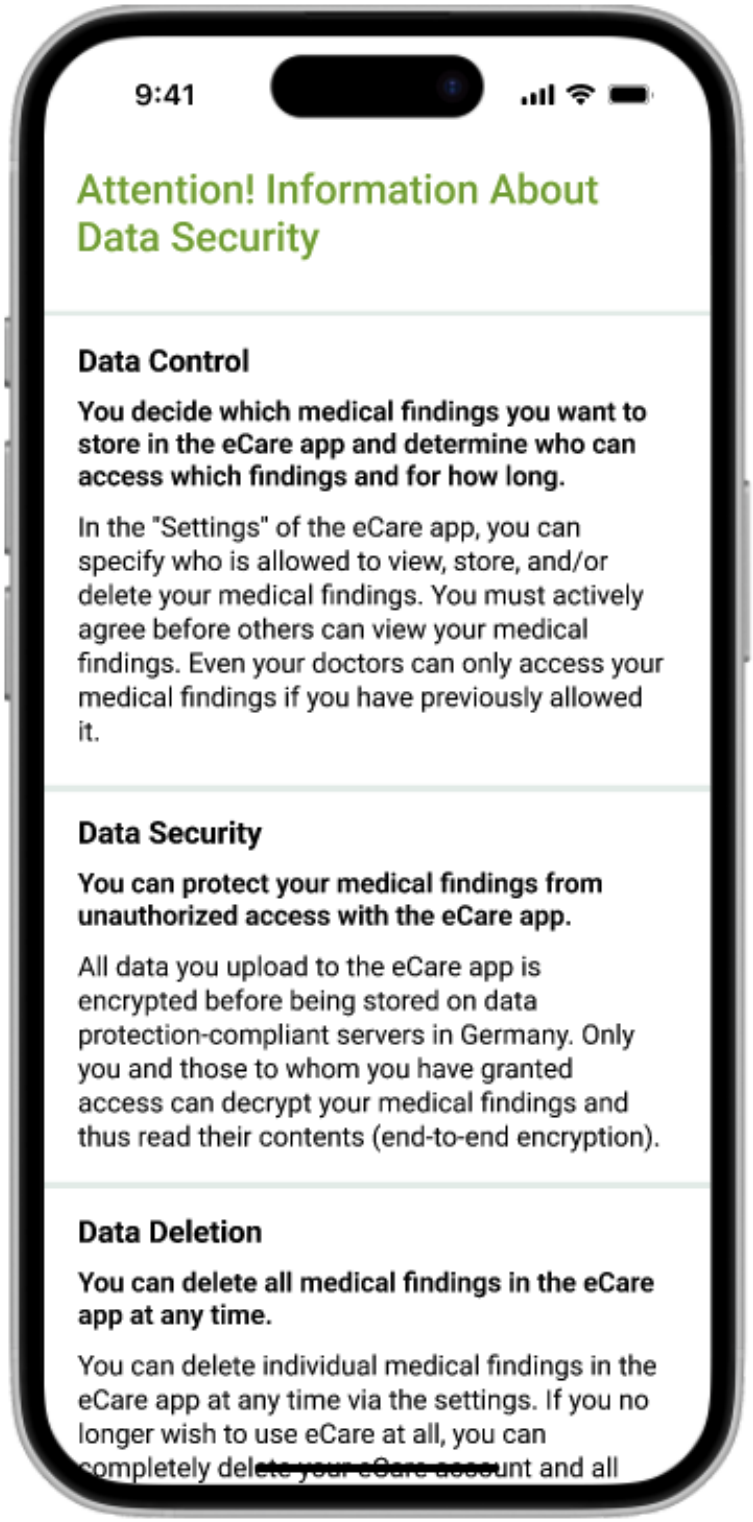
for the purpose of the study. The medical reports were provided by hospitals and a medical association. To make the reports appear as realistic as possible, they were edited on the official document heads of these institutions. This was done with the permission of the institutions concerned. In selecting the diseases, both the related stigma and their TC were systematically varied. Disease-related stigma covered different risks for professional and social life, such as tests for sexually transmitted diseases (ie, gonorrhea and HIV) [53-56] and fractures or rheumatoid arthritis as diseases with low stigma. To reflect different TCs, diseases were divided according to an acute TC (eg, wrist fracture and gonorrhea) and a chronic one (eg, rheumatoid arthritis and HIV). Furthermore, diseases were selected to occur regardless of age, meaning they can affect individuals across different age groups, so that they would be perceived as realistic diseases by an age-diverse sample. Table 1 shows the diseases used as stimuli, categorized by level of perceived stigma and TC.

Table . Diseases used as stimuli, categorized by SP[a] and TC[b].

SP and TC	Acute	Chronic
Low	Fractured wrist	Rheumatoid arthritis
High	Gonorrhea	HIV infection

[a]SP: stigmatization potential.

[b]TC: time course.



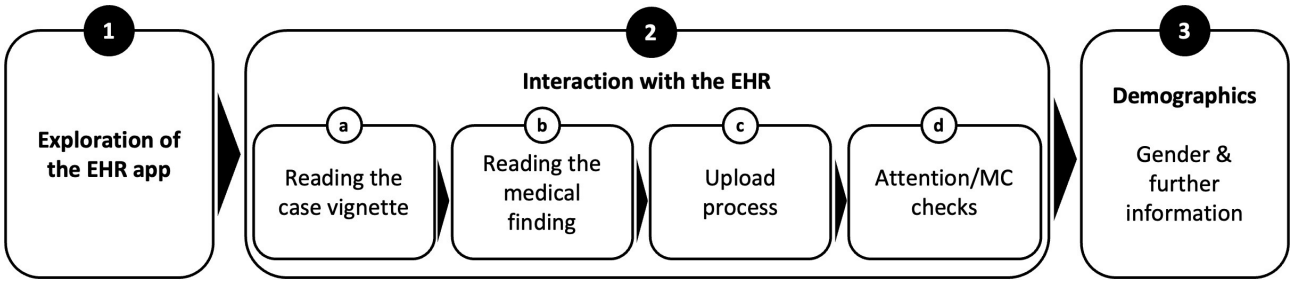
As in a previous study [19], an interactive prototype (a so-called click dummy) was used, which we created after the mobile EHR app of a German health insurance company (the BARMER) using software for interface design (FIGMA). This prototype allows for a realistic interaction with an EHR. Specifically, the prototype gave participants the ability to upload findings, grant or revoke permissions to view findings, and create medication plans. Only the "Upload findings" function was used in this study.

We used the most effective PFS that we identified based on preliminary studies [40,44], which was marked by a concise but comprehensive content and a patient-centered framing, that is, a description of what the EHR allows its users to do to control their data (eg, you can control all of your data) rather than what it does for them (eg, the EHR keeps all of your data safe). Figure 1 shows the English version of the PFS used. The English translation of the full text can be found in the Multimedia Appendix 3.

We used LimeSurvey (version 3.28.66+230719) to create and conduct a 9-page online survey. The EHR prototype was embedded into the survey using iFrame. LimeSurvey software was used to ensure that all questions had to be answered to complete the study and receive the compensation. As in previous studies, we tested the effect of the IVs by querying the perceived risk and perceived benefit of uploading findings to the EHR using validated items [18-20]. Also, we assumed that people perceived more risk when the SP was high and more benefit when the TC was chronic [19,20]. Perceived risk and perceived benefit were measured using a 7-point Likert scale ranging from 1 ("Strongly disagree") to 7 ("Strongly agree"). The decision to upload the finding was measured using a validated dichotomous item (yes/no) [18,19].

XSL•FO
RenderX

Figure 1. Privacy fact sheets used in the study.



Procedure

The study procedure is shown in Figure 2. The survey consisted of 3 parts. After giving their written informed consent according to the Declaration of Helsinki of the World Medical Association, (1) participants had several minutes to interact with the EHR prototype. (2a) Participants then read a randomly selected case vignette addressing the use of the EHR in the context of uploading a medical finding. (2b) Additionally, the participants read the medical findings of the respective illness (low or high SP and acute or chronic TC, depending on the experimental group), as well as a brief description of the respective disease. (2c) Afterwards, as part of the upload process, the participants were asked to select the medical finding for upload. Depending on the experimental group, either a PFS was displayed before the disease could be selected or not. Participants then decided whether they wanted to upload the report to their EHR. (2d) After uploading, participants who were shown a PFS were asked

XSL•FO
RenderX

a question about the content of the texts to ensure that the texts were read (attention check), and all participants were asked about the perceived privacy risks and benefits of uploading the report (manipulation check). (3) The survey was completed with the collection of demographic characteristics (age, gender, education level, and experience with mobile health [mHealth] apps) as control variables, as well as the opportunity for participants to declare their responses invalid due to lack of care in processing them (see Multimedia Appendix 4 for the questionnaire).

Figure 2. Overview of the study design. EHR: electronic health record; MC: manipulation check.

Hypotheses

As mentioned above, we hypothesize that diseases with high stigma would result in a high perceived risk and a chronic TC in a high perceived benefit. Hence, we hypothesize that the upload decision is negatively influenced by high disease stigma (H1) and positively influenced by a chronic TC (H2). Based on previous studies, we also assume that a PFS will generally increase upload behavior compared to the no PFS condition (H3). More specifically, regarding the aim of our study, if a PFS can mitigate disease-related concerns, we hypothesize that showing a PFS mitigates the negative influence of disease-related stigma on the upload decision (H4). Furthermore, we hypothesize that the positive influence of a chronic TC on the upload decision will be enhanced by the presence of a PFS, as it enhances perceived benefits related to long-term health management (H5). Textbox 1 provides an overview of the hypotheses regarding the IVs.

Textbox 1. Overview of the hypotheses.

The following were the hypotheses regarding the independent variables:

- H1: The number of uploads of medical findings to the electronic health record (EHR) is lower for diseases that are stigmatized compared to those that are nonstigmatized.
- H2: The number of uploads of medical findings to the EHR is higher for chronic diseases compared to acute diseases.
- H3: The number of uploads of medical findings to the EHR is higher when transparency regarding data privacy and security is high compared to when it is low.
- H4: The increase in the number of uploads when showing a privacy fact sheet (PFS) is higher for stigmatized diseases than for nonstigmatized diseases.
- H5: The increase in the number of uploads when showing a PFS is higher for chronic diseases than for acute diseases.

Analyses

We cleaned and analyzed the data using RStudio (version 2023.09.1+494). The analysis regarding the manipulation checks of perceived privacy risks and benefits was performed using *t* tests, a statistical method used to compare the means of 2 groups. The influence of the IVs (disease-specific stigma, TC, displaying a PFS) and the interaction effects between stigma and the display of a PFS, as well as between TC and the display of a PFS on the upload decision, were tested using multiple logistic regression with dummy coding, a method used to model the probability of a binary outcome based on one or more predictor variables.

We also included a robustness check of the results regarding the upload decision. To control for potential influences of demographic and interindividual variables that could bias coefficients and *P* values, we used multiple logistic regression. To not bias *P* values as a result of controlling, we only included variables in the model that have been shown to have a causal relationship with the IVs (ie, causal confounders): age, education level, and experience with the technical system [38,57,58]. *P* values were adjusted for multiple testing using the Benjamini-Hochberg procedure [59].

Results

Survey Characteristics

A total of 471 observations were collected. A total of 78 (16.5%) records were excluded, of which 70 (14.9%) were excluded because of incomplete questionnaires, 4 (0.85%) because participants failed the attention check, and 4 (0.85%) because responses were marked as invalid by participants. A sample of 393 observations (156 female participants, 231 male participants, and 6 with no information) was used for further analysis. Figure 3 shows the participation and distribution process according to the guidelines of the CONSORT (Consolidated Standards of Reporting Trials) statement [60].

XSL•FO
RenderX

Table 2 summarizes the demographic characteristics of the entire sample. The demographic characteristics of the subsamples for each experimental group are shown in the Multimedia Appendix 5.

Table . Demographic data of the sample (n=393).

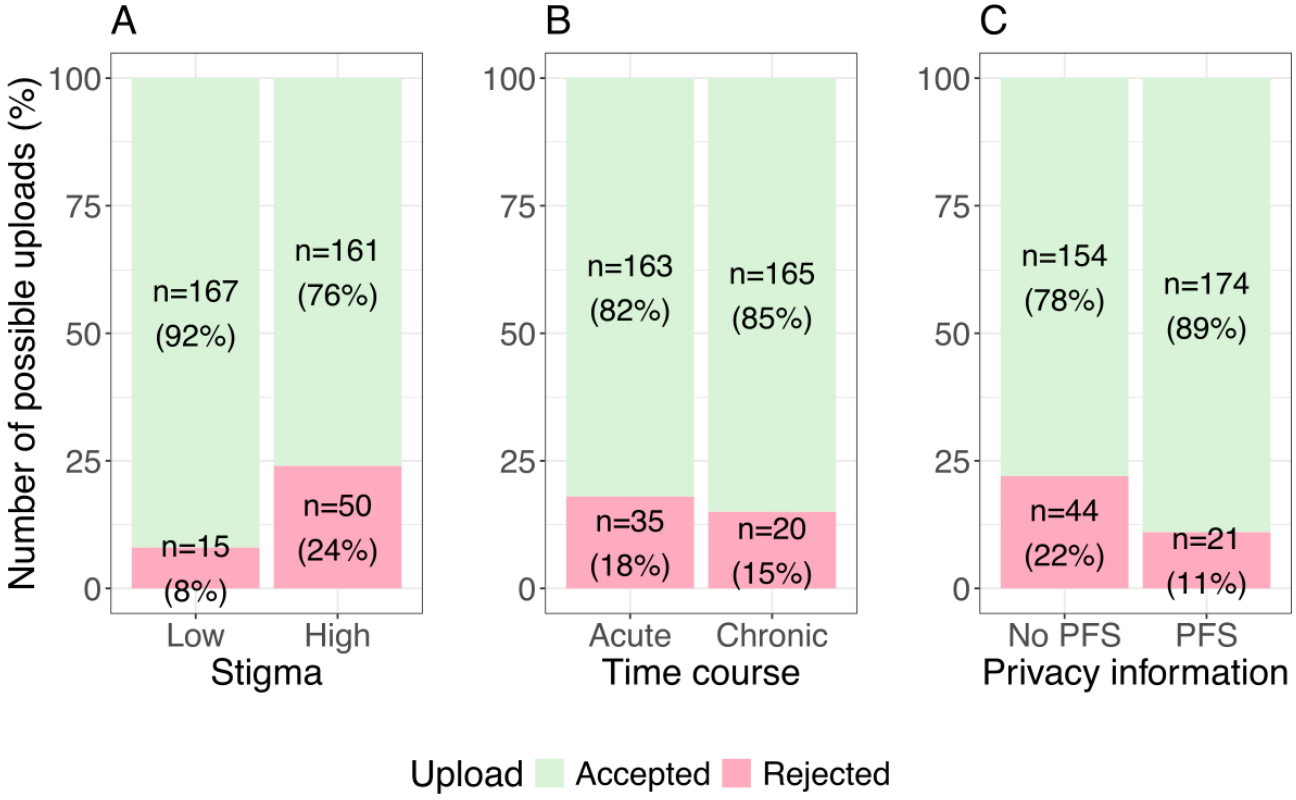
Demographic characteristic	Respondents
Age (y), mean (SD)	31.67 (9.94)
Sex, n (%)	
Female	156 (39.7)
Male	231 (58.8)
No answer	6 (1.5)
Education, n (%)	
No degree	11 (2.8)
High school/vocational education	179 (45.5)
Bachelor	102 (26.0)
Master	90 (22.9)
PhD	11 (2.8)
Experience with mHealth[a] apps, n (%)	
No use	226 (57.5)
Regular use	167 (42.5)

[a]mHealth: mobile health.

Risk and Benefit Perception

Similar to the preliminary studies [18,19], risk and benefit perception of uploading served as a manipulation check to test the validity of our manipulation (ie, the medical reports) with respect to the perception of risk (stigma) and benefit (TC). As expected, uploading medical findings of stigmatized diseases was perceived as riskier than those of nonstigmatized diseases (low: mean 3.88, SD 1.68; high: mean 5.15, SD 1.6; t_{391}=7.648; P<.001). Consequently, we assume that our risk manipulation was successful. There was no significant difference in the perceived benefit regarding the TC of the disease (acute: mean

XSL•FO
RenderX



5.63, SD 1.41; chronic: mean 5.72, SD 1.16; t_{391}=0.703; *P*=.483). Consequently, we assume that our benefit manipulation was not successful.

Additionally, we analyzed the benefit perception in relation to stigma and the risk perception in relation to TC, even though these were not part of the initial manipulation checks. Uploading medical findings of nonstigmatized diseases was perceived as more beneficial than those of stigmatized diseases (low: mean 5.84, SD 1.16; high: mean 5.54, SD 1.39; t_{391}=2.345; *P*=.02). Furthermore, uploading medical findings of chronic diseases into the EHR was perceived as riskier than those of acute diseases (acute: mean 4.31, SD 1.83; chronic: mean 4.82, SD 1.64; t_{391}=2.893; *P*=.004).

Upload Behavior

Upload behavior was negatively associated with disease-related stigma (*z*=4.568; *P*<.001), thus supporting H1. Specifically, when stigma was high, it was more than seven times less likely that the report was uploaded to the EHR (76.3%, 161/211) than when stigma was low (91.8%, 167/182). TC of the disease was not associated with the decision to upload a report (z=0.877; *P*=.38). Consequently, H2 is rejected. The PFS was positively associated with the decision to upload a medical report to the EHR (*z*=3.298; *P*<.001), supporting H3. When a PFS was given, participants were more than 4 times as likely to upload the diagnosis to their EHR (89.2%, 174/195) than when a PFS was not given (77.7%, 154/198). The absolute number of uploads is shown in Figure 4 as a function of the IVs disease-related stigma, TC, and PFS vs no PFS.

Figure 4. Number of uploads to the electronic health record as a function of disease-related (A) stigma, (B) time course, and (C) privacy information. PFS: privacy fact sheet.

We also tested for interaction effects between stigma and privacy information, as well as between TC and privacy information, to explore potential moderating effects. The interaction between stigma and privacy information was significant (*z*=2.734; *P*=.006), indicating that the increase in the number of uploads when showing a PFS is higher for stigmatized diseases than for nonstigmatized diseases, thus supporting H4 (see Figure 5A). In contrast, the interaction between TC and privacy information was not significant (*z*=0.094; *P*=.92), suggesting that displaying a PFS did not differentially impact the upload decision based on whether the disease was acute or chronic (see Figure 5B). Consequently, H5 is rejected. The summary of the results of the logistic regression is shown in Table 3.

XSL•FO
RenderX

Table . Results of the logistic regression.[a]

Variable	z value	*P* value	ORs[b] and 95% CIs		
			Lower	OR	Upper
Stigma (high vs low)	4.568	<.001	0.050	0.130	0.296
TC[c] (acute vs chronic)	0.877	.38	0.672	1.382	2.869
Privacy information (PFS[d] vs no PFS)	3.298	<.001	1.888	4.527	11.490
Stigma*privacy information	2.734	.006	1.661	5.952	21.739
TC*privacy information	0.094	.92	0.325	1.058	3.390

[a]R^2=0.107 (Hosmer-Lemeshow), 0.297 (Nagelkerke), 0.284 (Cox-Snell). Model χ^2_5=37.68; *P*<.001.

[b]OR: odds ratio.

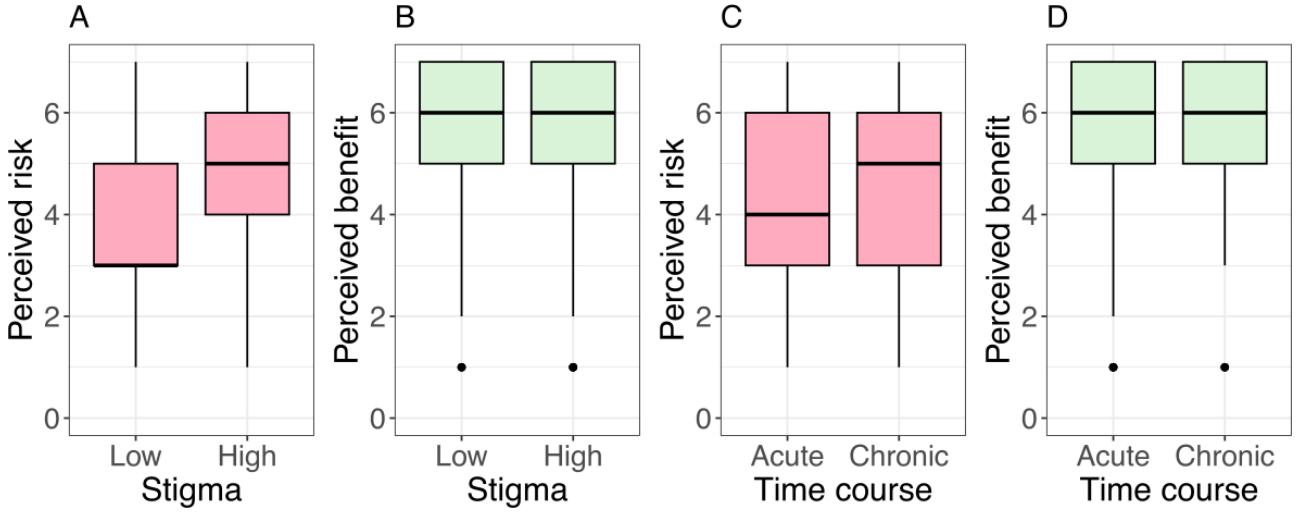
[c]TC: time course.

[d]PFS: privacy fact sheet.

Robustness Check

When controlling for interindividual variables (age, gender, education, and mHealth experience), the effects of stigma (*z*=4.820; *P*<.001) and information transparency (*z*=3.548; *P*<.001) and their interaction (*z*=3.086; *P*=.002) remained robust. Age had a negative effect on the upload behavior (*z*=2.531; OR 0.965, 95% CI 0.939 - 0.992; *P*=.01). With an increase in age, users were less likely to upload medical findings into their EHR. The other control variables did not influence the upload behavior.

Discussion



Principal Findings

The results of our study show that the decision to upload an individual medical report to an EHR click dummy is influenced by disease-related stigma as well as by privacy notices, that is, concise but comprehensive information about data privacy choices and security measures in the form of PFS. As in our preliminary studies [18,19], uploading diseases with high stigma was associated with increased privacy risk perceptions compared

XSL•FO
RenderX

to diseases with low stigma (see Figure 6A), which increased the likelihood of rejecting uploads for stigmatized diseases 6 fold compared to nonstigmatized diseases (see Figure 4A). This finding is surprising given a generally high rating of potential benefits of uploading reports to the EHR (see Figure 6B D) and an overall high willingness to upload medical findings to the EHR. In addition to the nonsignificant manipulation check regarding perceived benefits, uploads did not vary with the TC of the disease (see Figure 4).

Figure 6. Perceived risk as a function of disease-related (A) stigma and (C) time course, and perceived benefit as a function of (B) stigma and (D) time course. The horizontal line in the box represents the median.

Furthermore, a PFS positively influenced the decision to upload. When a PFS was displayed, the likelihood of uploading medical findings to the EHR was more than 3 times higher than when it was not given (see Figure 4C). This is in line with the findings of various studies showing that effective communication of data privacy choices and security information enables people to make informed decisions, thereby reducing general privacy concerns and increasing the use of EHRs [7,24,33,35,61,62]. A plausible explanation for this effect is that a PFS increases users' perceived control over personal data—allowing them to understand and oversee how their health data are handled—which in turn reduces perceived risks and facilitates the decision to upload their data [7,38,40].

Displaying a PFS did not influence the decision to upload medical findings for nonstigmatized diseases, as nearly all nonstigmatized medical reports were uploaded regardless of whether a PFS was given (see Figure 5A). In contrast, for stigmatized diseases, the PFS significantly increased the likelihood of uploads (see Figure 5B). This suggests that showing a PFS shortly before a decision to upload medical findings to the EHR must be made not only is effective in mitigating general privacy concerns but also helps to reduce specific fears related to stigmatized diseases and increase upload decisions [36,37,40].

More generally, studies in nonmedical domains, involving low-risk scenarios such as a shopping assistant [43] and an event finder [36], showed that transparency features or the transparency of privacy policies had no effect on behavior, for instance, on the decision to access the location [43] or the intention to disclose personal data to the event finder [36]. Our findings help to explain these differing findings by showing that the relevance of transparent privacy notes is mainly contingent upon the level of perceived risk associated with the data. In low-risk scenarios, such as nonstigmatized diseases, privacy concerns are typically low, which means that transparency features cannot meaningfully change the decision because there are no substantial concerns to alleviate. However, in high-risk scenarios, such as those involving stigmatized health conditions, privacy concerns are more likely to arise. In these situations, transparency features can help strengthen users' perceived control, reducing perceived risks and thereby increasing acceptance. This highlights the importance of situational context for transparency measures to matter. Transparent information about data privacy and security is not necessary in low-risk situations (although it does not hurt behavioral outcomes), but it becomes crucial for decision making in high-risk contexts, such as the handling of sensitive health data in EHRs.

Implications

The opportunities offered by implementing transparency features in the EHR should be considered by health care stakeholders. Transparency features can not only reduce general privacy concerns but can also address situational concerns triggered by disease-related stigma [18]. Thus, transparency features can ultimately help to ensure equal access to EHRs, even for users who suffer from stigmatized diseases, thereby promoting health equity [49,50,63]. This way, more patients get a chance to benefit from the EHR and, as their illnesses, allergies, and medications can be considered for future diagnostics and therapies, receive better and more targeted treatment.

Limitations and Future Directions

There are several limitations in our study, which need to be considered in subsequent studies. While our manipulation checks for perceived risk (related to stigma) were successful, the manipulation of perceived benefit (related to TC) was not. This may be due to the between-subjects design of our study. In a previous within-subjects design, where participants evaluated

XSL•FO
RenderX

both acute and chronic reports, the TC significantly impacted upload behavior [19]. It seems that participants, when comparing multiple conditions, can better discern when uploading is more or less beneficial. In our study, however, participants may have perceived the benefits of uploading as uniformly high, regardless of TC, leading to a diminished ability to detect differences.

It is clear that the adoption and approval of data-gathering technologies are strongly influenced by cultural differences [64]. In comparison to other European nations, the German population exhibits a heightened level of caution regarding the use of personal information online [65]. Given that in this study, data collection was conducted solely with residents of Germany, future studies should validate the applicability of these findings in other countries.

We deliberately excluded participants who already had a medical history with the diseases addressed in the stimuli to avoid bias in their responses. Individuals living with a stigmatized disease are more cautious to disclose the information, especially if the disease is not immediately apparent [45,66]. The question arises to what extent the behavior of stigmatized individuals can be simulated under experimental conditions. To further strengthen the validity and generalizability of our results, a follow-up study should examine the perspective of already affected individuals.

Although we captured actual click behavior, the upload decision occurred in a simulated EHR environment using fictitious diagnoses and did not involve participants' actual health data. As such, the behavior measured in this study reflects a behavioral proxy rather than real-world EHR upload behavior. Future work should examine the robustness of these findings and investigate how patients behave when real data, real accounts, and real consequences are involved.

Moreover, this was a survey study with limited immersion despite the use of an interactive click dummy. In a follow-up study, researchers could collaborate with health insurers to gather real-world data on upload behavior with a real EHR and an integrated transparency feature as used for this study. Conversely, our study faced limitations due to uncontrolled conditions like participants' locations and potential distractions, as participants completed the questionnaire online. Future research could validate our findings through a laboratory study, ensuring a more controlled environment.

Another limitation is that the distribution of our sample in terms of gender, age, and level of education does not correspond to that of the average German population [67,68]. In particular, the level of education of our sample was above average. Although we were unable to detect any effects of the control variables, gender and level of education, in the analysis, the results of this study should be validated with a more representative sample in the future.

Conclusions

Our results show that although general upload rates to the EHR are high, stigmatized diseases—even if simulated—negatively affect simulated upload behavior. However, displaying a transparency feature in the form of a PFS increases the likelihood that people upload stigmatized health data when interacting with an EHR click dummy by mitigating privacy concerns. Our findings indicate that the role of transparency features is contingent upon the level of perceived risk associated with the data to be uploaded. When the perceived risk is low, users do not need detailed privacy information to trust the technology and upload their data. However, when uploads involve sensitive data and are seen as risky, users consider privacy information and modify their upload behavior based on the information provided, potentially because transparency features help strengthen users' perceived control in such high-risk situations. Implementing transparency features in EHRs may thus help to ensure that users who perceive high privacy risks when confronted with sensitive health information are not excluded from the benefits of these systems due to privacy concerns, thereby promoting digital health equity.

Abstract

Background: Despite growing evidence demonstrating the connection between oral and systemic health, medical and dental care remain institutionally divided. A significant consequence of this division is the lack of information sharing, which is particularly problematic in dental care, where knowing patients' medical information is crucial for providing safe and effective treatments. This separation poses additional challenges in Swedish regions with limited resources, such as Dalarna, where dental care practices would benefit from improved access to relevant medical information in their electronic dental record (EDR) systems.

Objective: This study aimed to explore how current documentation workflows and EDR systems support the medical information needs within dental care practices in Dalarna and consider what influence direct access to medical information could have.

Methods: The study adopted an exploratory-descriptive qualitative approach. Semi-structured interviews were conducted with dental practitioners working in general dental practices. Data collection followed a sociotechnical framework, and thematic analysis was performed to identify key medical information needs, as well as current workflow and system limitations. Conceptual models were developed to reflect these findings.

Results: Eighteen dental practitioners were interviewed. The identified medical information needs included specific types of medical conditions, pharmacological information, treatment history, and laboratory values. Furthermore, dental practitioners highlighted substantial challenges in existing documentation workflows and the EDR system. Proposed conceptual models demonstrated how integrating EDR systems with the Swedish National Patient Overview ("Nationell Patientöversikt") via National Service Platform ("Nationell Tjänsteplattform") could streamline workflows and enhance information accessibility.

Conclusions: The findings show a clear need to improve medical information accessibility in dental care. A solution is to facilitate interoperability and align digital infrastructure with the identified needs. The proposed recommendations offer a feasible starting point for improving medical information access in Swedish dental care, particularly in resource-constrained regions like Dalarna.

Introduction

Medical Information in Dental Care

Comprehensive medical information is essential in dental care, as inaccurate or incomplete patient medical history assessments can lead to adverse treatment outcomes [1]. In addition to patient safety, the absence of accurate medical information exposes dental professionals to potential harm, as many procedures are invasive, carrying risks of occupational hazards such as cross-contamination and disease transmission [2]. The literature highlights several types of medical information as particularly relevant to dental care. Medical history, especially patients' diagnoses and current medications, is consistently prioritized [3-5]. Information about allergies and adverse drug reactions is also essential, as overlooking these may lead to severe or even life-threatening scenarios [3,4,6]. Additionally, details such as medical treatment plans, hospitalization history, and surgical history are considered highly valuable, as they support improved

XSL•FO
RenderX

care coordination and more effective treatment planning [3-5]. Together, these categories form the foundation of the medical information that dental professionals rely on to deliver care. Unfortunately, challenges arise due to inconsistencies in the documentation and communication of such information, particularly as it is often self-reported by patients [7]. This raises the question of whether health information technology can possibly address this gap and support more reliable access to critical medical information in dental care.

Information Technology for Record-Keeping

In dental care, patient information is primarily managed through electronic dental records (EDRs), whereas medical care relies on electronic health records (EHRs) [8-10]. The advent of such information systems has facilitated the process of recording patient information in data format, thereby giving professionals in both dental and medical care a more structured and streamlined approach to record-keeping [9,10]. This also includes the process of enabling information exchange.

Interoperability

To enable the exchange of patient information between EHR and EDR systems, interoperability is required [11]. Interoperability refers to the ability of different systems to exchange, process, and use patient data effectively, and it is commonly described across four levels. The technical level involves a shared technical infrastructure that allows systems to communicate. The syntactic level requires data to be structured in a standardized format for processing. The semantic level ensures that data are interpretable and meaningful across systems. Finally, the organizational level emphasizes that interoperability at the technical, syntactic, and semantic levels depends on alignment with regulatory, administrative, and policy frameworks, including agreements that enable data exchange while ensuring compliance with laws and regulations.

Current Dental-Medical Interoperability Efforts

The literature identifies two main approaches to achieving interoperability between dental and medical care systems. Health information exchange (HIE) serves as an intermediary to facilitate data exchange between different systems [3,12-14]. Integrated EHR-EDR (IEHR), on the other hand, operates on a single-system architecture [14]. This system has become widely adopted by organizations offering integrated dental-medical care services [15].

While both IEHR and HIE aim to facilitate information exchange between dental and medical care, their feasibility depends on organizational size, infrastructure, and financial resources. IEHR can provide data conformity and reliability, but may be financially and technically restrictive for smaller organizations [4,7,14]. In contrast, HIE can offer a more flexible and cost-effective solution, though usability barriers may impede its adoption [3,12-14].

Understanding how these approaches are implemented within a specific national context is essential for assessing their real-world applicability. Here, Sweden offers a particularly instructive case due to its publicly funded health care system, high digital maturity, and ongoing efforts to advance HIE [16,17]. In fact, Sweden's broader aim is to become a global leader in health care digitalization by 2025, a vision that includes both medical and dental care [18].

The Swedish Interoperability Strategy

Sweden is a country divided into 21 administrative regions, each governing its publicly funded medical and dental care services autonomously [19]. Due to this decentralized administrative structure, challenges have arisen in ensuring the accessibility and exchange of patient data across regions and organizations [17,20]. Hence, the Swedish government enacted the Integrated Health and Social Care Documentation Act (2022:913), establishing a legal basis for the sharing of patient information across health care services [21]. This legal foundation was followed by the implementation of nationwide digital infrastructure, the national patient overview (nationell patientöversikt; NPÖ), and the national service platform (nationell tjänsteplattform; NTjP) [22-24]. NPÖ is a nationwide digital platform primarily provided to public health care providers, allowing authorized health care professionals to retrieve patient data across organizations and regions [23]. NTjP refers to the technical infrastructure that facilitates the exchange of patient data in a standardized and secure manner [22,24]. This concept is similar to HIE, as it acts as an intermediary layer between different systems in organizations and regions.

Currently, the digital infrastructure does not support information exchange between dental and medical care services [25]. It may pose particular challenges in regions where access to both services is already constrained, particularly in underserved or rural regions [26-29]. To illustrate the relevance and urgency of such an approach, the region of Dalarna provides a meaningful context for further discussion.

The Dalarna Region

One of the most pressing issues in Dalarna is the shortage of dental professionals, with the lowest dentist-to-population ratio in Sweden [30]. Due to its vast land area, patients in remote regions may need to travel long distances to reach a general dental practice (GDP). In addition, Dalarna has an aging population, with nearly 25% of residents aged 65 years or older, compared to the national average of 19% [31]. This demographic trend places further strain on an already limited dental workforce, as older adults often require more frequent and complex dental and medical care [32]. Facilitating access to medical information in dental care in Dalarna could therefore support more effective and higher-quality care outcomes for patients.

Problem Description

Sweden's digital infrastructure, the NPÖ and the NTjP, support information exchange between health care information systems across regions and organizations [22-24]. However, these platforms do not currently provide access to medical information in dental care [25]. This lack of integration presents a missed opportunity to enhance both patient safety and efficiency of dental workflows, especially in rural regions where access to medical and dental services is limited [26-29]. The Dalarna region exemplifies this challenge, facing one of the most severe shortages of dental professionals in the country. This shortage

XSL•FO
RenderX

forces many residents to travel long distances for dental care [30]. Yet, addressing this gap does not necessarily require extensive structural or financial reforms. Rather, a pragmatic path forward may lie in leveraging existing infrastructure to enable dental professionals to access relevant medical information directly through their EDR systems. However, without a clear understanding of what specific medical information is needed and how it fits into dental workflows, such interoperability efforts risk being ineffective or even disruptive. Although existing literature reports the types of medical information relevant to dental care [3-5], it lacks specificity. Therefore, it is crucial to identify the specific medical information needs of dental professionals and examine how these can be supported within current workflows, systems, and organizational structures. This necessitates a sociotechnical approach that accounts for both technical components and end-users [33,34], primarily dental professionals.

Aim

This study aims to explore how current documentation workflows and EDR systems in dental care practices in the Dalarna region in Sweden support or limit the fulfillment of the medical information needs, and to examine the potential impact of having direct access to accurate and relevant medical information within EDR systems.

Methods

Research Design

This study adopted an exploratory-descriptive qualitative research approach to allow for a comprehensive yet structured and contextualized examination of the experiences, challenges, and needs on the subject matter [35].

Study Setting

The study was decided to be conducted in GDPs operated under the Public Dental Service Dalarna (PDSD), which is administered by the regional authority Region Dalarna and is responsible for providing dental care services within the region [36]. Consequently, private dental clinics or organizations and specialist clinics were excluded.

Participants and Sampling

The primary participants consisted of dental practitioners, as they are directly responsible for patient care [37]. Only dental practitioners having their main professional duties within GDPs operated by PDSD were considered. Purposive sampling was used to identify participants who were able to provide detailed, precise, and reliable information aligned with the study's aim [38]. Conversely, other dental professionals were excluded.

Data Collection

Interviews were deemed the most appropriate data collection method as they offered an opportunity for participants to share their perspectives in-depth related to the subject matter [39]. The interviews followed a semi-structured format to ensure a balance between systematic inquiry and flexibility. The interviews needed to capture the sociotechnical aspects relevant to the subject matter. To achieve this, an interview guide was designed following a sociotechnical framework. The sociotechnical framework defined by Sittig et al [40] provides a comprehensive lens for evaluating health information technology by examining the interaction between information systems and the social context in which they operate. It comprises 8 dimensions, where for this study, 6 dimensions were chosen based on their alignment with the research aim [40]: (1) clinical content to identify the specific medical information considered important and what should be accessible in EDR systems; (2) people to explore experiences and challenges in obtaining medical information from patients, the medical domain, or other sources; (3) human-computer interface to assess the usability of the current EDR system regarding accessibility and documentation of medical information; (4) workflow and communication to understand how medical information is obtained and documented within current workflows, focusing on the patient and EDR system; (5) internal organizational policies, procedures, and culture to examine existing policies on documentation and retrieval of medical information within PDSD; and (6) external rules, regulations, and pressures to explore the awareness of guidelines or requirements for documenting medical information in dental care. These dimensions informed the development of the interview guide in Swedish and English (Multimedia Appendix 1).

Assessment and Pilot Testing

Following development, the interview guide was reviewed by the co-authors, SB, ND, and the Head of Division at PDSD, to confirm its suitability. The guide was subsequently pilot-tested, which confirmed that the questions elicited comprehensive responses. Individuals involved in the review and pilot testing were excluded from the final study to avoid diluting the results. A bilingual consent form in both Swedish and English was developed in parallel (Multimedia Appendix 2).

Recruitment and Interview Sessions

The head of division at PDSD facilitated recruitment by distributing interview invitations to GDPs. Interviews were conducted digitally via Microsoft Teams between March 7 and July 28, 2025. Digital interviews were chosen to accommodate participants from various locations and minimize travel-related costs. All interviews were audio-recorded and transcribed using Microsoft Teams' built-in tool. Supplementary notes were taken during each session to capture contextual and paralinguistic cues. Transcripts were carefully reviewed, compiled, and returned to participants to confirm accuracy. Interviewing concluded when data saturation was reached, meaning no new information emerged, and the data were sufficiently rich to address the study's research questions [41].

Data Analysis

Thematic Analysis

Thematic analysis was conducted to identify and interpret patterns within the interview data, guided by the sociotechnical framework from Sittig et al [40]. The analysis followed Braun and Clarke's 6-phase approach [42]. Transcripts were read repeatedly to gain an in-depth understanding of the data, with audio recordings revisited when meaning was unclear. Excerpts

XSL•FO
RenderX

were then collated into potential themes, which were reviewed and refined to ensure they accurately represented the data. Themes were organized under the following columns: sociotechnical dimension, participant (anonymized), excerpt, subtheme, and theme. The entire analysis was iterative, with frequent revisions of subthemes and themes to ensure a valid and coherent representation of the findings [43].

Conceptual Modeling

Following the analysis, conceptual models were developed to illustrate current and proposed workflows for accessing medical information in dental care. These models considered integration with existing Swedish infrastructures. Unified Modeling Language (UML) was used due to its use in health system planning and stakeholder communication [44,45]. Three UML diagrams were created. Activity diagrams were used to show current and improved workflows for obtaining and documenting medical information in dental care. Use case diagrams were developed to present expected system functionalities derived from the interview data. Finally, a sequence diagram was created to illustrate how medical information could be exchanged from regional or national infrastructures to local EDR systems.

Ethical Considerations

The study was carried out in Sweden. According to the Swedish Ethical Review Act (SFS 2003:460) [46] and guidance from the Swedish Ethical Review Authority [47], the type of research presented in this article does not require formal ethical approval, as it does not involve sensitive personal data as defined by the European Union General Data Protection Regulation (EU 2016/679) [48]. Nonetheless, we emphasize that all ethical standards were strictly followed in accordance with relevant legislation, the Declaration of Helsinki [49]. Participants were fully informed about the study's purpose, their rights, and data handling procedures. Informed consent was obtained both in writing and verbally. Participation was voluntary, and withdrawal was permitted at any time. Anonymity was guaranteed, and participants were informed that findings would be publicly disseminated.

Results

Descriptive Overview of the Interview Sample

In total, 18 interviews were conducted, after which no new information emerged beyond the 11th interview. All participants reported using the T4 EDR system, developed by Carestream [50]. Fifteen participants identified as female and three as male. Key characteristics of the participants are presented in Table 1. All participants treated diverse groups of patients and performed a broad range of general dental treatments, where 8 participants identified oral surgery as their main focus. All participants primarily used free text.

P18	25 - 30	0 - 5	0 - 5	General Dentistry

The Specific Medical Information Needs – Clinical Content

Under the sociotechnical dimension of "clinical content," the interview data revealed three overarching categories of medical information needs: "conditions, pharmacological information, treatment history and laboratory values." Each category contains specific types of information that participants deemed essential for providing dental care (Table 2).

XSL•FO
RenderX

Table . Specific medical information identified within the sociotechnical dimension "clinical content."

Surgical procedures	P1, P5, P10, P13, P18
Blood coagulation marker	P8, P11, P14

Conditions

Among conditions, oncological diagnoses and cardiovascular diseases were the most frequently emphasized because of the associated risks when providing invasive treatments. For patients with oncological diagnoses, participants highlighted that treatment planning and risk management are directly influenced by the potential effects of cancer on oral healing and immune response. Similarly, participants reported that patients with cardiovascular diseases require special attention due to systemic risks associated with invasive procedures:

> *Knowing if a patient has cancer or has had it in the past can influence the treatment we provide in terms of healing outcomes […] healing can be delayed, and there is a greater risk for them to get infected.* [P9]

> *To be aware of patients with cardiovascular diseases, where the choice of anesthesia matters. There is also a bleeding risk, and some may need antibiotic prophylaxis.* [P14]

Psychiatric and neurological disorders were also commonly mentioned due to their impact on patient cooperation and communication:

> *Neurodivergent conditions matter, particularly when working with children. It influences how you communicate and treat them.* [P4]

Allergies in general were also deemed important, as considerations need to be taken in relation to the materials used in dental care:

> *Some patients have sensitivities to certain materials, so we need to be careful. This is particularly important to know in [dental] prosthetic treatments, where you are dealing with crowns or removable dentures.* [P14]

Additionally, infectious diseases were highlighted due to their relevance in maintaining a safe clinical environment for both patients and dental professionals:

XSL•FO
RenderX

> *Being aware of any infectious diseases is important, not only for our own safety but also to prevent cross-contamination between patients.* [P11]

Other conditions were brought up by individual participants. Though each was mentioned less frequently, they reflect the complexity of the oral-systemic health correlation in the context of coordinating dental care:

> *Patients often have several different diagnoses, such as heart problems, kidney issues, liver disease, or lung conditions, and each of those can have a real impact on oral health. Sometimes it is not clear how it all is related [for the patient], but it definitely affects how we manage them chairside.* [P3]

> *For patients with diabetes, wound healing is affected, and there is a higher risk of infection and periodontal disease.* [P14]

Pharmacological Information

The pharmacological information theme comprises medications that participants regarded as critical, primarily due to the procedural risks associated with specific drugs. The most frequently mentioned medication category was antiresorptive agents and anticoagulants due to complications associated with dental treatments:

> *If we miss that someone has been on multiple blood thinners or bisphosphonates, and they do not mention it because they're no longer taking them or do not think it is important [to mention], it can lead to problems like excessive bleeding or delayed wound healing.* [P13]

Additionally, several participants expressed the importance of knowing whether patients are taking psychiatric medications, since that would increase their understanding of patient behavior and anxiety-induced responses during care:

> *I would actually like to see more information about psychiatric medications and prescriptions. I feel like we often miss that type of medication. We could better tailor our care for these patients, particularly in cases where these medications, combined with anesthetics or sedatives, affect how a patient responds to treatment, like increased anxiety.* [P2]

Penicillin allergies and substance abuse were also mentioned, as there were concerns about prescribing antibiotics or analgesics, particularly due to risks of adverse reactions or potential misuse by patients:

> *Someone who lived in another region started coming to clinics here in Dalarna asking for morphine. We did not know about the substance abuse at first, but then we received a warning from the local pharmacy saying we should not prescribe anything to her. […] If the patient is allergic to penicillin, we need to know so we do not prescribe it.* [P11]

Treatment History and Laboratory Values

In treatment history and laboratory values, participants frequently considered ongoing oncological treatment as essential information for treatment planning and to prevent complications:

> *If they [patients] undergo radiation therapy [for cancer], it is really important that we know about it. Not just that they had treatment, but also which region was irradiated. That kind of detail affects how we approach even routine dental procedures.* [P9]

Surgical procedures were also referenced since such information is used to assess potential risks and determine whether treatment should be delayed:

> *If someone has had an operation, we need to know, because they may have to receive antibiotic prophylaxis. I may also decide to postpone treatments.* [P18]

Likewise, information on blood coagulation markers was commonly sought to support decisions around the timing of treatments for patients and to evaluate their bleeding risks:

> *For patients on warfarin, having access to their International Normalized Ratio value is essential. It helps me determine whether I can proceed with treatment immediately or if I need to postpone or take extra precautions.* [P8]

Current Workflow: People

The sociotechnical dimension of people focused on identifying who the participants interact with in relation to obtaining medical information. As summarized in Table 3, it revealed that medical information is predominantly derived from patient reporting, proxy reporting, or through medical consultation. In general, the findings demonstrated how human factors influence the workflow, suggesting the need for medical information to be made more accessible.

Coordination limitations	P1, P2, P4, P5, P6, P7, P8, P10, P13, P14, P15

Patient Reporting

Participants reported that medical information was often obtained through verbal recall, medication lists, or by asking patients to access their online patient portal. Verbal recall relied on patients remembering their medical history; medication lists were paper documents brought in by patients; and the online patient portal was used to verify details when verbal reports were insufficient, or no list was available:

> *Medical history is mostly obtained from the patients themselves verbally.* [P4]

> *Sometimes I ask the patient to log in to their online patient portal. The elderly do not know how, so I usually rely on what they say, or ask them to bring a medication list later.* [P8]

A recurring issue was incomplete or inaccurate reporting, mainly due to patients forgetting diagnoses or medications, particularly amongst the elderly or those without a caregiver:

> *Older patients may not know their diagnoses or medications. Also, some patients deliberately leave things out. Just asking is not always enough.* [P4]

Participants also noted that patients often unintentionally omitted relevant details or assumed they had nothing to report:

> *Some patients say that they do not take any medications, but then later it turns out that they take seven!* [P3]

Some also faced barriers when patients were unwilling or unable to disclose their history due to communication breakdowns:

> *Sometimes there are communication difficulties, particularly with foreign patients who may struggle with the [Swedish] language. Some patients are also unwilling to share their medical history.* [P14]

Proxy Reporting

There are situations where medical information is obtained through proxy reporting, which in this case refers to: direct relatives, companions, or care home personnel. Companions refer to those physically accompanying the patient. There were challenges presented here as well:

> *I remember one patient who arrived with a care home worker who did not know the patient's medical history. The patient had a neurodegenerative condition, so we were unable to obtain the information directly. We tried contacting the care home, but there was no nurse available at the time. Eventually, we received a phone number for a direct relative, who was able to provide us with the necessary information.* [P2]

Medical Consultations

Participants described engaging in medical consultations to obtain relevant information or seek advice on complex cases. Primary care units were the most frequent point of contact, although secondary care was also involved, depending on the patient's condition:

> *I would estimate that I contact primary care units about 1–3 times per month. Occasionally, I call specific doctors directly to confirm details if I suspect*

XSL•FO
RenderX

> *the information provided by the patient is inaccurate or incomplete.* [P4]

> *I contact medical departments several times a month. Hematology for chemotherapy patients, oncology for treatment schedules, as well as nephrology and cardiology for patient-specific matters.* [P9]

However, participants often encountered coordination limitations, such as delayed or absent responses, which hindered decision-making and delayed treatments:

> *The main issue with calling medical professionals is that they are hard to reach. You often have to call multiple times, and that takes time. This often leads to postponing treatments, even for emergency cases. I cannot proceed if I am not sure about a patient's medical history.* [P4]

Some reported being redirected or denied help, further complicating access to essential information:

> *I once called a primary care unit, and they responded strangely. They asked how I had gotten their number. Even after I explained that I was a dental practitioner and provided the necessary patient details, they refused to share any information.* [P5]

To cope with these challenges, some participants began asking patients to coordinate directly with their medical providers:

> *I once tried to contact a pediatrician, but it was very difficult to reach them. They had many patients, and it took nearly a year to get a phone appointment. Since then, I have let the patients handle the contact themselves. […] They [patients] ask their doctor, for example, whether they need antibiotic prophylaxis or if they should stop their blood thinner before an extraction, and then they get back to us with the answer.* [P14]

Current Workflow: Human-Computer Interface

The sociotechnical dimension of the human-computer interface examined the interaction with the EDR system when retrieving, documenting, and managing medical information (Table 4). Overall, participants emphasized the interface's critical role in the efficient and reliable handling of medical information, revealing both challenges and opportunities for improving usability.

Table . Aspects of current interface design and expressed design needs, categorized under the sociotechnical dimension of "human-computer interface."

Integrated external data accessibility	P1, P2, P3, P4, P5, P6, P7, P8, P9, P10, P11, P12, P13, P14, P15, P16, P17, P18

Free Text Input

All participants relied solely on free text input when documenting medical information in the EDR. This was done either in the medical history section (a structured form with predefined fields) or in progress notes (where other dental care activities are recorded).

> *There is a medical history section form that covers common illnesses like asthma, osteoporosis, cancer, diabetes, cardiovascular disease, liver and kidney diseases, rheumatism, mental health issues, history of radiation therapy, bleeding disorders, allergies, etc. If yes to any question, we ask them what medications they take and type it in.* [P14]

Some participants preferred documenting directly in progress notes due to time constraints and navigational hurdles:

> *In the EDR, we have a medical history section to fill in information. […] However, due to time constraints, I do not have time to go through everything, so I type in the progress notes instead.* [P2]

Most adopted an adaptive documentation behavior, using both sections to reinforce critical information:

XSL•FO
RenderX

> *I use the dedicated medical history section for documenting medical information. If there is something important, like bisphosphonates, I also type it in the progress notes.* [P6]

Current Interface Limitations

The category current interface limitations revealed several usability issues. One major concern was information reliability, where participants questioned the accuracy and completeness of previously entered medical information in the EDR system:

> *The problem with the current system is that we do not know if the medical information is recorded accurately or not by previous colleagues, or even if it is reliable.* [P1]

Another issue was information visibility, where inconsistent documentation across sections made it difficult to locate medical details:

> *If medical information is buried in the progress notes, it takes time to find. Time is also wasted when it is missing or outdated.* [P7]

Manual data entry was also a major limitation. Participants described it as time-consuming and prone to errors, especially when documenting long medication lists:

> *When there is a lot of medical information, entering it manually is a burden because it takes time, which could have been spent with the patient. Also, correctly spelling the names under time pressure can lead to mistakes.* [P17]

Design Needs

The findings in design needs emphasized the need for better system integration, interface enhancements, and improved visibility of patient data. All participants expressed a strong preference for integrated external data accessibility, where medical information should be directly accessible within the EDR:

> *Compared to EHR systems, which display all medications and diagnoses, EDR systems fall short. […] Our work is also time-pressured, which is why an integrated solution providing access to medical information would save time. […] Even if in another program, that is still better than nothing.* [P5]

Some also emphasized the need for access control, ensuring that only authorized personnel could view sensitive data:

> *Ideally, all relevant medical information should be retrieved in a controlled process to safeguard patients' privacy.* [P15]

Additional interface improvements suggested included:

> *Annotations: If there was a built-in description of each entry, that would be incredibly helpful. Like a pop-up suggestion that says what a particular drug is for.* [P5]
>
> *Improved Information Overview: An overview of the [medical] information is preferable, but it must be possible to filter it, so the overview stays clear and focused.* [P17]
>
> *Confirm Review Feature: It would be best if there was a function where you could sign to confirm that you have reviewed the medical history. […] to ensure accountability.* [P6]
>
> *Substance Abuse Alerts: We had a patient […] who seeks emergency care only to obtain narcotic medications. […] In EHR systems, this patient has a warning that flags up for that reason. I would like to see such functionality integrated into the EDR.* [P10]

Current Workflow: Workflow and Communication

Workflow and communication focused on broader clinical activities involving interactions with both the EDR system and patients in the context of managing medical information (Table 5). Overall, the findings indicate that workflow efficiency and patient safety are strongly linked to the availability and clarity of medical information. When such information is incomplete or difficult to retrieve, it disrupts clinical routines and compromises care.

Table . Challenges and limitations of the current workflow, as well as perceived benefits of direct medical information access, categorized under the sociotechnical dimension of "workflow and communication."

XSL•FO
RenderX

Current Documentation Workflow

Participants overwhelmingly described the current documentation workflow as time-consuming, marked by frequent disruptions when obtaining and recording medical information:

> *Asking patients about their medical history, then reading and documenting it accurately, takes up valuable time from the appointment.* [P18]

These issues often led participants to delay treatments, which often involved canceling or rescheduling appointments:

> *"Sometimes, I cannot proceed with the treatment if I do not have the patient's full medical history. I have to explain to the patient that I cannot do anything at that moment because it would pose a risk to their health.* [P2]

In some instances, essential medical information would emerge during procedures, posing potential in-treatment hazards**:**

> *One time, a patient told me he was healthy, and just before the [tooth] extraction, he casually mentioned […] a serious condition. […] We had to stop the procedure immediately.* [P7]

Finally, repeated appointments caused by information gaps contributed to patient frustration:

> *I had to postpone the treatment […] The coordination turned out to be difficult, and the patient became increasingly frustrated.* [P8]

Direct Information Accessibility

Having direct information accessibility was consistently identified as a key improvement. The most frequently perceived benefit was enhanced clinical time management, as direct access would reduce administrative tasks and allow more focus on patient care:

> *"It would be incredibly helpful to have access to patients' full medical history. Then, I would not need to ask the patients because I would be able to look it up myself directly. That way, I could plan treatments faster instead of calling around for additional information.* [P2]

Others highlighted how improved treatment planning would be possible by enabling better scheduling and avoiding unnecessary visits:

> *If I had direct access, I would be able to plan better. Like, if a patient takes a certain medication, I would know that they need to come within 6 months before their next dose.* [P3]

Also, better decision-making was noted as a distinct benefit. Several participants stressed that it would reduce uncertainty, improve efficiency, and enhance patient safety:

> *Having direct access to medical information would speed up decision-making and let patients get treated faster. I would also feel more secure making the right call.* [P6]

A final point was the reduction of patients' cognitive load, as they would no longer need to recall or bring documentation themselves:

> *Patients would not have to recall or remember to bring documents, which would offload them of responsibilities.* [P3]

Current Workflow: Internal Organizational Policies, Procedures, and Culture

The findings from internal organizational policies, procedures, and culture suggest a need for stronger organizational support, more equitable access to medical information, and support for consistency in information management practices (Table 6). These are in relation to managing medical information within PDSD, but also in the context of Region Dalarna.

Table . Perspectives of organizational and procedural aspects categorized into the sociotechnical dimension of "internal organizational policies, procedures, and culture."

RenderX

Current Documentation Practices

In the category of current documentation practices, it was widely acknowledged that there are existing routines in place. The existing routines involved checking and updating information for every appointment, as well as reminding patients to bring their medication lists:

> *We must always complete and review the patient's medical history before starting treatment, in order to check whether anything has changed since their last visit.* [P3]

> *The routine is that, when booking an appointment, the receptionist tells patients to bring their medication list.* [P9]

It also involved using a dedicated medical history section of EDR. Yet many participants noted inconsistencies in how these were applied, for example, documenting in progress notes or not updating medical information at all:

> *We have a dedicated medical history section that patients fill out for every visit. Though some colleagues only record information in the progress notes instead of using it. That makes things difficult because you then have to dig through the entire record to find relevant information.* [P5]

System Access Limitations

An initiative mentioned by participants was "Förskrivningskollen" [51], an online platform enabling authorized users to view patients' prescribed medications. However, it was described to be inaccessible due to technical issues or not provide enough information:

> *There is a platform that we technically have access to […]. It is called 'Förskrivningskollen.' While it shows prescriptions, it does not indicate what the patient is actually taking or the reasons behind those prescriptions.* [P4]

The second barrier concerned EHR access inequities. While hospital-based or specialized dental clinics within PDSD have access to EHR systems, GDPs do not. Participants viewed this as an unjustified discrepancy:

> *Dental practitioners working in hospital settings have access to EHR systems […] I asked around why we do not have the same access in GDPs, but no one could give me a clear answer.* [P9]

Organizational Support

Organizational support reflects how participants perceived the level of support provided for managing medical information in dental care, where organizational inaction refers to the lack of follow-through on identified issues, even after concerns were raised, and devalued captures the sense of not being prioritized by the broader organization:

> *People often do not realize that dental treatments also depend on knowing about diseases and medications. I think many decision-makers do not understand our professional needs. We are frequently treated like the poor cousins of medical professionals, but what we do has a big impact. We do not want the information out of curiosity. We need it to work safely and effectively.* [P11]

> *Dentists need access to relevant medical information, and physicians also need greater knowledge of how diseases and medications affect oral health. More collaboration is needed, because it is ultimately about the patient.* [P17]

Current Workflow: External Rules, Regulations, and Pressures

The last sociotechnical dimension examined was external rules, regulations, and pressures. What can be derived from Table 7 is a need for clearer guidance and communication regarding applicable regulations in dental care regarding the subject matter.

Table . Overview of the categorization under the sociotechnical dimension of "external rules, regulations, and pressures."

Themes	Participants
External regulations	
Awareness	P1, P2, P3, P5, P6, P10, P11, P14, P16
Standard practice	P4, P7, P8, P9, P12, P15, P17, P18
Patient consent	P5, P6, P11, P12, P14, P17, P18

External Regulations

The results show that there is uncertainty about external regulations guiding the management of medical information in dental care. While many participants demonstrated awareness of existing regulations, several assumed that obtaining and documenting medical information is standard practice:

> *I do not know of any rules that tell us explicitly to record medical history. I think it is obvious that we need to.* [P9]

> *National guidelines require us to document patients' medical information.* [P16]

Furthermore, the role of patient consent was perceived as crucial for retrieving medical information from both internal and external sources:

> *Yes, the Patient Data Act states that dental practitioners and hygienists may access medical information, but only what is necessary for [providing] dental care. However, if we want to know patients' medical history, we need their consent.* [P14]

Current Workflow: Conceptual Model

A UML activity diagram was developed to illustrate the current workflow for managing medical information in dental care based

XSL•FO
RenderX

on the interview data (Multimedia Appendix 3). It outlines the key steps involved in acquiring, updating, and documenting medical information in the EDR system before proceeding with treatments. The diagram includes multiple actors, including receptionist, patient, dental practitioner, accompanying proxy, proxy, and medical care unit, each with defined responsibilities represented within separate partitions.

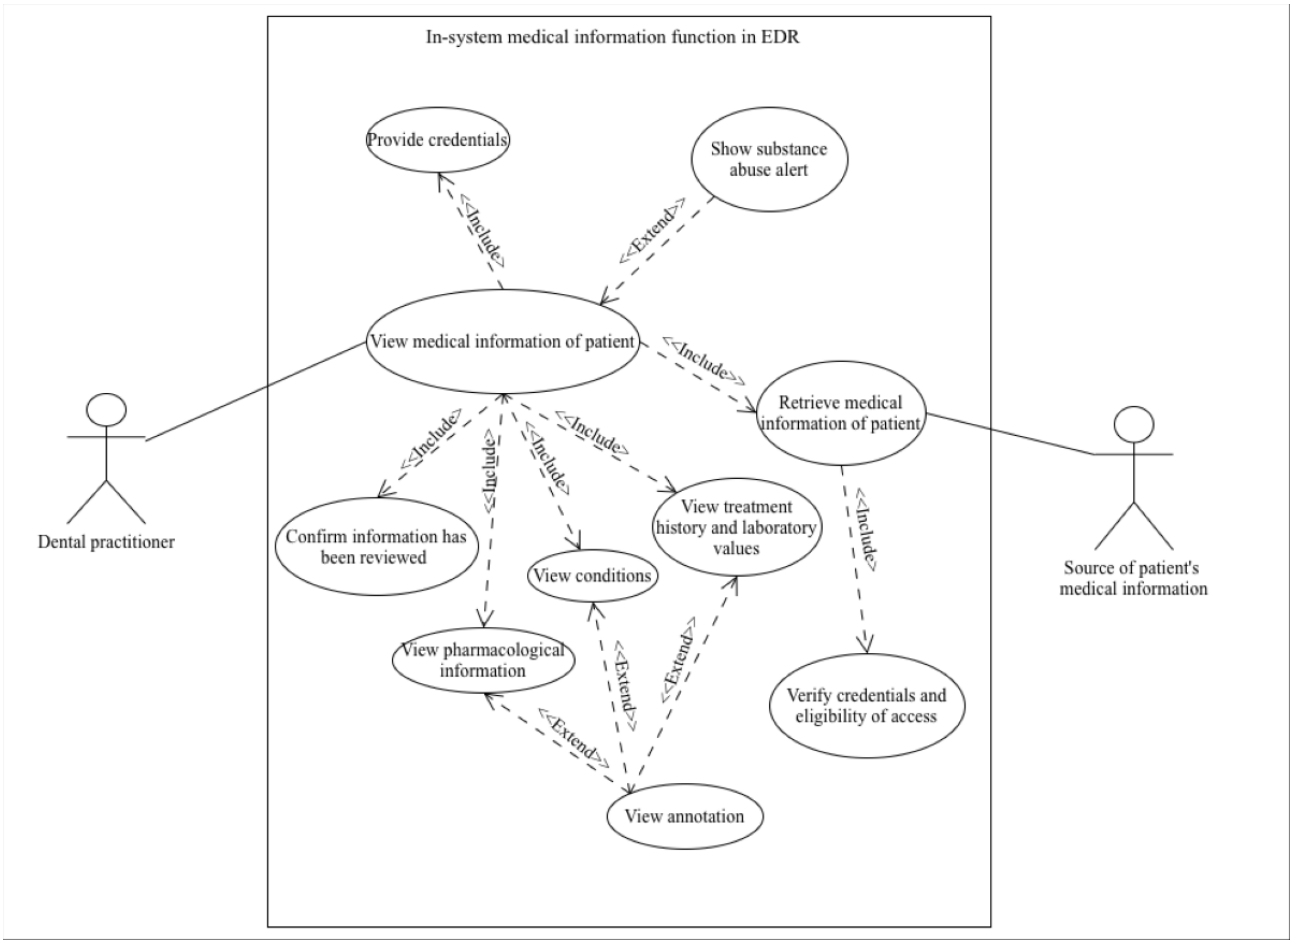
The workflow begins with the receptionist scheduling the appointment and reminding the patient to bring their medication list. Upon arrival, the dental practitioner checks the EDR to determine whether the patient is new or returning. For returning patients, the medical history section and progress notes are reviewed to assess whether updates are needed. If updates are required, or the patient is new, the dental practitioner checks if an accompanied proxy is present and able to provide the necessary information. If not, alternative steps may involve contacting another proxy or a relevant Medical Care Unit.

If no proxy is involved, the dental practitioner evaluates whether the patient can provide sufficient information via verbal recall, a medication list, or their online patient portal. If these sources are insufficient, attempts are made to contact a proxy or medical care unit, with the option to postpone the appointment.

Once the necessary information is obtained, it is documented in the EDR, either in the medical history section or progress notes. The dental practitioner may seek further medical consultation if needed. Once all relevant information is confirmed and documented, treatment can proceed.

Potential Workflow: Conceptual Model

A UML activity diagram of a proposed workflow reflects potential improvements if medical information were made accessible in the EDR system (Multimedia Appendix 4). This revised workflow removes several steps previously required to manage information gaps and instead introduces a more linear progression toward care provision.



The dental practitioner begins by accessing and checking the medical information of the patient in their EDR system, with the receptionist not having to remind the patient to bring their medication list. Furthermore, there is no reliance on an accompanied proxy, proxy, and medical care unit to obtain medical information. Only if further clarification or consultancy is needed does the process escalate to contacting the medical care unit.

Use Case Related to the Potential Workflow

A UML use case diagram (Figure 1) was developed to represent conceptual expectations and functional needs described by participants regarding an EDR system with access to medical information. This model also assumes that medical information is accessible via a regional database or NPÖ through NTjP, referred to as the source of the patient's medical information in the diagram. It is important to emphasize that the use case diagram does not depict a user interface. Rather, it consolidates qualitative insights into conceptual recommendations. System-level specifications and exceptions are therefore not included.

XSL•FO
RenderX

Figure 1. A use case with an electronic dental record system that involves providing access to medical information. EDR: electronic dental record.

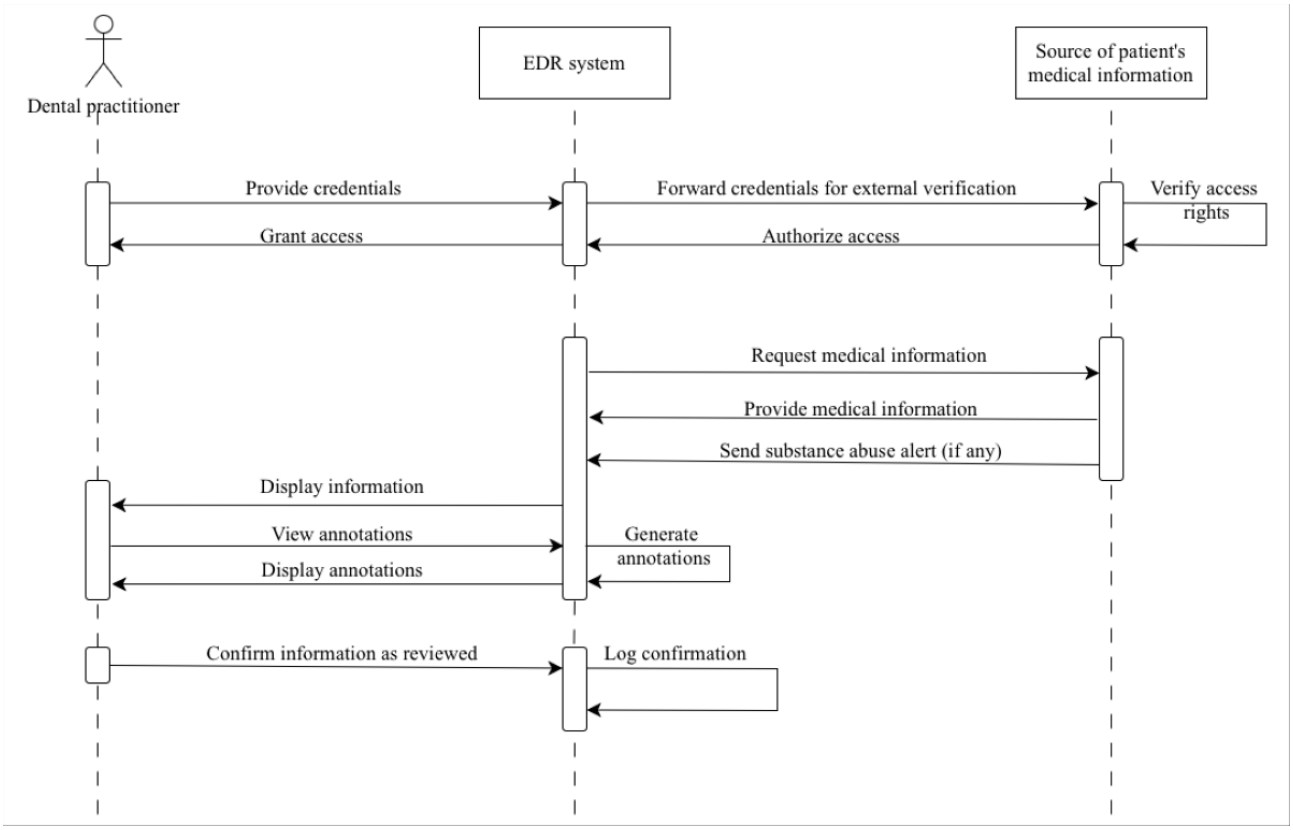
Below follows the use case, with its corresponding process flow detailed in Table 8**:**

1. Use case name to view the medical information of a patient.
2. Description to describe the steps required for a dental practitioner to securely retrieve and review a patient's medical information via an in-system function in the EDR system.
3. Alternative flow to ensure controlled data access, step 5 includes an alternative flow where, if the forwarded credentials are invalid or belong to a user without authorization, the data request is not processed.
4. Preconditions: the patient has given consent for a dental practitioner to access and view information, and the dental practitioner is directly involved in their care.
5. Postconditions: the patient's medical information has been securely accessed and reviewed by the dental practitioner. The system has logged the confirmation of the reviewed information.

XSL•FO
RenderX

Table . Normal flow of events for accessing medical information.

Steps	Actors	Actions
1	Dental practitioner	Initiates action to view the patient's medical information using an in-built function within the EDR[a] system
2	In-system function	Prompts user authentication to verify access rights
3	Dental practitioner	Provides credentials
4	In-system function	Sends a data access request to the external system, including credentials
5	Source of patient's medical information	Validates the access request and verifies that the credentials are valid and authorized to access medical information
6	Source of patient's medical information	Retrieves and returns relevant medical data
7	In-system function	Displays relevant data in the conditions, pharmacological information, and treatment history and laboratory values sections
8	Dental practitioner	Reviews the provided information
9	Dental practitioner	Confirms that the information has been reviewed
10	In-system function	Logs the confirmation
11	Not applicable	End of use case



[a]EDR: electronic dental record.

Sequential Flow of Accessing Medical Information in Potential Workflow

As shown in Figure 2, the UML sequence diagram depicts the interaction between the dental practitioner, the EDR system, and the source of patient's medical information. After the dental practitioner provides credentials to the EDR system, a verification request is sent to the external source. Upon successful authorization, the EDR system sends a request and receives the patient's medical information as a message. This may include substance abuse alerts, if applicable. The EDR system then displays the retrieved data to the dental practitioner, who may also choose to view system-generated annotations. Finally, the dental practitioner confirms that the information has been reviewed, which is logged in the system.

Discussion

Principal Results

Identified Medical Information Needs

Overall, the interviews consistently highlighted the need for accessible medical information to support safe, timely, and informed dental care provision. The findings predominantly aligned with what is reported in prior literature [3-5]. However, this study provided additional granularity regarding the specific medical information needs and their clinical relevance. Participants emphasized 4 main categories: conditions, pharmacological information, treatment history, and laboratory values.

Medical conditions such as cardiovascular disease, cancer, and psychiatric disorders were repeatedly cited due to their implications for procedural risk and treatment planning. Pharmacological needs centered on antiresorptive agents and anticoagulants, given their link to complications such as bleeding and osteonecrosis. Substance abuse history was also flagged as critical, particularly in the context of narcotic misuse. Allergies were a concern, especially penicillin allergy, due to its prescribing relevance. Moreover, relevant medical treatment history and laboratory values were also considered essential for planning and safety.

Identified Workflow Challenges

At GDPs in Dalarna, the current workflows are hindered by several challenges. These include a reliance on patients or third parties, which often leads to incomplete information gathering. Additionally, documentation workflows are fragmented, characterized by frequent interruptions and manual redundancy. The use of EDR for documenting medical information is inconsistent, and there is limited access to supportive information systems. These challenges represent a sociotechnical gap, where systems exist to store medical information but are not designed to meet the information needs or workflow constraints of the participants. In other words, the mere availability of medical information in EDR systems is insufficient, as usability, reliability, and contextual alignment were regarded as critical elements.

Workflow Barriers and Limitations

The findings underscore a misalignment between the current system design, organizational priorities, and clinical expectancy. Participants described relying heavily on patient self-reports, proxy input, or contacting external medical care units to obtain information. Patient self-reports were often unreliable, especially with elderly patients. Proxy or medical consultations introduced additional delays and communication gaps.

Despite the existence of routines, widespread inconsistencies in how medical histories are recorded were reported. Participants believed that having direct access to relevant medical information via the EDR would enhance treatment planning and reduce delays. However, they felt unsupported by the organization**,** citing failed efforts such as the online prescription check platform “Förskrivningskollen.”

The EDR system itself relies heavily on manual input, causing duplicated entries between the medical history section and progress notes. Manual data entry was perceived as burdensome, error-prone, and inefficient. Inconsistent documentation practices also impaired information reliability and visibility,

XSL•FO
RenderX

requiring participants to spend additional time navigating and interpreting records.

There was also uncertainty about legal permissions for accessing medical records, despite the existence of the Integrated Health and Social Care Documentation Act (2022:913) and explicit clarifications from Swedish authorities [21,52]. This points to organizational and educational shortcomings rather than legal barriers. The forthcoming European health data space regulation may help address such ambiguity at the European Union level [53].

Proposed Improvements for Information Access

Enabling direct access to medical information via the EDR could streamline workflows by reducing reliance on manual data retrieval. This would improve time management, decision-making, and care coordination. A feasible path forward involves leveraging Sweden's national interoperability infrastructure. By connecting EDR systems to NPÖ through NTjP, authorized dental professionals could retrieve relevant medical data across institutional boundaries [22-24].

Addressing Interoperability Levels

To implement this vision, interoperability must be achieved at four levels [11]: (1) technical, which must be supported through NTjP; (2) syntactic, which requires EDR systems to align with NTjP service contracts; (3) semantic, to provide a view-only use of external medical information, due to current dental records being largely unstructured; and (4) organizational, which requires commitment from vendors and stakeholders to align with interoperability frameworks and recognize dental professionals' medical information access needs.

Toward a User-Centered Design Approach

Interface inefficiencies and inconsistent documentation stem not only from system limitations but also from design misalignment. Poorly designed systems, even with access to the right data, can obstruct rather than support care [3,13]. Given the high cognitive load and time pressure in dental care [54], systems should minimize user burden. Preferences expressed by participants underscore the need for user-centered EDR design regarding medical information.

Implications for Scalability and Policy Considerations

In highly urbanized or well-resourced Swedish regions, the proposed integration model would require significant adaptations to ensure scalability. These environments typically involve higher patient volumes, greater clinical complexity, and a more diverse ecosystem of EHR and EDR systems. To operate effectively under such conditions, the model must support real-time data synchronization, load balancing, and robust multisystem interoperability through standardized APIs, for example, applying the Health Level Seven Fast Healthcare Interoperability Resources standard and a modular system architecture. Larger regions may also necessitate granular, role-based access controls and comprehensive audit trails to uphold security and regulatory compliance. Scalable infrastructure, potentially leveraging cloud-based or hybrid deployment models, will be essential to accommodate periods with high system workload.

Beyond technical enhancements, successful large-scale implementation will depend on policy and infrastructural measures. These include enforcing national interoperability and terminology standards (eg, Fast Healthcare Interoperability Resources and Systematized Nomenclature of Medicine Clinical Terms), updating the Swedish Patient Data Act to explicitly enable cross-sector data sharing between dental and medical care while maintaining General Data Protection Regulation compliance, and allocating targeted funding to modernize legacy dental systems and support workforce training. Together, these considerations enhance the workflow's scalability and support its potential application in settings that differ from the region studied.

Challenges of Integrating Artificial Intelligence–Driven Dental Imaging and Analysis Into EDR

Beyond the information needs described in this study, the rapidly expanding use of specialized dental software, such as artificial intelligence (AI)-driven digital smile design systems [55] and video-based smile analysis tools like Dynasmile [56], introduces additional challenges for integrating diverse data types into EDRs. These applications generate complex non-textual outputs, including high-resolution images, videos, and AI-derived esthetic or diagnostic metrics, which are increasingly used for treatment planning. Recent reviews of AI-based digital smile design indicate promising improvements in patient and clinician satisfaction, as well as esthetic outcomes [57]. Integrating such data into EDRs requires overcoming significant interoperability barriers. For instance, digital imaging data must comply with standards like Digital Imaging and Communications in Medicine to ensure consistent storage, retrieval, and portability across systems [58]. Similarly, AI-derived outputs (eg, landmark coordinates and esthetic scores) need semantic mapping to standardized clinical concepts to ensure meaningful linkage with diagnostic and treatment data. Furthermore, exchanging large multimedia files through NTjP raises practical considerations regarding storage, capacity, bandwidth, consent, and privacy compliance [59].

Acknowledging these challenges underscores the broader implications of our findings and highlights the need for future research on incorporating advanced dental imaging and AI-generated data into EDR workflows without compromising usability, interoperability, or patient confidentiality.

Limitations

Certain limitations need to be declared. First, the sample consisted of 18 dental practitioners from PDSD-operated GDPs in Dalarna. Although the generalizability was limited due to the limited number of participants and the homogeneity of the sample, with most participants having fewer than five years of professional experience and working in similar clinical settings, thematic saturation was achieved in this study. Qualitative studies, besides providing an in-depth understanding of contextualized experience, may also support theoretical generalizability or, more appropriately for qualitative research, transferability when rich contextual information is provided [60]. This study supports the transferability of the findings to other contexts with similar characteristics. However, to strengthen the generalizability of these findings, future studies

XSL•FO
RenderX

should include a broader and more diverse sample. A quantitative or mixed-methods study would also be valuable to validate and generalize the medical information needs identified here [61].

Future research could use quantitative methods to validate and prioritize the information needs identified in this study across a broader population of dental practitioners. Large-scale surveys using structured instruments (eg, Likert-scale items) could assess both the perceived importance and frequency of specific information needs, providing estimates of their prevalence and variability at regional or national levels. Additionally, a Delphi approach incorporating iterative rounds of quantitative scoring could facilitate structured expert consensus and systematic ranking of priorities.

Conclusions

This study identified a clear need to improve access to medical information within EDR systems in GDPs in Dalarna. While medical information needs such as diagnoses, medications, and allergies are widely acknowledged in the literature, this study contributed detailed insights into the types of information most relevant to dental care. Current documentation practices were found to be fragmented, inefficient, and overly reliant on patients and third parties. Usability limitations in the EDR interface further hinder information access and consistency. Collectively, these issues reflect a sociotechnical misalignment between user needs and system capabilities. To address these gaps, the study proposes leveraging Sweden's existing interoperability infrastructure, particularly by integrating EDR systems with NPÖ via NTjP. However, achieving this requires not only technical alignment but also organizational commitment, regulatory clarity, and a user-centered system design.

Future research should validate these findings at scale and explore system design and policy solutions to ensure that medical information can be securely, efficiently, and meaningfully integrated into information systems used in dental care.

Acknowledgments

The authors want to thank the Public Dental Service Dalarna (PDSD) for their cooperation, and to all the participants who took the time to contribute to this study. It needs to be declared that the main author is a licensed dental practitioner employed by PDSD. However, employment at PDSD did not affect the research process, as no funding was received. Interactions with PDSD were solely limited to recruitment coordination.

Funding

No external financial support or grants were received from any public, commercial, or not-for-profit entities for the research, authorship, or publication of this article.

Authors' Contributions

SHR conducted the data collection and carried out the initial analysis, which was subsequently reviewed and refined in collaboration with ND and SB.

Conflicts of Interest

None declared.

Abstract

Background: While patient health records (PHRs) are becoming ubiquitous, nationwide evidence on the drivers of user satisfaction in the United Kingdom remains scarce.

Objective: This study aimed to quantify determinants of PHR user satisfaction in a nationally representative sample of United Kingdom adults and to contrast real-world experiences with hypothetical expectations among individuals without PHR exposure.

Methods: We conducted a cross-sectional online survey in March 2022 using stratified quota sampling (eg, age, sex, ethnicity) through the Prolific platform. Of 1001 respondents, 533 (53%) were female (mean age 41, SD13) years, 468 (47%) reported previous PHR use ("experienced" cohort), and 533 (53%) respondents did not ("hypothetical" cohort). Primary outcomes were five satisfaction items (5-point Likert), overall PHR evaluation (0 - 100), and stated/anticipated PHR functions. Two-sample *t*-tests with unequal variances examined between-group differences; multivariate analysis of variance (MANOVA) assessed demographic equivalence. Significance was set at $P<.05$.

Results: Respondents with PHR experience rated their record easy-to-use in 79% (370/468) of cases versus an anticipated 93% (498/533) among nonusers ($P<.001$). Experienced users rated appointment-scheduling time-saving at 68% (319/468) compared with 72% (387/533) of nonusers ($P=.17$). Mean overall evaluation scores were 71.0 (SD 19.5) versus 74.2 (SD 18.6) ($t=2.25$, $P=.02$). MANOVA confirmed demographic balance (Wilks $\Lambda=.99$, $F_{3}=1.48$, $P=.18$). Preferred functions across cohorts were viewing personal health information (experience 81%, hypothetical 90%) and lab results (50% vs 76%). Users lacking experience consistently over-estimated future use of carer-related functions (eg, children's data: 36% vs 12%, $P<.001$).

Conclusions: Adults in the United Kingdom value PHRs primarily for personal data access and scheduling convenience. Nonusers displayed optimistic expectations about carer-related features and breadth of functionality, indicating an information gap. Enhancing transparency about current capabilities and expanding features that facilitate caregiving could increase satisfaction and adoption.

KEYWORDS

patient health record; user satisfaction; national survey; digital health; United Kingdom

Introduction

Background

Electronic access to health information is integral to patient-centered care [1]. In the United Kingdom, 73% of adults go online first for health information [2], and the National Health Service (NHS) aims to universalize digital data access under the ethos of "no decision about me without me" [3]. People may view clinical data through provider-tethered electronic medical records (EMRs) or untethered patient health records (PHRs) [4-6]. PHRs allow patients to *access, manage, and share* their complete longitudinal health data independently of any single institution [6]. Evidence suggests PHRs can reduce costs and improve outcomes by empowering self-care [4,7,8], yet utilization and satisfaction remain variable [9].

The NHS app, launched nationally in 2019, now exceeds 22 million registered users and represents most United Kingdom adults' first exposure to a PHR ecosystem [10,11]. Previous research shows that activated patients can achieve higher levels of self-care and satisfaction by sharing all clinical notes with their clinical team, reducing their clinical workload, and improving the health information exchange [10,11]. A recent Canadian study surveyed national PHR users and highlighted time savings, reduced clinic visits, and high satisfaction [12]. They concluded that PHR users showed positive patient satisfaction, a measured decrease of appointment rates, and a decrease in their usage of the Canadian health system.

XSL•FO
RenderX

Comparable United Kingdom-wide data—including insights from individuals without PHR experience—are lacking. Understanding expectations and perceived utility among both groups is critical as PHR functions expand.

In the United Kingdom, digital access to personal health data has expanded rapidly. Approximately 73% of adults use the internet as their main health information source [13-15]. Despite the growing adoption of such tools, research on PHR user satisfaction in the United Kingdom remains limited and often focuses on small, nonrepresentative samples [16].

Objectives

We sought to (1) identify determinants of PHR user satisfaction in a nationally representative sample of United Kingdom adults [17] and (2) compare perceptions between adults with real-world PHR experience and those expressing hypothetical expectations.

Methods

Design and Setting

We explicitly identify the study as a *descriptive, cross-sectional survey*. Data were collected online between 23 - 25 March 2022. Informed electronic consent was obtained.

Participants and Sampling

Because the survey assessed attitudes toward PHRs, it was essential to provide respondents with a clear understanding of what a PHR is. Accordingly, participants were shown a lay definition adapted from the Canadian study [12]. Approximately half of respondents had real experience with a PHR—most commonly the NHS app, which enables access to medical records, vaccination status, appointments, and prescriptions [18-20]. Other PHR systems integrated with the NHS App were also represented among users.

Participants were recruited via Prolific Academic [21], which maintains a United Kingdom participant panel. Using Prolific's *nationally representative* option, we enforced quota stratification on age (six census bands), sex (male/female), and ethnicity (five ONS categories) to mirror 2021 United Kingdom Census proportions. Inclusion criteria were age ≥ 18 years and United Kingdom residence. A total of 1001 adults satisfied the quotas, resulting in margin-of-error±3 percentage-points at the 95% confidence level.

In addition to age, sex, and ethnicity, no further stratification variables (such as education level or household income) were available within the nationally representative Prolific panel profiles at the time of recruitment. Quotas were therefore restricted to Office for National Statistics census categories for age, sex, and ethnicity. The resulting sample distributions across these strata are reported in Multimedia Appendix 1.

Survey Instrument

The questionnaire replicated the Canadian instrument [12] with United Kingdom contextual modifications (eg, "accident and emergency" replacing "emergency room"). Two parallel versions were administered: an experience-based version for respondents confirming prior PHR use and a hypothetical version with isomorphic wording framed as "If you had a PHR…." Sections covered (1) user satisfaction (5 items), (2) utility (12 items), (3) impact, and (4) demographics. The full instrument is now provided as a Survey Instrument Multimedia Appendix 2 .

Statistical Analysis

Categorical variables (eg, gender, age group) were converted to dummy indicators. No missing data were observed. Between-group differences in satisfaction, utility, and impact outcomes were examined using independent two-sample t-tests with unequal variances (Multimedia Appendix 1). A multivariate analysis of variance (MANOVA) was conducted solely to assess demographic equivalence between respondents with and without prior PHR experience, using gender and age-band indicators as joint dependent variables. MANOVA was not used for outcome analysis.

All statistical tests used two-tailed p-values, with $P<.05$ considered significant. MANOVA assessed demographic equivalence across seven covariates (gender + six age bands). All analyses used STATA (version 17.0; StataCorp LLC), with $\alpha=.05$.

Ethical Considerations

The study is classified as a service evaluation per NHS REC guidance and is therefore exempt from formal NHS ethics review [22].

Results

Participant Characteristics

Data collection occurred between March 25, and April 5, 2022. A total of 1001 adults completed the survey (completion rate=99%). Table 1 compares sample demographics with 2021 Census benchmarks; deviations were <5 percentage points for all strata except adults aged ≥ 60 years (60 - 69: −6 pp;≥70: −8 pp).

XSL•FO
RenderX

Table . Participant demographics by sample [experienced-based versus hypothetical].

Characteristics	Experience-based sample (n=468), n (%)	Hypothetical sample (n=533), n (%)	Nationally representative sample (2021), %
Gender			
Female	247 (53)	255 (48)	51
Male	217 (46)	263 (49)	49
Other	4 (1)	15 (3)	—[a]
Age			
18 - 29	107 (23)	93 (17)	18
30 - 39	93 (20)	100 (19)	17
40 - 49	82 (18)	86 (16)	16
50 - 59	86 (18)	114 (21)	18
60 - 69	85 (18)	116 (22)	14
70+	15 (3)	24 (5)	17

Completely comfortable	11 (2)	15 (3)	—
Comfortable	3 (1)	3 (1)	—
Neutral	9 (2)	22 (4)	—
Uncomfortable	112 (24)	185 (35)	—
Completely uncomfortable	333 (71)	308 (58)	—

[a]Not available.

A MANOVA assessing joint differences in sex and age distribution between respondents with and without prior PHR experience showed no statistically significant multivariate differences (Wilks' Λ=0.99; $F_{,4}$ =1.48; *P*=.18), indicating demographic balance between cohorts.

Satisfaction, Impact and Utility

Among participants with PHR experience, 79% (370/468) agreed their PHR was easy to use and 68% (319/468) reported it saved time scheduling appointments. For those without experience, 99% (528/533) stated they would use a PHR to access personal health information and 72% (387/533) expected time savings. Ease of communication with care providers was reported by 60% (283/468) of experienced users versus 75% (398/533) of nonusers (*P*=.01).

PHR use reportedly avoided a clinic visit for 42% and an Accident and Emergency visit for 4% of experienced users. Hypothetical avoidance estimates were 32% and 9% among nonusers.

Impact on Healthcare Use

Forty-two per cent (200/468) of experienced users indicated their PHR helped avoid at least one clinic visit, and 4% (19/468) avoided an emergency-room visit. Among nonusers, 32% (193/533) anticipated avoiding a clinic visit and 9% (47/533) an emergency visit.

Preferred Features and Cost Savings

Experienced users most valued: viewing their own health information 81% (377/468); viewing lab results 50% (233/468); and scheduling appointments 47% (220/468). Nonusers prioritized: viewing health information 90% (479/533); lab results 76% (405/533); and appointment scheduling 58% (309/533). Cost savings most often related to time off work (40% (187/468) vs 57% (303/533), petrol/gasoline (30% (140/468) vs 52% (278/533), and parking (21% (98/468) vs 34% (181/533).

Experience-Based vs Hypothetical Comparisons

Table 2 presents mean differences across 35 survey items. Nonusers significantly over-estimated future use for caregiving data access (eg, child records: Δ =+24 pp, *P*<.001). Despite these discrepancies, overall evaluation scores were similar (71 vs 74, *P*=.02). Specifically, three main differences emerged:

1. Nonusers over-estimated the extent to which they would use PHRs for family members' data (eg, children: 36% vs 12%, *P*=.01).
2. They over-estimated available functionality, such as preclinic forms (55% vs 18%, *P*=.01).
3. Despite this, overall satisfaction scores were comparable (74 vs 71 out of 100, *P*=.01).

[a]PHR: patient health record.

Discussion

Principal Findings

This study examined factors influencing user satisfaction with PHRs among a nationally representative sample of adults in the United Kingdom. Two groups were compared—those with PHR experience and those without—to explore both lived and hypothetical perspectives on digital health record use. Demographically, the groups were comparable, indicating that observed differences in satisfaction and expectations primarily reflect PHR exposure rather than underlying population differences.

Overall, adults in the United Kingdom expressed strong support for access to their personal health information. Experienced users reported that PHRs were generally easy to use, time-saving, and useful for managing appointments, while nonusers anticipated similar benefits if they had access. These findings are consistent with evidence from other contexts demonstrating that PHR adoption enhances satisfaction, engagement, and communication with health care providers [4,6,12,13]. The results also mirror those from Canada [12], where PHR access was associated with improved efficiency and reduced appointment rates. However, users in the United Kingdom rated usability slightly lower than Canadian respondents, which may reflect differences in the maturity of the platforms, user training, and integration across healthcare systems [2,5,20].

Comparison With Prior Work

Our results align with prior literature indicating that PHR usability, data accessibility, and perceived time savings are central determinants of satisfaction [3,4,6,17]. Participants with PHR experience valued the ability to view their own health and laboratory information, schedule appointments, and communicate with care providers—features frequently cited as key enablers of digital engagement [6,9,16]. These findings correspond with previous systematic reviews highlighting that patient portals improve convenience and empower users to manage their own health [4,5,7]. In contrast, our respondents rated United Kingdom systems slightly less favorably than those in comparable studies from Canada or the United States, suggesting ongoing challenges related to user interface design and interoperability within the NHS infrastructure [2,15,20].

Participants without prior experience tended to overestimate potential benefits and functionalities, a trend documented in earlier research on digital health optimism and hypothetical bias [10,15,16]. Woods et al [10] and Cunningham et al [16] found similar patterns of expectation inflation among new users of health portals, often due to limited understanding of actual system capabilities. Such insights underscore the importance of managing user expectations during onboarding and designing transparent communication strategies to clarify what PHRs can—and cannot—do.

In line with other studies, both experienced and hypothetical users viewed PHRs as tools that could reduce unnecessary clinical visits and associated costs such as travel, parking, and time off work [12,13,17]. This perception supports previous evidence that digital access to records can improve service efficiency and convenience for patients [4,7,9]. However, real-world data often indicate more modest effects, emphasizing the need for longitudinal studies assessing actual behavioral and economic outcomes [4,5].

Those with PHR experience expressed a desire for expanded functionality, greater interoperability, and simplified authentication—issues also raised by Turner et al [17] and Schneider et al [8], who highlighted the importance of usability and integration with existing clinical workflows. Improved personalisation, data richness, and accessibility were repeatedly mentioned, echoing prior calls for more inclusive and user-centered portal design [3,6,9,23].

From a policy perspective, the comparison between users and nonusers contributes new insights to the literature. While most previous studies focus solely on active users, our inclusion of a nationally representative sample allows for broader generalization. This approach complements earlier research that used local or condition-specific samples [8,16,17]. As digital transformation accelerates across the NHS, understanding perceptions among both users and nonusers is crucial for equitable and scalable implementation [15,18,20].

Finally, our findings align with recent studies demonstrating that both system and patient factors strongly predict portal use and satisfaction. Agrawal et al [24] reported that usability,

XSL•FO
RenderX

system reliability, and patient demographics influence electronic medical record engagement. Ndabu et al [23] observed that access type and age group significantly affect portal breadth of use, highlighting digital literacy and inclusivity as enduring challenges. Moreover, Whittemore et al [25] showed that targeted interventions can increase patient portal use among adults with type 2 diabetes, particularly when support is localized and tailored to patient needs. Collectively, these studies reinforce our conclusion that user experience, accessibility, and system design remain the primary drivers of satisfaction and long-term adoption.

Strengths and Limitations

Strengths include national representativeness and parallel assessment of users and nonusers. This is among the first nationally representative analyses of PHR satisfaction in the United Kingdom. It uniquely contrasts real and hypothetical users, offering insights into both actual experiences and potential barriers to uptake.

In terms of the limitations, first, the study's cross-sectional design limits causal inference. Second, older age groups (60 - 69 and ≥ 70 y) were under-represented in the sample, which may affect generalizability, particularly regarding digital literacy and accessibility. Third, hypothetical responses may reflect "hypothetical bias," where participants without prior experience imagine more positive outcomes. Fourth, participation was voluntary, raising the possibility of self-selection bias toward more digitally engaged individuals. Finally, all measures were self-reported, and experience was not verified independently. Future research could employ longitudinal designs and link survey data with usage metrics to validate self-reports.

Second, education level and household income were not available as stratification or analytic variables within the nationally representative panel profiles used for recruitment. As socioeconomic status may influence digital access, health literacy, and engagement with patient-facing technologies, future studies should incorporate education and income measures where feasible to further refine equity-related insights.

Conclusions

United Kingdom adults—both users and nonusers—demonstrate a strong interest in accessing their health data electronically. Experienced users report time and cost savings, while nonusers anticipate similar benefits. However, nonusers' expectations often exceed current system capabilities, highlighting opportunities for continued system improvement and patient education. Ongoing evaluation of the NHS App and similar platforms will be crucial to achieving equitable, efficient, and user-centered digital health access in the United Kingdom.

Abstract

Background: Previous studies indicate that 37% to 92% of patients presenting to hospital emergency eye clinics (EECs) could be seen in commissioned community optometrist enhanced service schemes (ESSs), reducing pressure on hospital services and moving eye care into the community. Digital triage tools may have the potential to support effective triage and use of ESSs.

Objective: This study sought to evaluate the effectiveness of a recently developed online symptom triage tool in real-world EEC practice and assess its usability and acceptance by patients.

Methods: This was a prospective, real-world study comparing automated dispositions suggested by the eye+dot online triage tool with nursing triage, using ophthalmologist dispositions and subsequent clinical findings as the reference standard. Patients aged 13 years and older were sent an SMS text message invitation to use eye+dot prior to their scheduled EEC appointment. Age, time required to complete the symptom questionnaire, and acceptability (using an in-application visual Likert scale) were also recorded. The accuracy of the different triage methods at assigning patients to eye assessments within 24 hours, 48 to 72 hours, or a week based on symptom urgency was compared. Eye+dot's accuracy in identifying patient suitability for ESSs was analyzed.

Results: A total of 282 eligible patients with a mean age of 53.14 (SD 19.8; range 13-92) years were included. The mean eye+dot test duration was 5.6 (SD 2.4) minutes, with 80.4% (168/209) of patients rating the test as good or excellent. For high-acuity symptomatology (defined via retrospective ophthalmologist recommendation for assessment within 24 hours), sensitivity was similar between eye+dot and nurse triage (58/76, 76.3%; 95% CI 65.2%-85.3% and 65/76, 85.5%; 95% CI 75.6%-92.5%, respectively; *P*=.19). However, eye+dot specificity was significantly higher (132/206, 64.1%; 95% CI 57.1%-70.6% vs 47/206, 22.8%; 95% CI 17.3%-29.2%; *P*<.001). Of 224 urgent nursing dispositions, 203 (90.6%) patients were downrated (considered suitable for nonurgent assessment) by ophthalmologist assignment, and 93 (41.5%) were downrated by eye+dot. In total, 90.8% (256/282) of the patients were considered suitable for ESS assessment through eye+dot triage. A total of 56.6% (145/256) of these patients subsequently received only medical advice without specialist investigations or management at their EEC visit, suggesting suitability for community eye care.

Conclusions: Eye+dot–automated triage has similar sensitivity but superior specificity to nursing triage for identifying high-acuity symptomatology. This small study suggests its potential to improve patient scheduling in EECs throughout the working week and improve the use of community services. A larger study is planned to establish the utility of the triage tool and develop an implementation model to scale up and spread the technology.

Introduction

The demand for urgent eye care in the United Kingdom continues to rise, adding to capacity pressures in hospital emergency services. New-patient eye care attendance is estimated at 20 to 30 per 1000 person-years, and ophthalmic emergencies make up 1.4% to 6% of emergency department (ED) attendances [1]. Primary care triage staff may tend to be risk averse in referring patients to hospital services, and studies of emergency eye clinic (EEC) attendance demonstrate that 37% to 92% of referred patients could have been seen in community enhanced service schemes (ESSs), including minor eye condition services or community urgent eye services, or scheduled outpatient eye clinics [2-5]. Redirecting suitable patients from hospital to community care is a key component of the Royal College of Ophthalmologists emergency eye care commissioning guidelines and the UK National Health Service (NHS) 10-year plan [6-8].

Triage support charts are used in many EECs to rate symptom acuity and guide urgency disposition for less experienced triage staff. Given the pressures on emergency services, interest in digital support tools is increasing. Active public-facing UK websites that signpost patients to eye care services include EuroEyes, NHS inform, and the NHS 111 Wales Eye Problems Symptom Checker tool. New clinician-facing triage support digital platforms, such as DemDx and ASSORT (Artificial Intelligence–Based Symptom Stratification in Ophthalmology for Rapid Triage), use machine learning and large language models to support triage decisions. Eye+dot is a new online triage tool that effectively functions as a digital symptom acuity chart using Royal College of Ophthalmologists triage urgency recommendations for use by patients at the direction of the triage provider. Patients complete an online multiple-choice questionnaire, which then provides the triaging service or clinician with a symptom report, suggestions as to the urgency with which the patient should be seen, and which eye care service provider would be suitable.

The objectives of this study were to evaluate the effectiveness of the eye+dot triage tool in real-world EEC practice and assess its usability and acceptance by patients.

Methods

Eye+Dot Triage Tool

Eye+dot has been designed for evaluation of recent-onset (within 1 week) ophthalmic symptoms and is suitable for patients aged 13 years and over. To undergo the test, patients use a web link contained in an invitation sent via email or SMS text message. Where eye+dot has been integrated, the invitation can be sent using an order from the organization's electronic patient record (EPR). The test consists of a branching logic questionnaire where each response determines the next question or question sequence. Each patient is asked a maximum of approximately 25 questions covering symptomatology, ophthalmic history, and medication use. On completion, the symptom report and suggested disposition can be viewed by the triage provider using a link either sent via email or available in the EPR. The suggested disposition includes both urgency (requiring assessment within the same day, 24 hours, 48-72 hours, or a week) and the most suitable eye care service (ED or EEC, hospital or community urgent eye service, private optometry, or pharmacy). The patient does not see the report or suggested triage disposition. However, if their responses warrant it (eg, a history of recent sight-threatening injury, recent sudden loss of vision, or symptoms of stroke), the patient is fast-tracked to the end of the questionnaire and receives a link to online NHS advice, including first aid and need for immediate ED attendance. Other than age, eye+dot does not collect any personal data, and the results must be linked to the patient by the triage provider (or their EPR) using the unique order reference provided when the invitation is sent.

The eye+dot web application (Cambridge Medical Innovation Ltd) has been developed and tested over several sequential proof-of-concept and validation studies based on simulated and real-life scenarios in 3 hospital trusts of the Cambridgeshire and Peterborough Integrated Care Service and, most recently, in minor eye condition service optometry practices 9. The initial process involved the development of multiple-choice questions, with the question set, branching logic structure and triage disposition algorithm being iteratively improved over a series of patient feedback studies since the application was first developed in 2021.

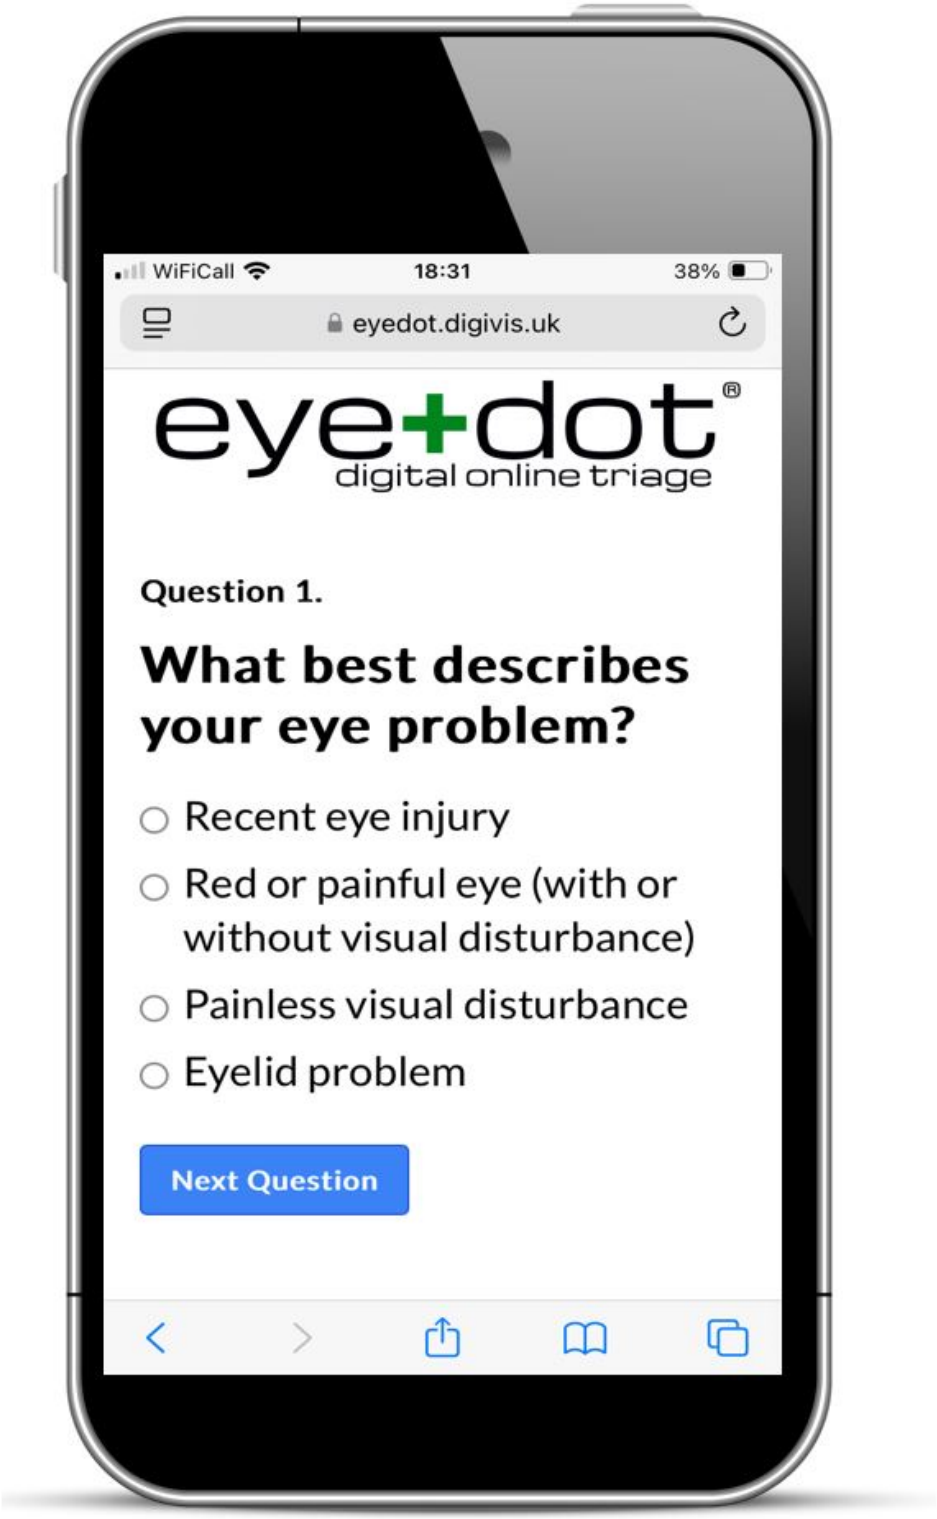
The triage tool uses only self-reported symptoms and history, and the disposition algorithm is based on the scoring system used by accepted published chart-based guides (Figure 1 [7]). Integration with an EPR (Epic) enables clinicians to order and retrieve results directly through the patient record. The application is currently in clinical use in the NHS.

XSL•FO
RenderX

Figure 1. Symptom triage support chart (adapted from the Royal College of Ophthalmologists emergency eye care guidelines) [7]. CL: contact lens; ED: emergency department; EEC: emergency eye clinic; MECS: minor eye condition service

Primary problem	ED or EEC same day High acuity—emergency	EEC or MECS within 24 hours High acuity—urgent	Hospital or MECS 48-72 hours	Community service within the week
Trauma	• Chemical injury • High-velocity injury • Severe blunt trauma • Lid laceration	As in emergency presentations but onset >24 hours ago	Low-velocity injury such as that caused by fingernail or wind-blown foreign body	Other low risk injury
Red or painful eye	• Severe pain rated ≥3 out of 5 with systemic symptoms • Generalized lid swelling with systemic symptoms	• Severe pain rated ≥3 out of 5 without systemic symptoms • Pain rated ≥2 out of 5 in a CL wearer • Increasing pain within 2 weeks of an intra-ocular procedure • Photophobia to room lighting • Halos in vision • Red eye with impaired vision and unable to read large print	• Pain rated ≤2 in CL wearer • Red eye with near-normal vision and able to read normal print	• Gritty or itchy pink or red eye with no reduction in vision and no CL history • Eyelid cysts or localised lid swelling and able to open eye fully
Painless visual disturbance	• Acute-onset floaters (too many to count) with reduced vision (unable to read large print), or visual field defect • Acute-onset diplopia with systemic symptoms	• Acute onset of >10 floaters with risk factors such as high myopia or vitreoretinal history • Painless reduction of vision within 2 weeks of an intraocular procedure • Acute-onset double vision without systemic symptoms	• Low-risk floaters (<10 floaters, no sudden onset, no visual deterioration and no ophthalmic history) • Photopsia in isolation • Low-risk blurred vision – able to read titles of print and gradual onset • Subacute-onset binocular diplopia	Gradual or >1-week onset of <10 floaters without visual deterioration
Painless visual deterioration	Acute deterioration in vision (counting fingers or worse) or visual field loss within 24 hours Deterioration in vision (unable to read large print) associated with: • systemic symptoms, • halos, or • photophobia to normal room lighting	Acute reduction in vision >24 hours and unable to read large print	Subacute visual deterioration for <1 week and unable to read large print	Gradual reduction in vision for ≥1 week and unable to read normal print
External eye	Unable to open eyelids and systemically unwell	Swelling of whole lid with erythema and limited lid opening	Swelling of whole lid with erythema	Localized swelling

Study Design



This was a prospective, single-center, real-world evaluation study that compared eye+dot triage dispositions with those generated by the standard nursing triage process. Independent triage decisions made by ophthalmologists based on their interpretation of the eye+dot symptom report were used as the standard of reference. Subsequent tests, diagnosis, and management at the scheduled EEC appointment were documented and reviewed.

The EEC at our NHS trust does not offer walk-in appointments, although patients already under the care of the trust's ophthalmology department can self-refer to this EEC. More commonly, patients are referred from primary care services via email or phone call. The specialist nurse triage team phones the patients, assesses their history, and triages them to either a scheduled EEC session or out-of-hours assessment by the on-call team. Currently, no patients are referred to local ESS optometry practices by nursing triage.

Over a 3-month period, patients aged 13 years and older with a documented mobile phone number who had scheduled appointments in EEC clinics were sent an eye+dot invitation via SMS text message prior to attendance. Patients accessing the eye+dot questionnaire were also asked to accept a General Data Protection Regulation–compliant data use notice. Data collected from the eye+dot system included the selected primary concern on the initial filter question (Figure 2), the compiled symptom report, suggested disposition, test duration, and visual Likert-scale score of acceptability (optional element of the eye+dot questionnaire; Figure 3).

XSL•FO
RenderX

Figure 2. Initial eye+dot symptom filter question as seen by the patient.

XSL•FO
RenderX

Figure 3. Visual Likert scale presented to patients after completion of the eye+dot questionnaire.

XSL•FO
RenderX

At the end of the 3-month period, records of patients who completed eye+dot triage were reviewed. Tertiary referrals, inpatient referrals, and patients referred with known diagnoses were excluded from analysis. For the remaining patients, the urgency assigned at nursing triage was documented and classified; this was defined as urgent for patients assigned for assessment on the same day (A) or within 24 hours (B), semiurgent for patients assigned for assessment within 48 to 72 hours (C), and lower urgency for patients assigned for assessment within the week (D). For the purposes of our analysis, patients were considered suitable for community care if no imaging or other diagnostic tests, prescription medication, or surgical procedures were required at the time of the EEC appointment.

To provide a reference standard, 2 ophthalmologists (a consultant and year 7 resident physician) masked to the other triage suggestions or decisions reviewed the eye+dot ophthalmic symptom report and graded the urgency using the A-to-D urgency grading criteria described above. In cases of disagreements between ophthalmologist reviewers, the higher-urgency disposition was used as the reference standard. Where a categorization of urgent by both ophthalmologists was not matched by the eye+dot and/or nursing dispositions, patient case notes were reviewed to determine whether the undertriage by eye+dot or nurses might have affected clinical outcomes.

Ethical Considerations

This service evaluation study was approved following ethical consideration by the Quality and Safety Committee at Cambridge University Hospitals NHS Foundation Trust and was conducted in accordance with the tenets of the Declaration of Helsinki. As an anonymized service evaluation study not involving randomization or deviation from the current standard of clinical care, this study was exempt from the requirement for an explicit informed consent process and national ethics committee approval (PRN13310) [10]. Patients could choose not to participate without any impact on their EEC appointment or care. The eye+dot software application replicates a chart-based symptom scoring chart and, thus, does not meet the criteria for classification as a medical device under the UK Medical Devices Regulations based on Medicines and Healthcare Products Regulatory Agency guidance [11,12].

Statistical Analysis

Patients' ages, test durations, and Likert-scale scores were analyzed using descriptive statistics. The frequency distributions of triage dispositions were compared between raters. Interrater agreement was analyzed using the percentage of agreement and quadratically weighted Cohen κ as the magnitude of disagreement in triage urgency categories is likely nonlinearly related to the resulting clinical risk for most patients. A priori interpretation of κ values was as follows: values of 0 or lower indicated no agreement, values of 0.01 to 0.20 indicated none to slight agreement, values of 0.21 to 0.40 indicated fair agreement, values of 0.41 to 0.60 indicated moderate agreement, values of 0.61 to 0.80 indicated substantial agreement, and values of 0.81 to 1.00 indicated almost perfect agreement [13]. The accuracy of eye+dot and nurse triage dispositions at identifying cases triaged as urgent (criterion A or B) by at least one ophthalmologist reviewer was calculated, and the difference in sensitivity and specificity for urgent cases was evaluated using the McNemar test with continuity correction. The number and proportion of lower-urgency patients (criterion C or D) correctly identified by eye+dot as being suitable for community ESSs was also assessed. Feedback from patients provided through a visual Likert scale (Figure 3) was converted into numerical values from 1 to 5 for analysis.

Results

Overview

Of 533 patients sent eye+dot questionnaire links, 319 (59.8%) started the questionnaire, and 315 (98.7%) of these patients completed it. In total, 33 (6.2%) patients were excluded from the subsequent analysis: of whom 17 (51.5%) already had a diagnosis at the time their appointment was scheduled, 5 (15.2%) had incomplete documentation, 10 (30.3%) did not attend, and 1 (3.0%) attended the EEC for imaging only. Therefore, full datasets from 282 (52.9% of total 533) eligible patients were available for analysis (Figure 4). Among these patients, red or painful eye and painless visual disturbance were the most common presenting concerns (Table 1).

XSL•FO
RenderX

Figure 4. Study flowchart.

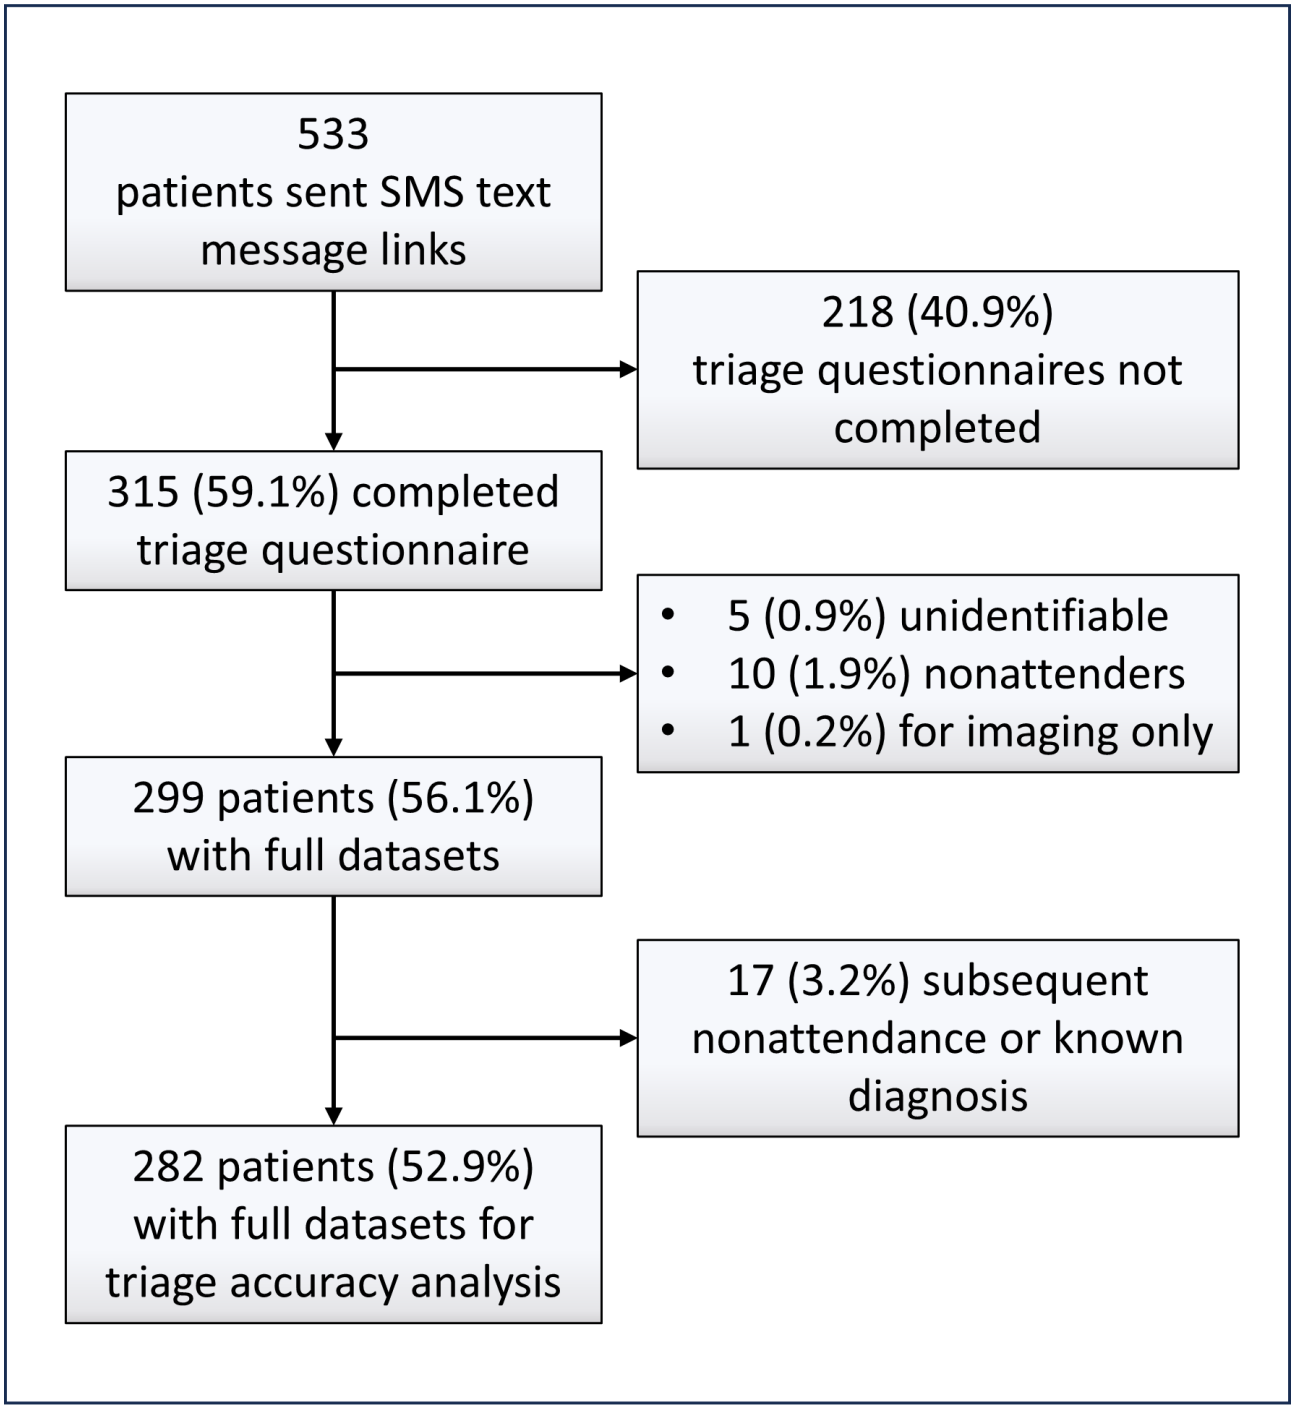


Table . Patients included for analysis by presenting concern based on response to the first question of the eye+dot questionnaire (Figure 2; N=282).

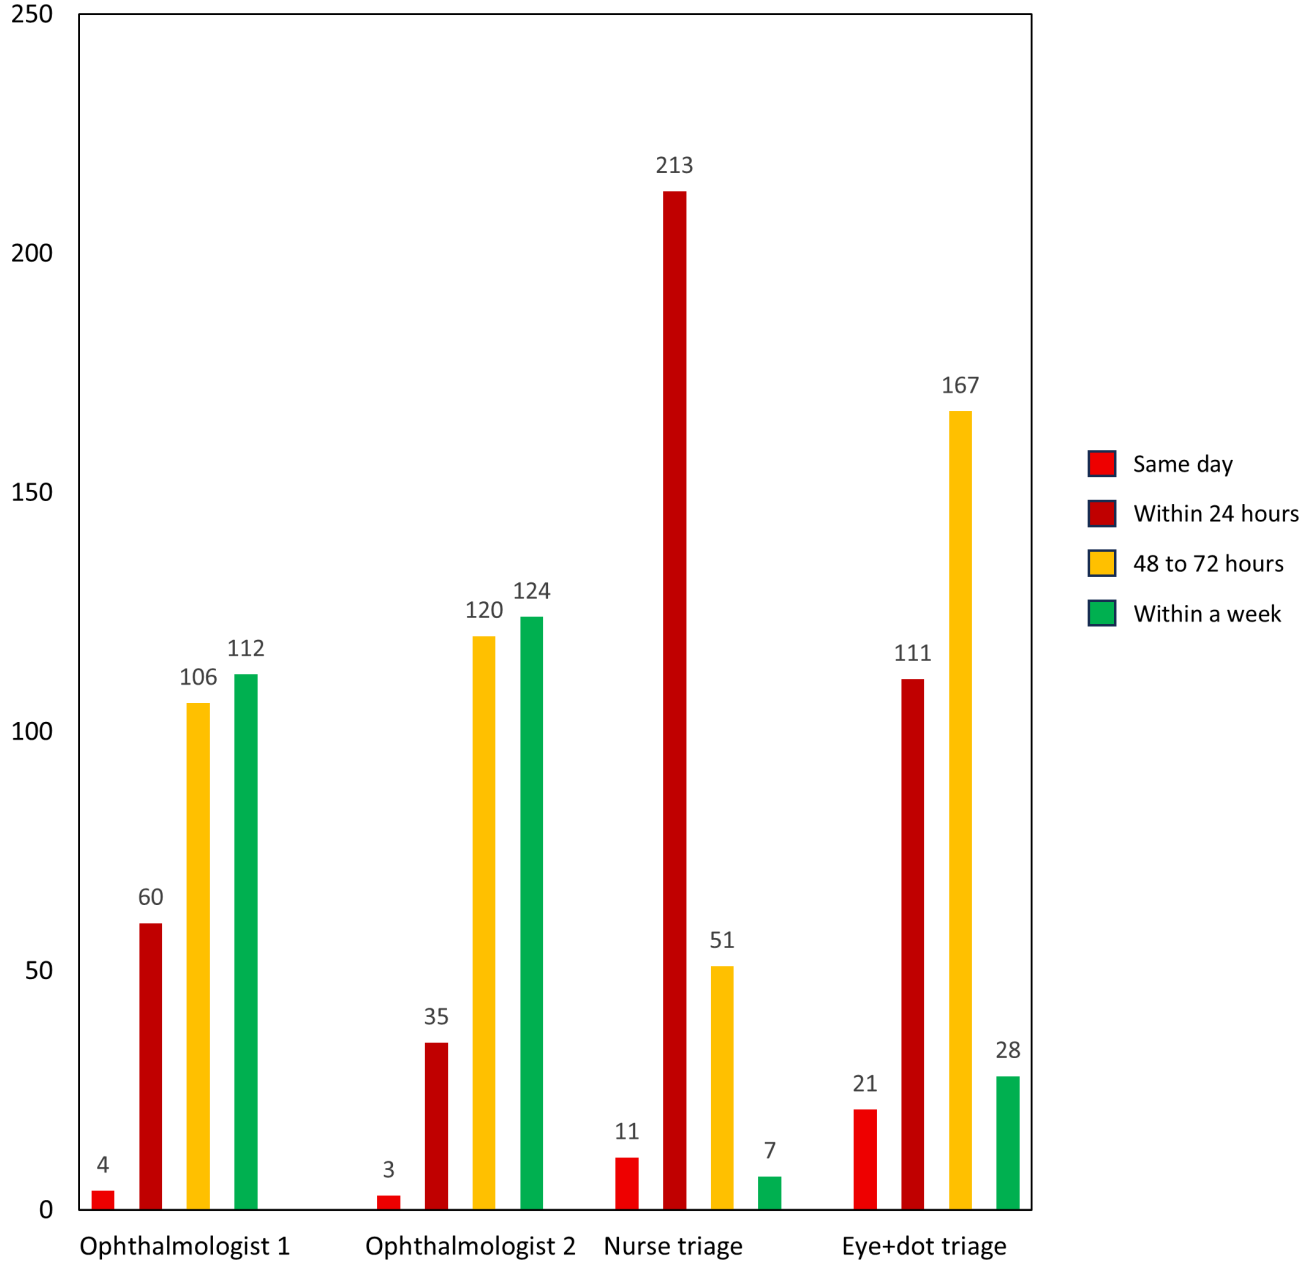
Presenting concern	Patients, n (%)
Red or painful eye	141 (50.0)
Painless visual disturbance	116 (41.1)
Eye injury	18 (6.4)
Eyelid problem	7 (2.5)

Age of Patients and Eye+Dot Acceptability

The mean ages of the patients completing eye+dot triage compared with those who chose not to use it were similar: 53.14 (SD 19.8; range 13-92) years as opposed to 53.2 (SD 19.8; range 13-94) years, respectively.

A total of 80.4% (168/209) of the patients who gave voluntary usability feedback rated the application with a 4 or 5 (with 5



XSL•FO
RenderX

representing the most positive rating) on the visual Likert scale. The mean Likert-scale score was 4.21 (SD 0.82; range 1-5). Mean test duration was 5.6 minutes (SD 2.4 minutes; range 9 seconds-20.7 minutes).

Interrater Agreement on Urgency

The frequency distribution of urgency assignments for each rater (grades A-D) is shown in Figure 5.

Figure 5. Frequency distribution of rater urgency gradings

There was fair agreement (κ=0.22) between the 2 ophthalmologists and between ophthalmologist 1 and eye+dot (κ=0.38), but otherwise, there was only slight or almost no agreement (κ=0.01-0.2) between other raters (Table 2). Eye+dot overestimated the urgency compared with the combined ophthalmologist grading in 36.5% (103/282) of the patients and underestimated it in 1.4% (4/282); nursing triage overestimated the urgency in 59.6% (168/282) of the patients and underestimated it in 3.2% (9/282).

XSL•FO
RenderX

Table . Interrater agreements for urgency gradings A to D and percentage of agreement for urgent grades (A or B).

Raters	Cohen κ (95% CI)	Agreement with urgent grading (%)
Ophthalmologist 1 vs ophthalmologist 2	0.22 (0.10 to 0.34)	78.4
Ophthalmologist 1 vs nurse triage	0.06 (0.01 to 0.11)	37.6
Ophthalmologist 1 vs eye+dot	0.38 (0.30 to 0.47)	71.3
Ophthalmologist 2 vs nurse triage	0.01 (–0.04 to 0.06)	29.1
Ophthalmologist 2 vs eye+dot	0.05 (–0.04 to 0.13)	56.5
Eye+dot vs nurse triage	0.03 (–0.06 to 0.11)	47.9

Accuracy in Identifying Urgent Cases

Of the total 282 patients, 224 (79.4%) and 132 (46.8%) were assigned an urgent triage disposition (A or B) through nursing and eye+dot symptom triage, respectively, compared with 76 (27%) who were assigned an urgent triage disposition by at least one ophthalmologist. There was no significant difference (P=.19) in the sensitivity of nursing and eye+dot triage in identifying urgent cases as defined by ophthalmologist review, but there was a significant difference (P<.001) in specificity (Table 3). The percentage of agreement of nursing and eye+dot triage with cases graded as urgent by one or both ophthalmologists was 39.7% and 67.4%, respectively.

Table . Sensitivity and specificity of nurse and eye+dot triage for identifying urgent cases (compared with the reference-standard grades of A or B assigned by one or both ophthalmologist reviewers). *P* values were calculated using the McNemar test (N=282).

	Nurse triage vs reference-standard urgent grades (%; 95% CI)	Eye+dot triage vs reference-standard urgent grades (%; 95% CI)	*P* value
Sensitivity	85.5 (75.6-92.5)	76.3 (65.2-85.3)	.19
Specificity	22.8 (17.3-29.2)	64.1 (57.1-70.6)	<.001

Clinical Presentations and Outcomes of Urgent Cases

Further analysis was undertaken in the subset of 7.4% (21/282) of patients whom both ophthalmologists classified as urgent. In total, 19% (4/21) of these patients had been undertriaged by nursing or eye+dot triage. A total of 4.8% (1/21) of the patients' triage decisions were uprated by the ophthalmologists from both the nurse and eye+dot dispositions of C (assessment within 48 hours). This patient had added "I have a foreign object in my upper lid which is now protruding over my eyelashes and it's now blocking my vision in my right eye" in the free-text entry, which was visible to the ophthalmologists on the eye+dot report. However, upon review, this patient's injury had been sustained 1 year before, and he had a retained glass foreign body in the eyelid since that time; this history had been elicited during nursing triage.

Nursing triage was uprated from C to B in a further 14.3% (3/21) of the patients: one had a resolving corneal abrasion, the second had suspected migrainous aura with associated temporal tenderness, and the third had ophthalmic shingles with corneal involvement.

Of the 224 urgent nursing triage dispositions, 203 (90.6%) patients were downrated by ophthalmologist review, and 93 (41.5%) were downrated by eye+dot.

Service Disposition

In total, 46.5% (131/282) of the patients who attended the EEC did not require hospital diagnostic or medical management and, thus, were considered to have been suitable for community care through ESSs.

Eye+dot suggested suitability for ESSs in 90.8% (256/282) of the patients. A total of 56.6% (145/256) of these patients required assessment and advice only during their subsequent EEC visit and may have been suitable for community optometrist care. The other 43.4% (111/256) of the patients received diagnostic imaging or medical management in the EEC and may potentially have needed subsequent referral to hospital eye services (HESs) had they been seen in ESSs initially.

Discussion

Principal Findings

Triage systems should ideally have both high sensitivity and high specificity to ensure timely access to care and efficient use of resources. Triage accuracy particularly depends on factors such as clinical experience, evaluation time, and the use of support tools or frameworks [14,15].

A recent large retrospective study at Moorfields Eye Hospital ED reported nurse triage sensitivity of 96.4% and specificity of 25.1% for identifying emergency cases among patients attending the EEC [16].

This real-world validation study found similar results for nurse-led triage in relation to patients assigned an urgent grading, but the eye+dot triage support tool, although it had similar sensitivity (P=.19), showed significantly higher specificity for emergency cases than nursing triage (P<.001).

These results suggest that use of eye+dot could have safely downrated the triage category in 41.5% (93/224) of patients assigned as urgent via nurse triage, potentially enabling redistribution of patient load throughout the working week and redirecting 51.4% (145/282) of patients from a planned EEC

XSL•FO
RenderX

attendance to a community ESS appointment without the risk of a subsequent rebound referral back to the HES.

Comparison of Interrater Agreement to That in Prior Studies

It is notable that the interrater agreement in this study was poor between most triage modes (optometrists, eye+dot, and ophthalmologist reviewers), and was only fair between the 2 ophthalmologists (κ=0.22, 95% CI 0.10-0.34) and between eye+dot and the consultant ophthalmologist (κ=0.38, 95% CI 0.30-0.47). This stands in contrast to interrater agreements reported in other studies using digital triage tools. A real-world validation study at Scheie Eye Institute, University of Pennsylvania, reported excellent interrater agreement between their online symptom-based triage tool and reference standard (κ=0.91). However, this may be because prioritization categories were in wider, more discrete urgency bands of "emergency/urgent (same day)," "semi-urgent 1-4 weeks," and "nonurgent/elective" compared with the relatively narrow urgency categories used in this study [17]. Studies using large language models have also claimed relatively high interrater agreement (κ=0.773-0.751) for their models using simulated clinical scenarios, but this may not reflect the complex and sometimes inconsistent symptom reporting often encountered in the real world [18-20]. A recent pilot study of the GPT-4–powered ASSORT triage tool in 51 patients presenting in an EEC with concerns requiring prompt evaluation showed moderate interrater agreement between ASSORT and the triaging ophthalmologist (κ=0.54) with overestimation of severity [21]. In that cohort, 56.8% of patients were considered urgent by the ophthalmologist compared with the 27% (76/282) in our study population of nurse-triaged scheduled attenders, suggesting that the populations may not be comparable.

Utility of the Triage Tool as an Aid for Redirecting Patients to Community Services

Using the eye+dot triage tool, all patients with newly reported recent-onset symptoms would have had a professional eye assessment within the week, but the urgent workload would have been more evenly distributed, with most patients (256/282, 90.8%) potentially being assessed in the community ESSs first.

Of these, 43.4% (111/256) may have required diagnostic imaging or medical management, necessitating a subsequent rebound referral to HESs, although this is likely to be an overestimation as many ESS providers now have diagnostic imaging and prescribing optometrists available. A 2016 study reported that only 18.9% of 2123 patients attending ESSs in a South London area required a subsequent referral to HESs [22].

This potential benefit of redirecting patients to community ESSs before hospital assessment cannot be fully realized by some other triage tools which require the input of nurse-elicited symptoms and signs. Examples include DemDx, the Alphabetical Triage Score for Ophthalmology, and the Rome Eye Scoring System for Urgency and Emergency [16,23,24].

Usability Feedback and Potential Workflow Issues

A total of 59.8% (319/533) of the patients who were sent invitations clicked on the eye+dot link in the SMS text message, which we consider to represent a reasonable openness to engaging with the new technology, given that they had received no prior notification to expect this. Providing advance information regarding eye+dot at the time of initial contact might have increased uptake. The eye+dot application was generally well accepted and was rated within the top 2 out of 5 possible Likert scale options by 80.4% (168/209) of the patients in this study who responded to the request for feedback at the end of the questionnaire. All had already been scheduled for an EEC appointment, which may have influenced their acceptance, and it is possible that reported usability of the tool may decrease if the information collected is used to redirect patients to community services. A related potential issue, which requires evaluation in practice, is whether patients who had already been referred to the EEC by their primary care team would be resistant to being redirected to community eye care providers based on this triage process. Both ESSs and EECs are free-to-access NHS services, but patient resistance to triage advice based on financial cost may be a necessary factor to consider in other countries or contexts. NHS England is developing single point of access call centers for patients with recent-onset symptoms to be triaged and directed to a suitable service. This may be the ideal point to implement specialist digital triage tools such as eye+dot to prevent the patient from being bounced between health care providers.

There was no difference in age between those who responded to the questionnaire and those who did not; however, it is possible that older patients without mobile phone access may have been underrepresented. Systematic reviews of patient experience of primary care online triage describe the importance of issues of digital and literacy inequality, sight impairment, concerns regarding privacy, and distrust of online platforms. Some patients find that the convenience and speed of online triage platforms outweigh their transactional and impersonal nature, and for others, it is quite the reverse [25,26]. Access to the technology for the visually impaired may be considered a particular limitation for an eye symptom triage tool, although this is mitigated by the ease of responding to the eye+dot questionnaire over the telephone. None of the patients in this study cohort were identified as visually impaired, possibly because patients with preexisting eye conditions are more likely to have direct lines of access to specialist care and be less likely to use a primary triage tool. For staff, although there may be concerns that greater use of digital triage tools could lead to deskilling or even job losses, given the current staffing shortages and ever-increasing workload, this seems unlikely. Both they and patients may benefit from the advantages and support of an automated questionnaire that can be completed in the patients' own time and records important red-flag and negative symptomatology that can be documented in the EPR.

Conclusions

This real-world study demonstrates that eye+dot triage has similar sensitivity to but significantly higher specificity than nursing triage in assessing urgency for patients scheduled for EEC appointments. An implementation study is planned to determine its utility in safely downtriaging and redirecting appropriate cases to community eye care services and the effect

XSL•FO
RenderX

this has on ED and EEC service efficiency and to develop a model for the spread of the technology.

Acknowledgments

The authors are grateful to Alexandra Mirza-Davies for supporting data collection and analysis and to the staff of the emergency eye clinic at Addenbrooke's Hospital for their support with the study.

Funding

This research was unfunded but supported by the National Institute for Health and Care Research Cambridge Biomedical Research Centre (NIHR203312). Abstract

Background: Effective team communication is critical in pediatric cardiopulmonary arrest management, where delays or miscommunication can jeopardize survival. TeamScreen, a web-based interface displayed on a large screen, was developed to enhance cardiopulmonary resuscitation (CPR) by providing real-time visualization of clinical data and resuscitation steps aligned with the American Heart Association pediatric advanced life support algorithms.

Objective: This study evaluated the usability of the TeamScreen Figma prototype, evaluating how efficiently and accurately experienced emergency physicians and nurses retrieved critical information during a simulated pediatric in-hospital cardiac arrest scenario. Although no strict time constraints were imposed, participants were instructed to perform the tasks as spontaneously and as quickly as possible.

Methods: Usability testing involved 20 pediatric emergency physicians and nurses with varied CPR experience. Participants performed 21 information retrieval tasks within a simulated pediatric cardiac arrest scenario (shockable rhythm). The data collected included audio-video recordings via the think-aloud method and participant responses to the Post-Study System Usability Questionnaire (PSSUQ) version 3 and a posttest survey. Effectiveness, efficiency, and satisfaction were measured by task completion rates, time-on-task metrics, and PSSUQ scores, respectively. Think-aloud data were analyzed for usability issues using Nielsen Norman Group's rating scale and Bastien and Scapin's ergonomic criteria.

Results: Five physicians and 15 nurses achieved a mean task success rate of 81.19% (SD 16.87%), with a mean completion time of 8.13 (SD 7.07) seconds, calculated across all 21 tasks and all participants. PSSUQ scores reflected high satisfaction (mean 2.40 [SD 1.24] of 7.00; the lower the better), notably for information clarity and system utility. Qualitative analyses identified 16 usability issues, of which 5 were deemed major, primarily involving information visibility, navigation, and density, highlighting areas for interface and workflow enhancement.

Conclusions: The usability evaluation confirmed TeamScreen's potential to improve real-time information access during pediatric CPR, with high task success and satisfaction scores supporting its role in aiding decision-making. Challenges with visibility, navigation, and information density require further refinement. These findings will guide improvements and inform the design of multicenter trials to assess TeamScreen's efficacy in simulation-based resuscitation settings.

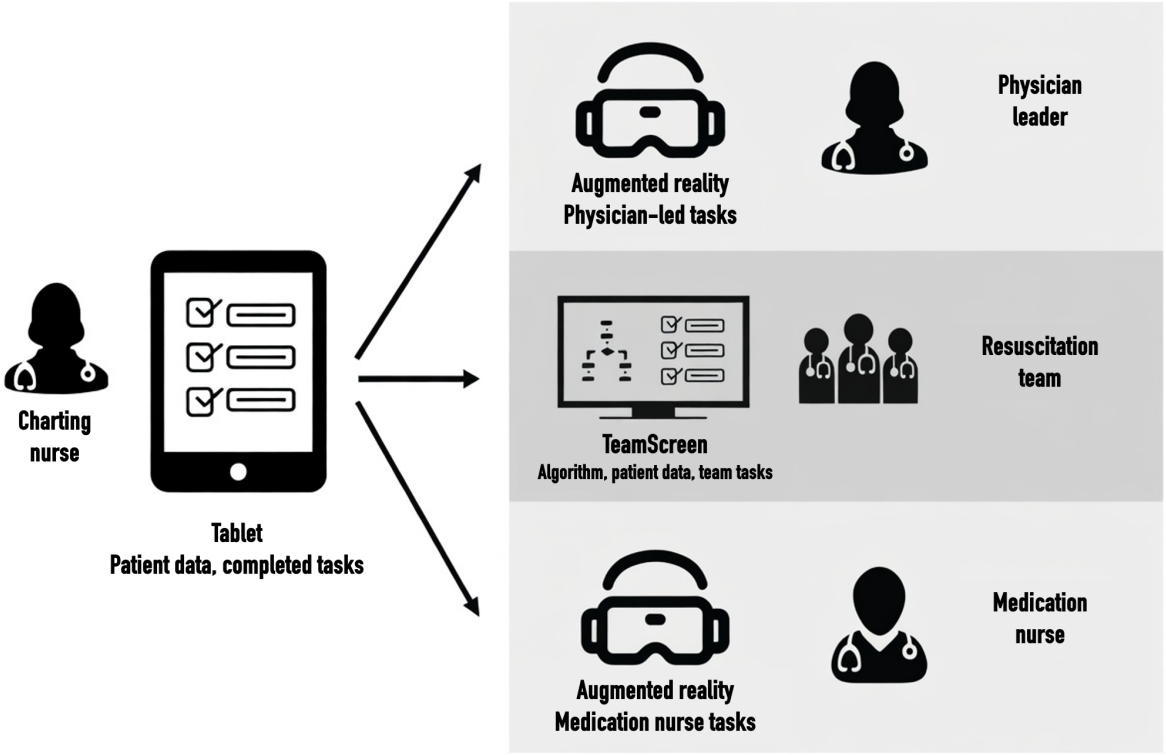
Introduction

Context and Problem Statement

In-hospital pediatric cardiac arrests (IHCA), although rare, require immediate, coordinated response from resuscitation teams under intense pressure to provide guideline-compliant clinical care [1]. Standardized protocols, such as the American Heart Association pediatric advanced life support (PALS) guidelines, emphasize uniform responses [2], yet adherence remains suboptimal, with frequent deviations from recommended timing of defibrillation and drug administration, errors in dosing, and omissions of key steps in both real and simulated pediatric cardiac arrest scenarios [3-6]. These deviations are strongly influenced by human factors such as high cognitive load, stress, impaired decision-making, communication breakdowns, and challenges in maintaining team situational awareness and a shared mental model during complex emergencies [4]. These lapses compromise quality of care and survival rates [7]. As a result, there is increasing interest in tools that support team cognition and real-time guideline adherence during pediatric cardiopulmonary resuscitation (CPR).

Digital cognitive aids and decision support systems have emerged as promising approaches to mitigate these problems. In adult and mixed emergency settings, cognitive aids and electronic decision support tools have been associated with fewer errors and better adherence to resuscitation algorithms in simulated IHCA [8-11]. In pediatrics, few are purpose-built for real-time use in resuscitation [12]. Tablet-based apps were developed specifically to support pediatric cardiac arrest management and showed good usability in high-fidelity simulation with reduced deviations from guideline recommendations [13-15]. A recent systematic review of cognitive aids in resuscitation similarly concluded that cognitive aids tend to reduce deviations from guidelines and improve resuscitation performance in simulated settings across adult and pediatric populations [16]. However, most existing systems are designed as single-user, handheld interfaces that primarily support the team leader, rather than functioning as shared, team-centered displays that make time-critical information visible to the entire resuscitation team in real time.



Only a few technological solutions have been conceived as large situation displays to enhance team communication and situational awareness during emergency resuscitations. Pilot work in emergency departments has suggested that dedicated situation displays can facilitate teamwork, communication, and perceived situational awareness among resuscitation teams [17,18]. More recently, an interactive, large-screen clinical decision display designed for team-wide viewing has been evaluated and shown to improve adherence to guideline time intervals in simulated advanced cardiac life support [8]. Despite these advances, pediatric-specific evidence for team-centered digital decision support during IHCA remains limited, and there is a need for tools explicitly designed around the information needs and workflows of pediatric resuscitation teams.

To address these limitations, we developed Interconnected and Focused Mobile Applications on Patient Care Environment (InterFACE), a suite of interconnected digital tools (Figure 1) designed to enhance team coordination and PALS adherence during pediatric CPR [19,20]. Building on an earlier prototype [15] that demonstrated improvements in defibrillation timing and adherence to resuscitation algorithms but also highlighted risks of cognitive overload, we refined the system into an updated concept. This system integrates role-specific, interconnected digital tools—TeamScreen, Guiding Pad (a tablet app), and augmented reality (AR) headsets [21]—to standardize care, reduce variability, and enhance CPR quality [22]. TeamScreen provides real-time resuscitation oversight, with shared access to drug and shock dose calculations and PALS workflows to support the entire team [20]. Developed iteratively with multidisciplinary input from 2 pediatric emergency departments, it addresses prior shortcomings and aligns with calls for innovative resuscitation aids [16].

The design and evaluation of InterFACE-AR followed human factors and usability engineering recommendations for high-risk medical technologies. Regulatory guidance from the US Food and Drug Administration on applying human factors and usability engineering to medical devices emphasizes structured processes, identifying critical tasks, conducting formative evaluations, and performing summative usability testing to minimize use-related risks [23]. Usability research in health information technology further supports the use of task-based testing and think-aloud methods as core, user-centered approaches to uncover interaction problems in complex interfaces [24,25]. In this context, this study focuses specifically on evaluating the usability of the updated TeamScreen interface during a simulated pediatric IHCA scenario, as an essential step before broader assessments of its impact on team performance and clinical outcomes.

XSL•FO
RenderX

Figure 1. Components of Interconnected and Focused Mobile Applications on Patient Care Environment–augmented reality (InterFACE-AR). The system integrates multiple digital tools to support pediatric resuscitation teams. The Guiding Pad (tablet), used by the charting nurse, captures patient data and completed tasks, distributing real-time information to role-specific interfaces. The TeamScreen (web-based app displayed on a large screen) provides a centralized overview of the resuscitation algorithm, patient data, and team tasks for the entire resuscitation team. Augmented reality (AR) headsets (HoloLens 2) deliver targeted, real-time guidance to the physician leader (for physician-led tasks) and the medication nurse (for medication preparation and administration).

Objective

This study aimed to evaluate the usability of the TeamScreen app in supporting resuscitation teams during pediatric IHCA management. By assessing the prototype's strengths and limitations, we sought to identify potential usability challenges and propose targeted improvements. The insights gathered were intended to inform the refinement of TeamScreen ahead of its full-scale clinical deployment and to contribute to the broader development of digital tools aimed at enhancing team performance and adherence to resuscitation guidelines.

Methods

Study Design

The usability of the TeamScreen app was assessed through a scenario-based information retrieval evaluation, combining both quantitative and qualitative methods. Multitask quantitative and qualitative usability metrics were used and are described in detail in subsequent sections. Usability was defined, according to ISO 9241‐210, as "the extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency, and satisfaction in a specified context of use" [26]. The usability of a digital tool can be assessed by how effectively and completely users are able to perform key tasks aligned with its core functionalities. In contrast, poor usability often results in reduced task efficiency, incomplete goal achievement, or even abandonment of the technology [27]. Effectiveness was measured by task completion rates. Efficiency was evaluated through time-on-task metrics. User satisfaction was assessed using the Post-Study System Usability Questionnaire (PSSUQ) version 3 [28] and a custom posttest evaluation questionnaire. In addition, think-aloud discussions were recorded verbatim and analyzed to extract key user insights and perceptions throughout the sessions.

TeamScreen App Overview: A Core Component of InterFACE-AR

TeamScreen is a web-based app designed to centralize and display, in real time, critical information related to the patient's condition and resuscitation progress to support adherence to PALS algorithms during CPR. Displayed on a 75-inch wall-mounted screen in the resuscitation room, it provides resuscitation teams with a clear, shared overview of clinical status and required actions, aligned with PALS algorithms. This dynamic interface offers a visual overview of key data such as patient information (eg, weight, pulse presence, cardiac rhythm, and ventilation status), intervention timelines, upcoming clinical tasks, and medication dosing details without requiring direct user interaction. Instead, it relies on input from the charting nurse via the Guiding Pad, a tablet app that dynamically records interventions tailored to the patient's status. TeamScreen is part of the broader InterFACE-AR suite [22], named for its AR foundation, which also includes AR headsets (HoloLens 2, Microsoft Corp), worn by the team leader and medication nurse [21]. These deliver role-specific guidance via mixed reality, an

XSL•FO
RenderX

advanced form of AR that—unlike standard overlays—enables interactive 3D holograms anchored in the environment [29], to support clinical decision-making and medication preparation. The usability testing approach mirrored this role distribution, reflecting real-world dynamics where the Guiding Pad feeds data to TeamScreen for team-wide visibility. These tools collectively aim to improve situational awareness, communication, and adherence to PALS guidelines during IHCA, ensuring more efficient and guideline-compliant interventions. The TeamScreen prototype used in this study replicated all core functionalities of the current InterFACE-AR TeamScreen module, including the algorithm flow, task lists, timers, and weight-based drug and shock displays, but it was operated as a stand-alone simulated interface that was not technically connected to the AR headsets or live clinical systems. The Guiding Pad and AR headset components will be described and evaluated in separate studies.

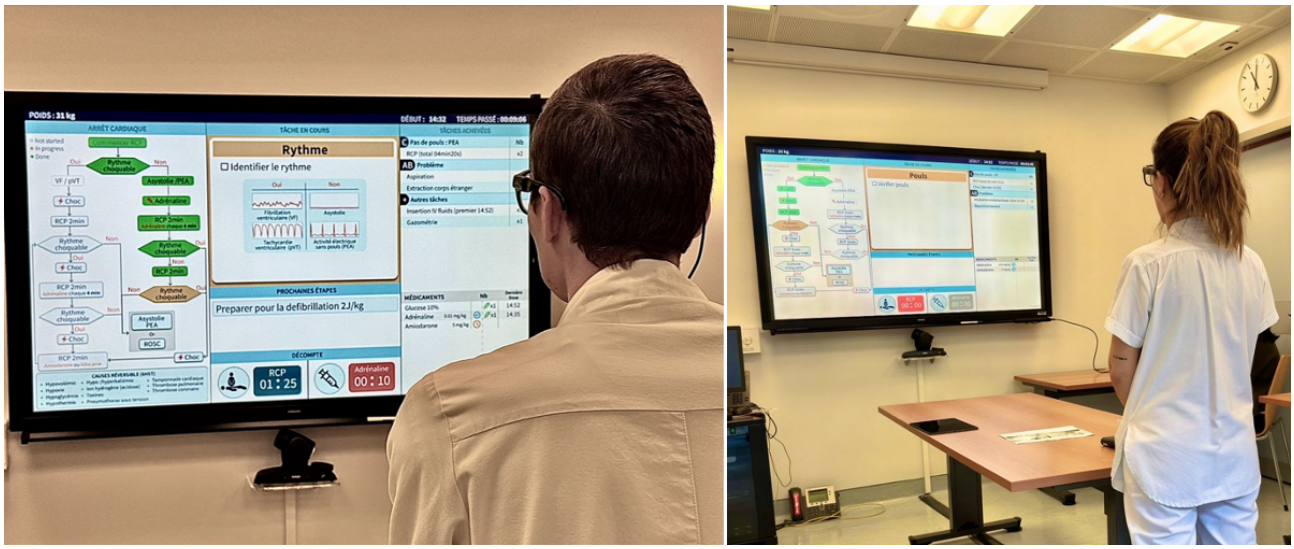
Participants and Setting

Inclusion Criteria and Recruitment

The inclusion criteria comprised physicians and nurses working in the Pediatric Emergency Department of the Geneva University Hospitals in Switzerland; fluent in French at a C1 level; and with prior experience in pediatric resuscitation, gained through real clinical practice, simulation training, or both. Individuals involved in the development of the InterFACE project were excluded from the study to avoid bias.

Sample size was established at 20 participants. This number is consistent with established guidelines for usability testing in high-risk, domain-specific systems, where 15 to 20 participants are generally considered sufficient to identify the majority of critical usability issues. This recommendation is supported by prior work in the field, particularly in the context of summative evaluations of medical technologies [30]. The evaluation framework focused on interactions between the user, the task, and the system, intentionally excluding the user's actual clinical environment from the assessment [31]. Recruitment was carried out by 2 senior attending physicians in pediatric emergency medicine (SM and JNS).

Ethical Considerations



The study received ethical approval from the Geneva Cantonal Research Ethics Committee (reference Req-2023 - 00162). All participants received an information sheet detailing the study's objectives and provided written informed consent before participating. Participants could opt out at any time without providing a reason and without any consequences. Participants received no compensation for their participation. All data were anonymized to ensure confidentiality. Explicit consent was obtained from participants to use their image for publication.

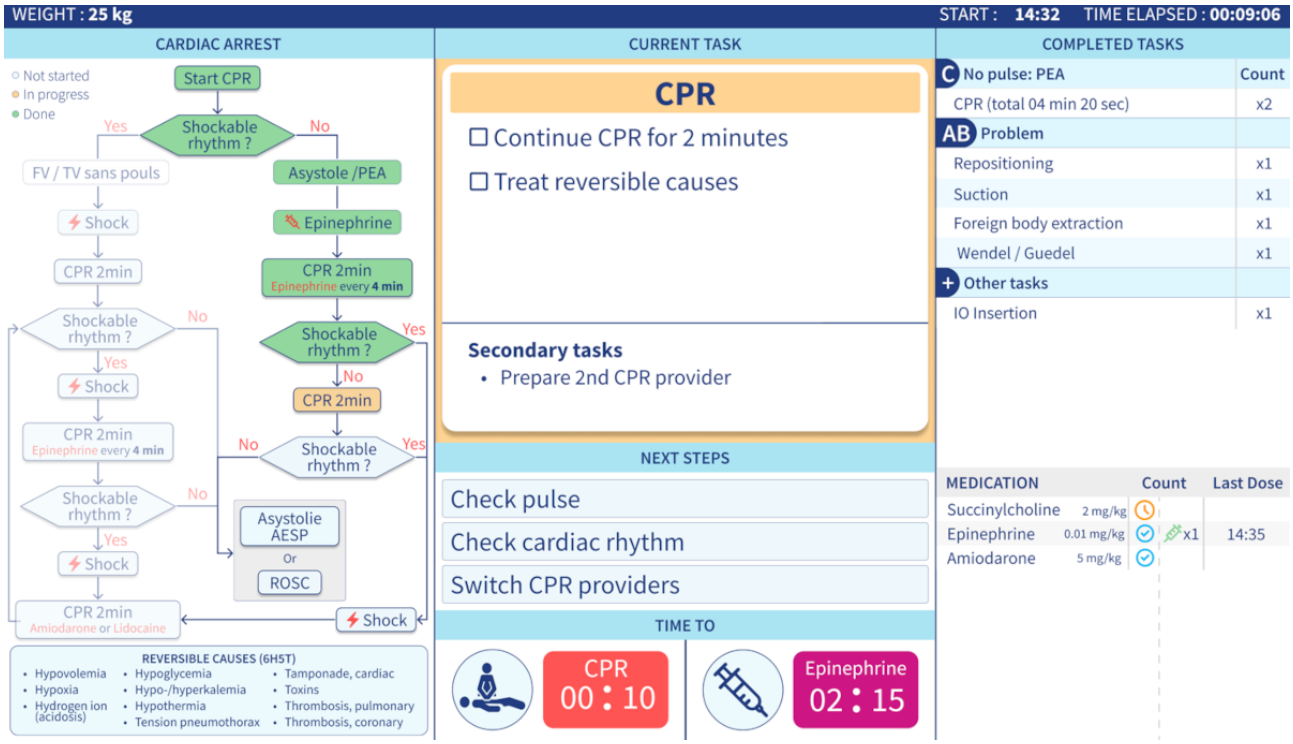
Test Setting

The usability evaluation was conducted in a conference room, equipped with a prototype of the TeamScreen system displayed on a 75-inch wall-mounted Samsung Neo QLED screen (model QE75QN90). This standardized setup was designed to simulate real clinical environment and enable technical data collection. Participants stood 2.7 meters from the screen, with a table placed in front of it to simulate a resuscitation bed (Figure 2). This conference room layout (screen position, distance, and table simulating the resuscitation bed) was chosen to approximate a pediatric emergency department resuscitation bay, with the TeamScreen acting as the central "wall monitor" around which the simulated scenario unfolded. Testing sessions were conducted by 3 examiners (ADM, SO, and AR), each responsible for different aspects of the evaluation. SO operated the Guiding Pad connected to the TeamScreen and acted as the charting nurse, simulating real-time input of clinical actions to drive the system forward in alignment with the usability tasks presented to participants. AR facilitated the sessions, administered instructions, and guided the participants through the PALS algorithm, questionnaires, and posttest survey. All verbal responses and think-aloud reflections were recorded using lapel microphones. Data collection tools included a demographic questionnaire, the PSSUQ version 3, and a custom posttest survey, all administered digitally via Microsoft Forms, with responses stored in real time.

XSL•FO
RenderX

Figure 2. Usability test setting with TeamScreen. Two health care professionals interact with TeamScreen, displayed on a 75-inch wall-mounted screen, during the usability testing session. The participants stand at a standardized distance while engaging in scenario-based tasks to assess system usability. The interface provides real-time guidance on pediatric advanced life support resuscitation algorithms. The test environment simulates a clinical setting, with technical equipment used for data collection and analysis.

Test Procedure



Procedure

Each session involved the same screen-based simulated pediatric resuscitation scenario, featuring a child aged 8 years (25 kg) who had sustained an electrification injury and subsequently developed a witnessed IHCA in an emergency department resuscitation bay. The initial rhythm was ventricular fibrillation/pulseless ventricular tachycardia, and the scenario was structured to follow the typical progression of a case of shockable IHCA requiring high-quality CPR, repeated rhythm checks, defibrillation, and drug administration. No manikin was used, and participants were not required to perform physical life-saving interventions; the focus was exclusively on interacting with the TeamScreen. Using TeamScreen as the shared "wall display" for the resuscitation, participants were required to complete a series of information retrieval tasks, covering key aspects of CPR resuscitation such as pulse assessment (no pulse), defibrillation, medication management (epinephrine, amiodarone, and succinylcholine as an intubation drug option), and cardiac rhythm identification (ventricular fibrillation/pulseless ventricular tachycardia). The scenario included several critical steps that had to be completed before return of spontaneous circulation (ROSC) could be achieved, such as recognizing the absence of a pulse, initiating chest compressions, performing defibrillation, and delivering the appropriate medications at the correct timing. The objective was to evaluate participants' ability to locate and interpret critical information displayed on the TeamScreen interface without prior training. The usability testing followed a standardized protocol:

1. Participant onboarding: upon arrival, participants were provided with an information sheet, and they signed an informed consent form. The study's purpose and procedure were explained, after which the participants completed a demographic questionnaire assessing their experience and expertise in pediatric resuscitation.
2. Equipment setup: participants were fitted with Tobii Pro Glasses 3 (Tobii AB) for eye-tracking analysis, and lapel microphones were used to record verbal feedback throughout the session.
3. Familiarization: clinicians who had been involved in the conception or technical development of the InterFACE-AR system were excluded. The remaining participants had not previously used the TeamScreen prototype and were exposed to it only through a short, standardized briefing immediately before the usability session. They were briefly presented with a static TeamScreen prototype (Figure 3) via FIGMA (Figma Inc) and asked to describe their observations. This phase served to ease their interaction with the interface before engaging in task execution.
4. Scenario execution and task completion: participants proceeded with the simulated IHCA scenario, performing 21 sequential information retrieval tasks (Table 1) using the think-aloud method [32]. Each task corresponded to a TeamScreen display, with additional information progressively introduced as the session advanced. These tasks were designed to assess comprehension and eye navigation on the interface. Participants were asked to verbalize their thought processes while retrieving information, guided by 1 examiner (AR), who intervened only if a participant struggled to reach a final answer. Task success, completion time, and time required for task presentation were recorded.
5. Posttest debriefing: upon completion, participants filled out the PSSUQ version 3; the responses were used to assess their satisfaction with TeamScreen. A semistructured interview was conducted to gather qualitative feedback regarding usability, strengths, and areas for improvement.
6. Closing and follow-up: participants were thanked for their time, informed about the next steps of the project, and invited to share any additional comments or suggestions.

XSL•FO
RenderX

Figure 3. TeamScreen prototype display during a simulated pediatric in-hospital cardiac arrest, showing the cardiopulmonary resuscitation (CPR) algorithm (left) and the current and upcoming tasks (center), with timer boxes for CPR cycles and epinephrine administration displayed at the bottom. The right-hand panel displays completed tasks and the medication list with weight-based dosing. Succinylcholine is included as one of several selectable intubation drugs to test navigation and selection within the interface and should not be interpreted as a recommendation for its use during ongoing cardiac arrest.

Scenario and Tasks

The IHCA scenario was standardized and tailored to each participant's professional role. Pediatric emergency physicians were assigned the role of team leader, and nurses were assigned the role of medication nurse. The scenario was co-developed by 2 pediatric emergency physicians (SM and JNS) and designed in parallel with 21 information retrieval tasks (Table 1) predefined by 3 examiners (ADM, SO, and AR), ensuring alignment between task execution and the corresponding TeamScreen displays.

Within the broader InterFACE-AR concept, the complete system is intended to provide individualized, role-specific decision support to the team leader and medication nurse through optically see-through AR headsets and to display a dynamic road map for patient care on TeamScreen, both components being coordinated via the Guiding Pad tablet app. This human factors study focuses solely on the usability of the TeamScreen app across a series of information retrieval tasks (Table 1). In the full system, weight-based medication doses are automatically calculated from the patient's weight and displayed as final numeric values on the AR headset of the medication nurse. In this TeamScreen-only prototype, dose-related panels (eg, tasks 8 and 16) primarily served to test whether participants could correctly locate where this information could be accessed rather than to verify the arithmetic itself. Similarly, the medication menu including succinylcholine (step 19) among other intubation drugs was configured to assess navigation and selection within the interface rather than as a recommendation for succinylcholine use during IHCA. An updated TeamScreen view reflecting the current implementation is provided in Multimedia Appendix 1.

Participants individually performed the 21 information retrieval tasks while progressing through a scripted walk-through simulated pediatric IHCA scenario, with clinical information and TeamScreen prototype screens presented in a structured, stepwise fashion. Each of the 20 participants completed the full scenario once, resulting in 20 standardized runs of the case.

XSL•FO
RenderX

Table . List of information retrieval tasks.

No.	Task name	Information retrieval task	Expected answer
1	Define weight I	Locate the weight entry area	Locate the weight entry area; no weight displayed[a]
2	Pulse check	Does the patient have a pulse?	Not indicated; it is in progress
3	Resuscitation time	How long has the resuscitation been going on?	15 s
4	Define weight II	What is the patient's weight?	25 kg
5	CPR[b] status	What is the status of CPR?	CPR has started; CPR was done once; CPR was performed for 10 s
6	Cardiac rhythm	What is the cardiac rhythm?	VF[c]; VF/pVT[d]
7	Shocks given	How many shocks were delivered?	1 (algorithm or completed tasks)
8	Medication status I	Can any medication be administered?	Yes (epinephrine)
9	CPR time	How much CPR time is left to do?	1 min
10	Secondary tasks	Which secondary task is proposed?	Prepare the second person for CPR
11	Next step	What is the next step?	Check the pulse; identify the cardiac rhythm; switch the CPR provider
12	A/B[e] problem assessment	Which tasks have been carried out to resolve the A/B problems?	ETT[f] intubation and repositioning
13	Intubation time	At what time did the intubation take place?	HH:MM[g]
14	Tasks in progress	Which tasks need to be done now?	Resume CPR for 2 min; administer epinephrine 0.01 mg/kg (0.1 mL/kg)
15	Shock time	At what time was the shock delivered?	HH:MM
16	Medication status II	Which medication was administered?	Epinephrine
17	Epinephrine time	How long until epinephrine must be administered again?	3 min 25 s
18	"Other tasks" section status	A team member placed an intraosseous line. Where is this information displayed?	Under "Completed Tasks"/"Other tasks"
19	Medication status	Which medication is being prepared?	Succinylcholine
20	Reversible causes	In the "Tasks in progress" area, the message "Treat the reversible causes" appeared. Where can you find help to recall the list of reversible causes?	Below the algorithm
21	Patient status: general understanding	What is the patient's current condition?	No longer in cardiac arrest; moved to ROSC[h]; ABCDE[i] assessment

[a]Success was defined as correctly identifying the relevant interface element rather than as giving a numeric answer.

[b]CPR: cardiopulmonary resuscitation.

[c]VF: ventricular fibrillation.

[d]pVT: pulseless ventricular tachycardia.

[e]A/B: airway and breathing.

[f]ETT: endotracheal tube.

[g]HH:MM: hours and minutes.

[h]ROSC: return of spontaneous circulation.

[i]ABCDE: airway, breathing, circulation, disability, exposure.

XSL•FO
RenderX

Outcome Measures

Quantitative Data

Performance Metrics

Participant performance was evaluated using 2 key efficiency metrics:

- Task success rate: tasks were classified as successful if the participant provided the expected answer (Table 1), either immediately or after a correction, as long as the final response was correct. Incorrect or incomplete responses were categorized as task failures.
- Time on task: This metric measured the average time (in seconds) taken to complete each task, starting from the end of the examiner's instructions until the participant provided a final answer (Table 1). Since participants had no prior training with TeamScreen, response time was not used as a determinant of task success.

User Satisfaction

User satisfaction was measured after completion of the tasks using the PSSUQ version 3 [28], a 16-item instrument rated on a 7-point Likert scale (Multimedia Appendix 2), rated from 1 ("strongly agree") to 7 ("strongly disagree"), in addition to a "not applicable" (N/A) option. Items 7 and 8, related to error messages and error recovery, were not applicable in this study because the TeamScreen prototype did not implement system error messaging or recovery workflows. These items were therefore marked "not applicable" and omitted from score calculations, in accordance with published PSSUQ scoring guidance [28,33], with overall scores computed as the mean of the remaining answered items.

The PSSUQ yields an overall usability score and scores on 3 subscales—system usefulness (items 1 - 6), information quality (items 7 - 12), and interface quality (items 13 - 15)—with lower scores indicating greater satisfaction in each category. Based on 21 studies including 210 participants, the benchmark means reported by Lewis [34] provided the reference values for interpreting the PSSUQ scores: overall 2.82, system usefulness 2.80, information quality 3.02, and interface quality 2.49. This comparison with published benchmark values was purely descriptive. No inferential statistical testing was performed against these reference data. Better performance and satisfaction are reflected in lower PSSUQ scores (closer to 1).

Qualitative Data

Error Analysis

All usability challenges encountered during task completion were systematically recorded and categorized using ergonomic criteria for human-computer interface evaluation [35]. Each usability issue was assigned a severity rating based on Nielsen Norman Group's rating scale [36], assessing its impact on user performance and experience. Severity level 3 indicates a major usability problem that significantly hinders task execution, forcing users to find alternative solutions and requiring urgent corrective action. A severity level 2 represents a minor usability issue that may cause frustration but does not prevent task completion, warranting moderate priority for resolution. A severity level 1 is considered a cosmetic issue, affecting only aesthetics, with no impact on usability, requiring resolution only if time allows. Finally, a severity level of 0 is considered as not usability related. Findings from the severity assessment informed targeted design refinements for TeamScreen's next iteration. The identified issues were addressed in a recently conducted multicenter simulation study, for which a manuscript is currently in preparation.

Think-Aloud Verbal Feedback

During testing, participants were encouraged to verbalize their thought processes while interacting with TeamScreen. These verbal reflections were analyzed to identify usability issues, inform content and design refinements, and improve system design for better real-world applicability.

Posttest Survey Feedback

To complement quantitative findings, qualitative feedback was collected via a standardized set of posttest interview questions (Table 2), ensuring consistency in data collection.

Responses provided a holistic understanding of user experience. Findings were systematically analyzed to refine TeamScreen's interface and functionality, ensuring alignment with user expectations and clinical workflows.

XSL•FO
RenderX

Table . Posttest survey.

Question	Type of question	Choice provided
Display understanding		
1. What is your overall impression of the display?	Open-ended question	—[a]
2. What did you find easy to understand in this display?	Open-ended question	—
3. What did you find difficult to understand in this display?	Open-ended question	—
4. What do you think of the readability of the information (eg, font size, colors, etc)?	Open-ended question	—
5. If you had to rearrange the entire TeamScreen display, what ideas or suggestions for improvement would you propose?	Open-ended question	—
Completed tasks		
6. What difficulties did you encounter while using the display, and why?	Open-ended question	—
7. What aspects of the display helped you complete the tasks (information retrieval)?	Open-ended question	—
8. What aspects of the display hindered you from completing the tasks (information retrieval)?	Open-ended question	—
Display preferences		
9. What do you think of the distribution of information in the “Algorithm” section?	Open-ended question	—
10. What do you think of the distribution of information in the “Current Task” section?	Open-ended question	—
11. To what extent did you find the display of secondary tasks helpful regarding patient status?	Likert-scale question	• Very useful • Useful • Neutral • Somewhat useful • Not useful at all
12. What do you think of the distribution of information in the “Next Steps” section?	Open-ended question	—
12a. How many “next steps” would you ideally want to see? One, two, three, or more?	Single-choice question	• One step • Two steps • Three steps • Other: _____
13. What do you think of the distribution of information in the “Countdown” section?	Open-ended question	—
14. What do you think of the distribution of information in the “Completed Tasks” section?	Open-ended question	—
15. What do you think of the distribution of information in the “Medications” section?	Open-ended question	—
15a. What do you think these three icons represent in the “Medications” section?	Closed-ended question	—

[a]Not applicable.

Data Collection and Analysis

Data Collection and Confidentiality

To ensure data confidentiality, all collected materials, including recordings, online questionnaires, and consent documents, were coded. Recordings captured only participants’ screen view, eye movements, and voice, ensuring privacy. When verbatim quotes were used in qualitative data analysis or reporting, only the assigned identifier was displayed. Each usability testing session was video- and audio-recorded for retrospective analysis of TeamScreen’s usability. Two researchers (SO and ADM) independently reviewed task success rates and completion times.

XSL•FO
RenderX

All PSSUQ scores were collected immediately after each test session and transcribed into Microsoft Excel spreadsheets for analysis. Half of the video recordings were independently assessed by SO and ADM to validate task success rates and completion times. Quantitative data collected during task execution underwent statistical analysis, and results were anonymized for reporting (see the *Results* section). During data collection and analysis, only 3 researchers (AR, SO, and ADM) had access to the audio and video recordings.

Data Analysis

Descriptive statistics were used to summarize continuous variables, including task success rates, time-on-task metrics, and PSSUQ scores. Frequency counts and percentages were used to analyze categorical variables, such as the types of usability errors. Additionally, a correlation analysis of task failure rates was performed to explore potential dependencies between tasks, indicating whether tasks shared common cognitive demands or interface elements. Quantitative data, including task durations and success rates, were analyzed using the *pandas* library in Python (version 3.12; Python Software Foundation) to identify trends and compute averages. Verbal feedback from the think-aloud sessions was audio-recorded, transcribed verbatim, and analyzed using a structured content analysis approach. Two researchers (AR and SO) independently reviewed the transcripts, segmented them into meaning units corresponding to distinct interface problems, and coded each unit using Bastien and Scapin's [35] ergonomic criteria for human-computer interaction (guidance, workload, explicit Ccntrol, adaptability, error management, consistency, significance of codes, and compatibility). These criteria were chosen because they provide a well-established, task-oriented framework for classifying usability issues in interactive systems [37] and have been widely used in the evaluation of medical and health information technology interfaces [26,38]. Coded segments were then compared between both researchers. Discrepancies were resolved through discussion, and similar issues were grouped into overarching usability problems, which were mapped to specific interface sections (header, algorithm, completed tasks, medications). For each distinct usability issue, we calculated its frequency (number of participants who mentioned it) and assigned a severity rating using Nielsen Norman Group's rating scale ranging from 0 to 4 (0=none, 4=catastrophic). Graphical representations were generated using *matplotlib*, an open-source Python library [39].

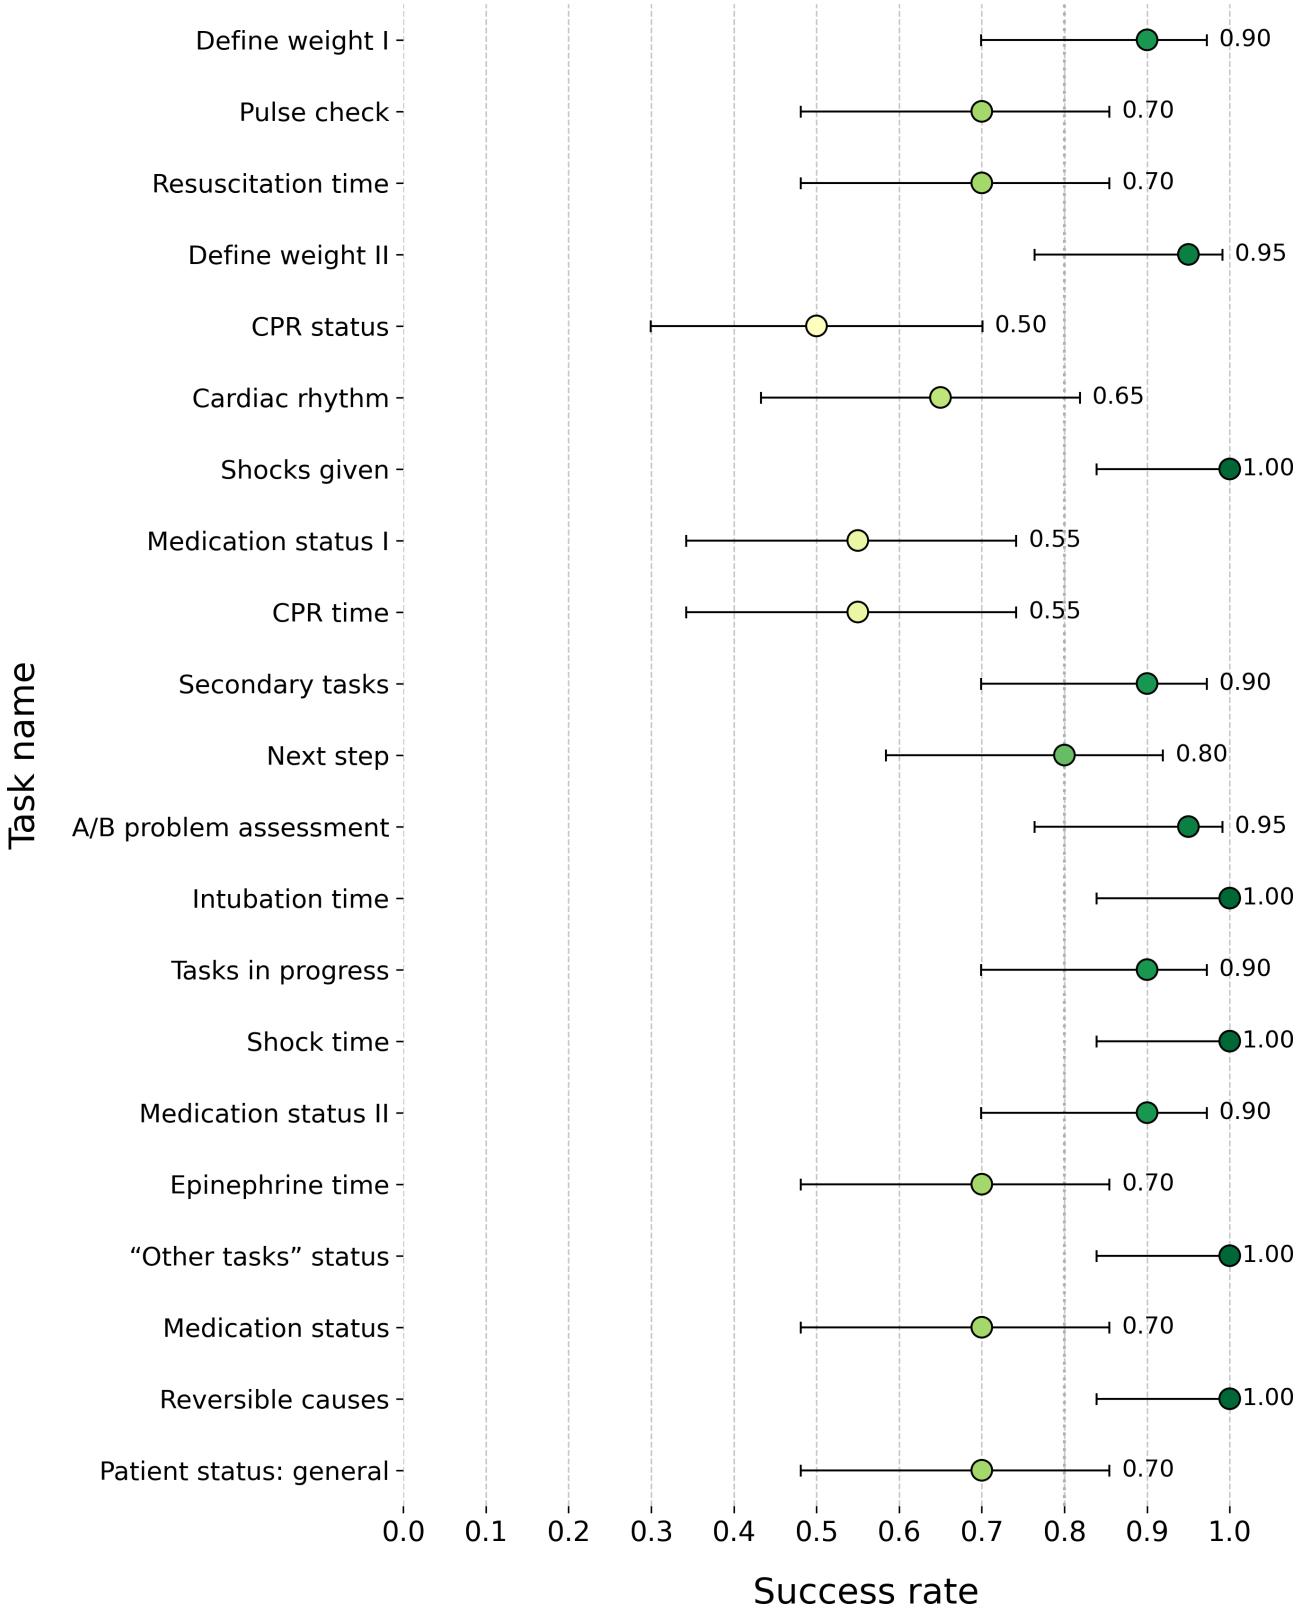
Results

Participant Characteristics

The usability tests were conducted in mid-September 2024. A total of 20 health care professionals participated in the study, of which 14 (70%) were women. The sample included 15 nurses (75%) and 5 physicians (25%). Of the 20 participants, 10 (50%) had completed PALS certification, including 3 of 5 physicians (60%) and 7 of 15 nurses (46.67%). Notably, 8 of 15 nurses (53.33%) had no PALS certification. The participants had a median experience of 6.00 (IQR 2.00-11.75) years in pediatric emergency care. All had prior exposure to real pediatric resuscitations, with the number of cases ranging from 2 to 100 and 30 cases being the most frequently reported value. Similarly, all had experience with simulated resuscitations, with the reported number of cases ranging widely, most commonly around 20 simulations.

Participants' self-reported familiarity with digital devices varied: of 20 participants, 10 (50%) described themselves as "comfortable" using tablets and smartphones, whereas 6 (30%) reported being "very comfortable." The remaining participants were either "neutral" (3/20, 15%) or "slightly uncomfortable" (1/20, 5%) with digital tools.

Usability Evaluation



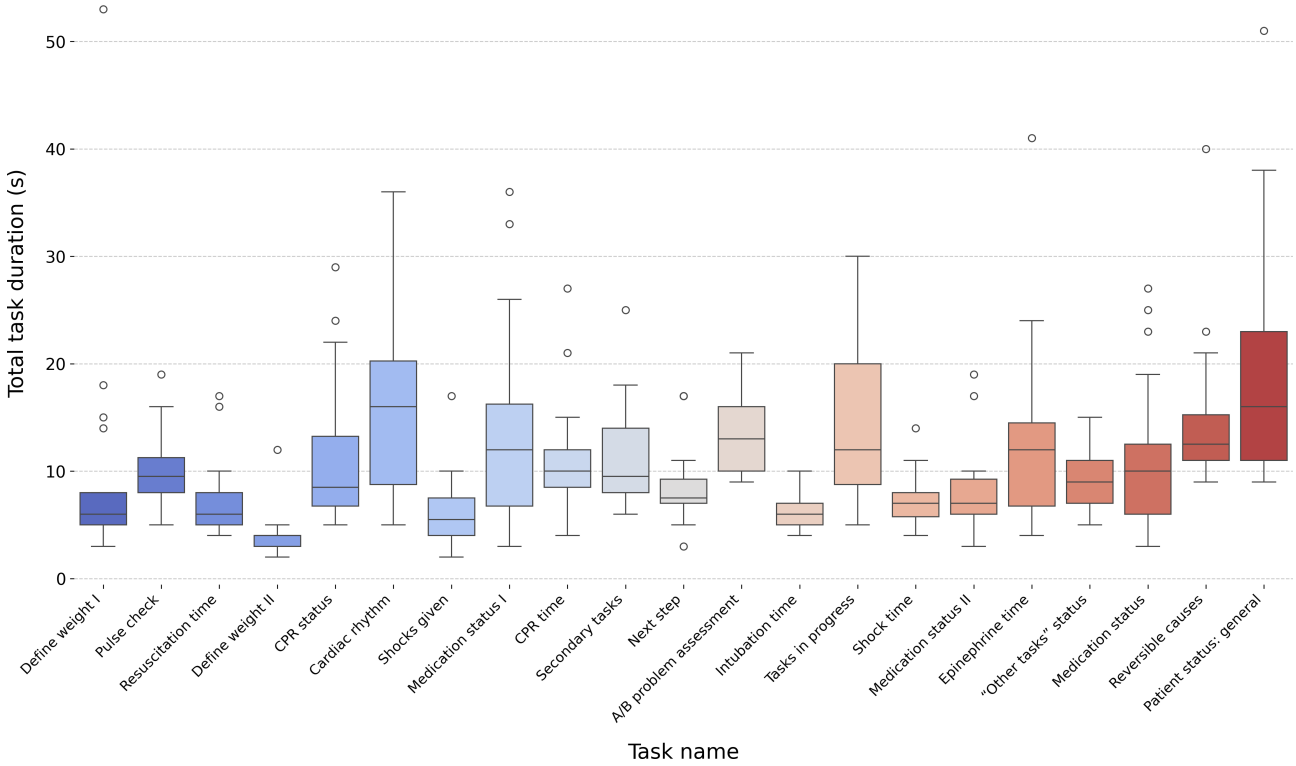
Quantitative Evaluation

Task Success Rate

Task success rates varied significantly across the usability assessment (χ^2_{20}=74.59, *P*<.001; Figure 4), ranging from 50% to 100%, with an overall success rate of 81.19% (SD 16.87%). Highest success rates (100%) were achieved for tasks 7 (*Shocks given*), 13 (*Intubation time*), 15 (*Shock time*), 18 (*"Other tasks" section status*), and 20 (*Reversible causes*), indicating that they were consistently completed without errors. The lowest success rates were achieved for task 5 (*CPR status*; 50%), followed by tasks 8 and 9 (55% each), suggesting that these tasks were more cognitively demanding or required greater user adaptation.

XSL•FO
RenderX

Figure 4. Mean (95% CI) success rate by information retrieval task. The color gradient indicates the task success rate, ranging from light yellow (lower success rates) to dark green (higher success rates). A/B, airway and breathing; CPR: cardiopulmonary resuscitation.

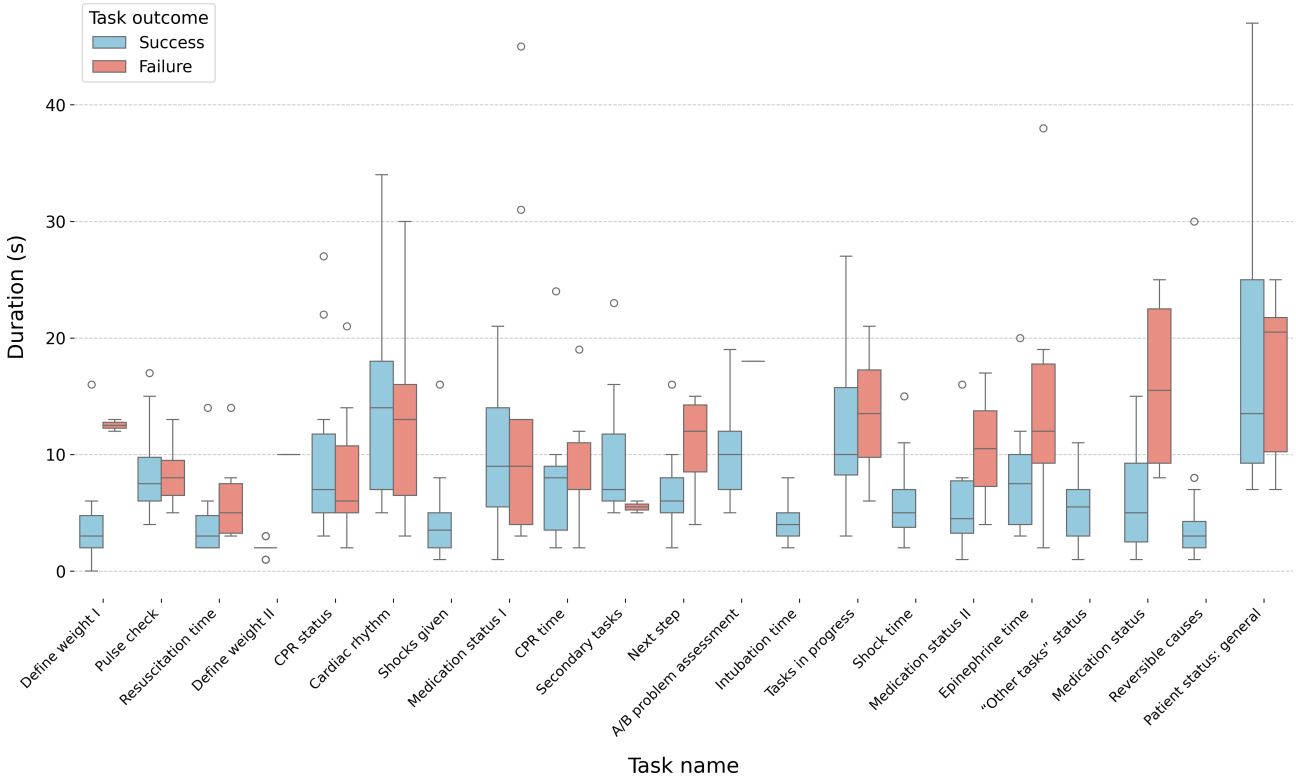


Time on Task

Task completion times varied significantly (Kruskal-Wallis H_{20}=154.99, P<.001; Figure 5), reflecting differences in task complexity. On average, participants spent 170.80 (SD 44.70) seconds completing all 21 tasks, corresponding to a mean completion time of 8.13 (SD 7.07) seconds per task across all participants. Task 21 (*Patient status: general understanding*) required the longest duration, with an average completion time of 18.45 (SD 12.19) seconds, whereas task 4 (*Define weight II*) was completed the fastest, averaging 2.35 (SD 1.90) seconds.

XSL•FO
RenderX

Figure 5. Box plot illustrating the distribution of task completion times across all 21 tasks performed during the usability study. Each box represents the IQR, with the median completion time indicated by the horizontal line inside the box. Whiskers extend to 1.5 times the IQR, and outliers are displayed as individual circles. Task 21 (Patient status: general understanding) exhibited the longest mean duration, suggesting higher complexity or additional steps required for completion, while task 4 (Define weight II) had the shortest duration, indicating a simpler information retrieval process. A/B: airway and breathing; CPR: cardiopulmonary resuscitation.

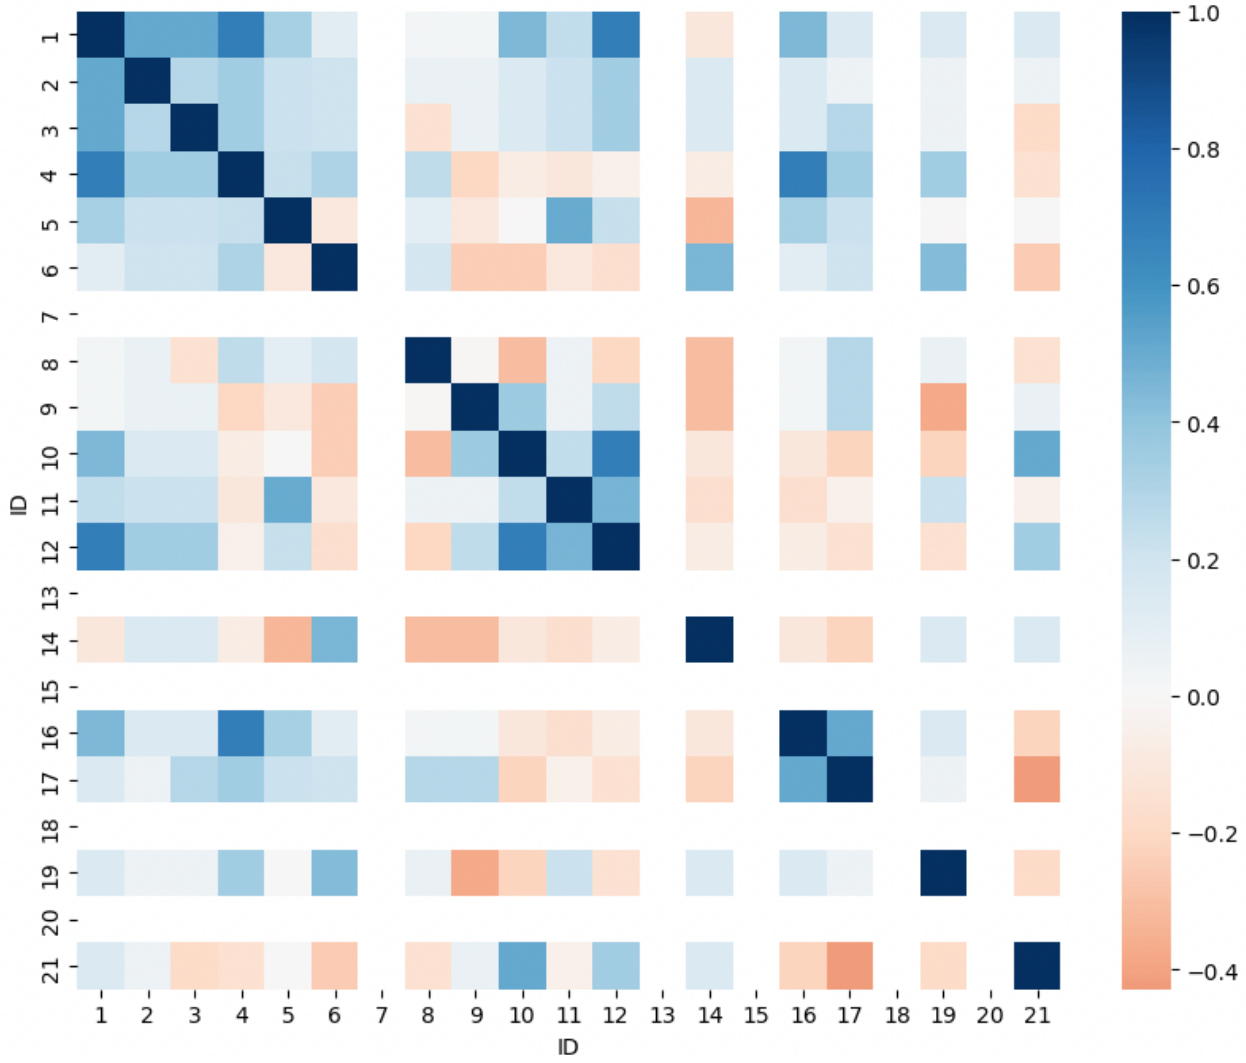


Average Task Duration by Success Versus Failure

Analysis of task completion times based on success or failure revealed a notable trend (Figure 6). In most cases, failed attempts were associated with significantly longer durations, suggesting that unsuccessful users required multiple attempts or encountered execution challenges. For example, in task 1 (*Define weight I*), failed attempts averaged 12.50 (SD 0.71) seconds, whereas successful attempts took only 3.78 (SD 3.42) seconds (P=.048), highlighting the impact of task difficulty on completion time. However, in task 5 (*CPR status*), the completion times for successful attempts (mean 10.00, SD 8.25 seconds) and failed attempts (mean 8.30, SD 5.81 seconds) were nearly identical (P=.73), indicating that participants invested consistent effort regardless of outcome.

XSL•FO
RenderX

Figure 6. Box plot comparing task completion times between successful (blue) and failed (red) attempts across all 21 tasks. Each box represents the IQR, with the median duration indicated by the horizontal line. Whiskers extend to 1.5 times the IQR, and outliers are shown as individual circles. Overall, failed attempts generally took longer to complete, indicating challenges in task execution or repeated attempts (eg, task 1 [*Define weight I*]: failures averaged 12.5 s vs 3.77 s for successful attempts). However, for task 5 (*CPR status*), success and failure durations were nearly identical, suggesting that participants required similar effort regardless of the outcome. A/B: airway and breathing; CPR: cardiopulmonary resuscitation.



Correlation of Failure Rates Among Tasks

A correlation analysis of failure rates across tasks revealed potential dependencies, indicating that certain tasks share underlying cognitive demands or interface elements (Figure 7). Tasks with similar failure rates suggest common user difficulties, likely due to overlapping knowledge requirements or proximity within the interface. Several tasks exhibited strong positive correlations, suggesting that errors in one task were predictive of errors in another. For example, tasks 1 (*Define weight I*) and 4 (*Define weight II*) were highly correlated with tasks 12 (*A/B problem assessment*) and 16 (*Medication status II*) (Pearson correlation of per-participant binary success: r=0.69, P<.001), as all of these required users to track updated patient data, such as weight changes, completed airway and breathing interventions, and medication details. Likewise, task 4 (*Define weight II*) and task 16 (*Medication status II*) showed a strong correlation (r=0.69, P<.001), likely reflecting the dependency between understanding the patient's weight and correctly administering weight-based medication. Task 10 (*Secondary tasks*) was significantly correlated with task 12 (*A/B problem assessment*; r=0.69, P<.001), suggesting that both tasks relied on the ability to monitor procedure logs or timeline view. Finally, tasks 16 (*Medication status II*) and 17 (*Epinephrine time*) exhibited a strong correlation (r=0.51, P=.02), as both involved understanding epinephrine administration; participants who struggled with one were likely to struggle with the other, highlighting potential cognitive or interface-related dependencies. Overall, these suggest that shared interface elements or related data points contributed to error clustering, emphasizing the need for enhanced visual cues or streamlined navigation to support information retrieval across interdependent tasks.

XSL•FO
RenderX

Figure 7. Heat map visualizing the correlation of failure rates across 21 usability tasks. Darker blue regions indicate strong positive correlations. Conversely, light red areas represent negative correlations, where failure in one task was less predictive of failure in another.

Qualitative Evaluation

Frequent Errors

Analysis of task failures showed that task 5 (*CPR status*) had the highest failure frequency, accounting for 12.50% (10/80) of failed attempts. This was closely followed by tasks 8 (*Medication status I*) and 9 (*CPR time*) (9/80 each, 11.25%). Task 6 (*Cardiac rhythm*) accounted for 10% (8/80) of failures, and tasks 2, 3, 17, and 19 each accounted for 7.50% (6/80) of failures. These trends indicate that certain tasks posed consistent challenges across participants, potentially due to interface complexity, cognitive load, or unclear task presentation. Table 3 provides a detailed breakdown of failed task occurrences across the 21 tasks, considering 80 total opportunities across all tasks.

XSL•FO
RenderX

Table . Task failure frequency (N[a]=80).

Task number	Content	Failure frequency, n[b] (%)
5	What is the status of CPR[c]?	10 (12.50)
8	Can any medication be administered?	9 (11.25)
9	How much CPR time is left to do?	9 (11.25)
6	What is the cardiac rhythm?	8 (10)
17	How long until epinephrine must be administered again?	6 (7.50)
2	Does the patient have a pulse?	6 (7.50)
19	Which medication is being prepared?	6 (7.50)
3	How long has the resuscitation been going on?	6 (7.50)
21	What is the patient's current condition?	5 (6.25)
11	What is the next step?	4 (5)
16	Which medication was administered?	3 (3.75)
14	Which tasks need to be done now?	2 (2.50)
1	What is the patient's weight?	2 (2.50)
10	Which secondary task is proposed to you?	2 (2.50)
12	Which tasks have been performed to address the A/B[d] problems?	1 (1.25)
4	What is the patient's weight?	1 (1.25)

[a]N: total number of opportunities.

[b]n: number of failed attempts.

[c]CPR: cardiopulmonary resuscitation.

[d]A/B: airway and breathing.

Encountered Usability Issues

A total of 16 usability issues were identified across different sections of the TeamScreen interface. These issues were analyzed using the heuristics of Bastien and Scapin [35] and classified by severity levels according to the Nielsen Norman Group's rating scale [36] (Table 4).

XSL•FO
RenderX

Table . Classification of usability issues identified by participants (N=20).

Usability issues (description and section)	Frequency, n	Bastien and Scapin's heuristics	Problem severity[a]
General issues			
Excessive information displayed: multiple panels (eg, algorithm, completed tasks, and medications) with many elements visible at once made it difficult to identify the most relevant information for the current resuscitation step (general screen layout).	10	*Workload*: brevity, information density	3
Confusing time notation of CPR[b] timer: the CPR timer label did not clearly indicate whether the value represents total arrest duration, current cycle length, or time since last intervention, leading to misinterpretation of the timer.	2	*Significance of codes*	2
Header section			
Location visibility of patient weight: patient weight was located in the upper banner but not visually highlighted; several participants reported difficulty locating it quickly when asked to verify the weight.	5	*Guidance*: legibility	2
Font size of patient weight: the font size of patient weight in the header was too small to be read comfortably from the standard viewing distance of 2.7 m.	3	*Guidance*: legibility	1
Lack of current time display: the current clock time was not displayed anywhere on TeamScreen, forcing users to rely on external clocks to track absolute time during the scenario.	1	*Adaptability*	2
Algorithm section			
Poor legend visibility: the legend explaining the algorithm and color codes was small, making it difficult for users to remember or quickly decode the meaning of icons or colors.	4	*Guidance*: legibility	2
Difficulty understanding transitions between algorithm branches: transitions between algorithm branches (for example, from shockable to nonshockable pathways or post-ROSC[c] care) caused uncertainty about which branch to follow next.	6	*Guidance*: prompting	3
Visibility of patient status: patient's current state (eg, "cardiac arrest") was not clearly highlighted near the active algorithm branch, which reduced situational awareness.	3	*Compatibility*	3

XSL•FO
RenderX

Usability issues (description and section)	Frequency, n	Bastien and Scapin's heuristics	Problem severity[a]
Font size of 6H5T[d] *text*: the text listing reversible causes (6H5T) was presented in a small font and dense format, which participants found hard to read and use during the scenario.	3	*Guidance*: legibility	1
Completed tasks section			
Overloaded with information: the list of completed tasks showed all previous actions with detailed timestamps, resulting in a visually dense list that was difficult to scan for the most recent or most important actions.	5	*Workload*: brevity, information density	3
Poor organization of task display in sections C[e]*, A/B*[f]	3	*Compatibility*	2
Insufficient separation between subsections	3	*Guidance*: legibility	2
Counterintuitive time notation	3	*Significance of codes*	2
Medications section			
Ambiguous icons: icons used to represent medication-related actions (ie, in preparation, ready to administer, and administered) were not self-explanatory without accompanying text labels, potentially leading to misinterpretation of their meaning.	15	*Significance of codes*	3
Missing calculated total doses/volumes: the medications panel did not display the final calculated total dose or volume for each drug, requiring users to mentally calculate weight-based dosage, which increased cognitive load and potential for dosing error.	5	*Compatibility*	2
Unclear listed medication doses	3	*Compatibility*	2

[a]Nielsen Norman severity score: 4=catastrophic, 3=major, 2= minor, 1=cosmetic, 0=none.

[b]CPR: cardiopulmonary resuscitation.

[c]ROSC: return of spontaneous circulation.

[d]6H5T: hypovolemia, hypoxia, hydrogen ion (acidosis), hypokalemia/hyperkalemia, hypoglycemia, hypothermia, tension pneumothorax, tamponade, toxins, thrombosis (pulmonary), thrombosis (coronary).

[e]C: circulation.

[f]A/B: airway and breathing.

The primary usability issues were general challenges rather than being confined to specific interface sections. These included cognitive overload due to excessive information displayed information; difficulty understanding task requirements, increasing mental workload; and medication-related confusion, particularly in interpreting drug administration icons. The most frequently reported issue was the lack of clarity in medication icons, making it difficult for participants to distinguish between medications in preparation, ready for administration, or already administered. Other issues, although present, were encountered by fewer than one-third of participants.

Overall, the study identified key usability challenges related to information visibility, navigation, and comprehension. The most critical usability issues (severity 3 - 4) included medication icon confusion (most frequently reported), excessive information density leading to cognitive overload.

User Satisfaction

PSSUQ Scores

Participants provided positive feedback on screen readability, with a mean PSSUQ score of 2.40 (SD 1.24) indicating high usability. However, they suggested improvements in information hierarchy and task simplification due to perceived cognitive

XSL•FO
RenderX

overload. Overall, PSSUQ scores were lower (better usability) than the PSSUQ version 3 benchmark (Table 5), confirming high system usefulness and interface quality.

Scores closer to 1 indicate higher usability. TeamScreen scores were descriptively lower than the published PSSUQ benchmark means, suggesting that participants found the system intuitive and effective, although information presentation still offers room for optimization.

Table . Comparison of TeamScreen PSSUQ[a] scores versus the PSSUQ version 3 (V3) benchmark.

	TeamScreen score, mean (SD)	PSSUQ V3 benchmark mean
Overall score	2.40 (1.24)	2.82
System usefulness (SysUse)	2.44 (1.22)	2.80
Information quality (InfoQual)	2.41 (1.20)	3.02
Interface quality (IntQual)	2.20 (1.41)	2.49

[a]PSSUQ: Post-Study System Usability Questionnaire.

Participant Verbal Feedback

Think-aloud verbalizations during task execution, combined with responses from the posttask debriefing survey, provided valuable contextual information that enriched the interpretation of the PSSUQ scores and offered deeper insights into users' experiences and expectations regarding the interface.

Overall, participants expressed mixed feelings about their experience with the TeamScreen interface. In terms of strengths, 8 of 20 (40%) participants highlighted the clarity and organization of the information, quality of the display, and good readability (in terms of font size and color). Several participants particularly appreciated the guidance provided through the algorithm section (12/20, 60%) and the associated color coding (8/20, 40%)—green indicating "finished" and orange indicating "in progress"—as well as the "Completed Tasks" section (9/20, 45%), which enhanced their situational awareness.

Regarding areas for improvement, 9 of 20 (45%) participants reported misunderstanding difficulties, particularly related to the middle section of the screen, not directly attributable to usability issues. Several users (10/20, 50%) reported that the amount of information presented was overwhelming, contributing to increased cognitive load. The "Current Task" area was also frequently overlooked, as 9 of 20 (45%) participants felt that the relevant information was already accessible within the algorithm panel on the left side of the screen, making it redundant. Furthermore, several users suggested making a clearer distinction between "Current Task" and "Next Steps" to better support cognitive processing under pressure. These insights emphasize the need for improvements in information hierarchy and cognitive load reduction in critical usage scenarios. Finally, participants indicated a need for greater clarity in the "Medication section" (5/20, 25%), specifically concerning the meaning of the 3 icons representing the medication status (in preparation, ready for administration, administered). However, it is important to acknowledge that many of these reported issues were, according to the participants, largely attributable to their lack of prior exposure to the app. Participants indicated that with appropriate training, the interface would become significantly more intuitive, enabling faster and more accurate information retrieval during real-time pediatric cardiac arrest scenarios, as well as more effective adherence to American Heart Association guidelines.

Modifications Based on Usability Findings

Following the usability analysis, several targeted refinements were implemented, each addressing a specific usability issue summarized in Table 4. First, limited visibility and ambiguous interpretation of the CPR timer led us to relocate the main timer to the top of the screen and clarify its label to ensure continuous and unambiguous visibility throughout the resuscitation process. Second, difficulties in reading and using the reversible causes (6H5T; hypovolemia, hypoxia, hydrogen ion [acidosis], hypokalemia/hyperkalemia, hypoglycemia, hypothermia, tension pneumothorax, tamponade, toxins, thrombosis [pulmonary], thrombosis [coronary]) prompted an increase in font size and a permanent display to provide immediate access to correction measures. Third, issues related to information overload and poor readability of the list of completed tasks motivated a restyling of the task list, replacing square markers with bullet points, and secondary tasks were repositioned higher in the interface to make them more noticeable and actionable. Fourth, in response to concerns that timers were easy to overlook as they approached zero, countdown timers were enhanced to blink when nearing expiry, drawing the team's attention and reducing the risk of delayed interventions. Finally, frequent misinterpretation of medication icons and confusion around drug administration stages led to the introduction of 3 distinct, clearly labeled icons indicating whether a drug was in preparation, prepared, or already administered. Collectively, these modifications aimed to alleviate information overload, improve navigation, and highlight essential cues in high - stress pediatric resuscitation scenarios.

Discussion

Key Findings

TeamScreen introduces a new generation of context-aware clinical displays aimed at reinforcing shared cognition and temporal coordination among resuscitation teams rather than replacing clinical judgment. This single-center, mixed methods study evaluating its usability during simulated IHCA management yielded several salient insights.

With an overall task success rate of 81%, most participants effectively located and interpreted essential clinical information under simulated urgency, despite challenges in early pediatric

XSL•FO
RenderX

IHCA response [40]. Tasks 7 (*Shocks given*), 13 (*Intubation time*), 15 (*Shock time*), 18 (*"Other tasks" section status*), and 20 (*Reversible causes*), covering shock delivery logs, intubation timestamps, and reversible‐causes guidance, achieved 100% success, suggesting that these interface elements were well designed and intuitive. Conversely, tasks 5 (*CPR status*), 8 (*Medication status I*), and 9 (*CPR time*) related to tracking ongoing CPR and upcoming interventions (eg, epinephrine administration) exhibited the highest failure rates. Participants who struggled with these tasks frequently cited uncertainty regarding the location of real-time information, highlighting a need for improved visual hierarchy in high-density interface areas, in line with cognitive load theory [41].

Task completion times demonstrated substantial variability across the 21 tasks, reflecting heterogeneity in task complexity and cognitive processing demands. Task 21 (*Patient status: general understanding*) exhibited the longest mean completion time, indicating that tasks involving a broader synthesis of patient information were more time-consuming. Conversely, task 4 (*Define weight II*) was completed most rapidly, suggesting minimal cognitive load and straightforward retrieval. This efficiency may also be attributed to task 4 representing the second occurrence of a previous task, that is, task 1 (*Define weight I*), whereby participants were already familiar with the location of the relevant information on the display.

Correlation analysis showed errors clustering around related data points, such as medication timing and dosage, underscoring the importance of consistent navigation cues and harmonized data presentation across the algorithm view, timeline, and "Completed Tasks" sections. This aligns with evidence that protocol adherence significantly improves IHCA outcomes [42], emphasizing TeamScreen's potential to enhance care quality through better design. The PSSUQ scores indicated high user satisfaction, with participants valuing TeamScreen's consolidation of vital parameters, current tasks, and next‐step recommendations into a central, readable display. These findings suggest that TeamScreen excels where clarity is prioritized (eg, timestamps and shock logs) but requires refinement in areas with visual clutter, icon ambiguity, or subtle task distinctions. Given varying roles in IHCA response where nurses often manage documentation and physicians lead decisions [43], future studies should explore whether task success or perceived usability differs across these groups.

Comparison With Literature

TeamScreen shares similarities with real-time dashboard systems aggregating patient vitals, medication records, and intervention timelines onto shared displays, as seen in prior work improving clinicians' access to critical data and reducing cognitive load [44]. However, unlike passive aggregators, TeamScreen integrates real-time visualization with interactive PALS-aligned algorithmic guidance, supporting both team situational awareness and decision-making during IHCA. This dual functionality addresses a gap in traditional dashboards, which often lack structured support for resuscitation guidelines. For instance, Siebert et al [45] demonstrated that AR glasses improved defibrillation dosing adherence compared to PALS pocket cards, although without broader workflow integration. A recent systematic review by Cheng et al [46] highlights the potential of AR and virtual reality to enhance resuscitation skills but notes inconsistent superiority over traditional methods, underscoring the need for integrated solutions such as TeamScreen. TeamScreen extends this concept by offering a centralized, algorithm-synchronized interface, positioning it within an emerging class of digital tools designed to optimize shared cognition and temporal alignment in high-acuity care.

Essential TeamScreen Enhancements

The usability evaluation of TeamScreen has identified critical areas for future refinement, and the following enhancements will be implemented to optimize its support for resuscitation teams. The information hierarchy will be restructured to minimize visual overload, consolidating related elements such as medication timing and dosage into a distinct, clearly labeled panel, guided by cognitive load principles [41]. This adjustment could streamline data retrieval and lessen cognitive strain during time-sensitive tasks. Dynamic visual cues, such as color shifts or blinking countdowns for medication intervals, could prompt timely actions, provided they adhere to ergonomic principles to avoid distraction in high‐stress settings. Functionally, adaptive role-based prompts tied to PALS algorithms could guide users step-by-step, improving coordination and adherence. Standardizing labels, icons, and visual styles (eg, font sizes, colors, and legends) would enhance consistency and reduce the likelihood of misinterpretation, particularly for the 6H5T mnemonic and streamlined task lists. Finally, given its intuitive design, brief, role‐specific onboarding is advised—especially for users with varying digital fluency—to ensure efficient navigation in multitasking, high-stakes scenarios such as CPR. Paired with these design refinements and enhancements, targeted training could maximize TeamScreen's potential to support resuscitation teams effectively.

Study Limitations

This study has several limitations. Testing TeamScreen in a simulated environment without direct user interaction limits conclusions about real-world PALS algorithms adherence or patient outcomes. The heightened stress of a real-life IHCA situation might exacerbate usability challenges not fully captured in this study. Additionally, evaluating TeamScreen isolation (ie, without AR Headsets or Guiding Pad) potentially reduces ecological validity, as the full InterFACE-AR suite's interplay was not assessed. This may also not fully capture the usability of the complete system. However, the Guiding Pad and AR headset modules have been evaluated in separate component-level usability studies, and the integrated InterFACE-AR system has recently been tested in a multicenter randomized controlled trial in a high-fidelity simulated setting. Third, the passive display design, reliant on a charting nurse's input via the Guiding Pad, aligns with its intended use but restricted participants' ability to explore the interface freely, potentially skewing engagement. Fourth, the study sample size and various clinical backgrounds of participants further limit generalizability. Fifth, our evaluation was supposedly conducted in a dedicated emergency department resuscitation bay using a fixed, wall-mounted TeamScreen display, which may limit generalizability to ward-based pediatric IHCA where mobile

XSL•FO
RenderX

configurations of TeamScreen and the Guiding Pad would be required and should be evaluated in future work. Finally, while cognitive overload was frequently noted in feedback, this dimension remained unquantified owing to the absence of a validated instrument such as the NASA-Task Load Index (NASA-TLX) [47]. This should be addressed in future studies.

Future Directions

Several of the usability issues identified in this study point to general design principles that are relevant for other digital tools in acute care. Information that is crucial for safe care (such as timers, current patient status, and key tasks) should be clearly visible on a shared team display. The amount of information on screen needs to be limited and well structured to avoid overload, and icons or color codes must be immediately understandable, even under stress. These lessons can guide the design of other real-time decision support systems that aim to support teamwork rather than only individual users.

The next phase of our program consists of 2 multicenter, simulation randomized controlled trials in 2025. The first, conducted in the second quarter of 2025, has now been completed, and the second, initiated in the fourth quarter of 2025, is currently underway, integrating TeamScreen with AR Headsets and Guiding Pad to evaluate clinical decision‐making, teamwork, communication, and patient safety outcomes across diverse hospital settings. Structured, role-specific onboarding will mitigate the learning curve effects observed in this study, offering a clearer performance baseline under realistic pressures. Because adherence to advanced life support guidelines is associated with better IHCA outcomes [42], metrics such as drug administration timing, error rates, and PALS adherence will provide deeper insights into how digital support influences care quality. Role differences (eg, nurses' documentation vs physicians' leadership [43]) will also be examined to further adapt the interfaces. Cognitive workload will be quantified using tools such as the NASA-TLX [47] to address qualitative feedback about overload and to test whether the system genuinely reduces cognitive burden.

Future iterations could incorporate artificial intelligence–driven predictive analytics to anticipate tasks (eg, rhythm reassessment), further reducing manual tracking demands. Qualitative feedback and high usability scores suggest that TeamScreen may alleviate cognitive load, although formal workload assessments are needed. Future work also needs to address more practical questions that apply to many medical digital tools, including feasibility of deployment, interoperability with existing hospital systems, and implementation costs, for widespread adoption. Integration with electronic health records, automated monitoring data capture, and tailored role-specific interfaces represent key translational goals to support clinical use of InterFACE-AR and similar decision support systems.

Conclusion

This study provides a structured usability evaluation of TeamScreen, a shared digital interface designed to assist pediatric resuscitation teams during IHCA, with its clinical impact still to be validated. Using a mixed methods approach, we identified its strengths and limitations in a simulated setting. Results revealed an 81% task success rate and high user satisfaction, confirming TeamScreen's ability to deliver accessible, interpretable clinical data under time pressure. However, issues with information hierarchy and task clarity, evidenced by correlated failures in navigation and updates, highlighted areas for refinement. The combined analyses of error categorization, verbal feedback, and questionnaire responses provided insights about the prototype's strengths and areas requiring refinement. This comprehensive evaluation not only identified critical usability challenges but also validated the potential of the TeamScreen prototype to optimize pediatric resuscitation workflows.

Abstract

Background: The Australian National Aged Care Mandatory Quality Indicator Program (QI Program) requires government-subsidized residential aged care service providers to report quarterly data on a set of quality indicators. These indicators measure provider performance across specific domains of care and are intended to support continuous quality improvement. Health care dashboards can enhance the use of indicators by presenting data in interactive and intuitive formats that enable actionable insights.

Objective: This mixed methods study aimed to develop an electronic dashboard to assist service providers' use of QI Program data to measure, track, and improve the quality of resident care.

Methods: A participatory design methodology was used to co-design and co-develop the dashboard. Initially, stakeholder participants for the co-design were identified. A combination of workshops, meetings, and email communications with co-design participants was then used to iteratively define and refine user requirements and to develop and improve the dashboard prototype. A 3-month pilot of the dashboard was conducted with a convenience sample of 30 end-users across 12 nursing homes and a post-pilot survey based on the System Usability Scale (SUS) was used to assess end-users' perceptions of the dashboard usability.

Results: The dashboard supports multiple user roles by enabling comparisons across homes and detailed views of all indicators for individual homes. A key feature is the ability to progressively view data at various levels of detail: groups of homes, individual homes, resident groups, and individual residents. The resident-level view enables more targeted, personalized care by helping staff identify and prioritize the specific indicators triggered by each resident. The average SUS score was 75.2 (SD 16.3), indicating good usability for the dashboard. Most survey respondents (12/14, 85.7%) were likely or extremely likely to recommend the dashboard to a colleague and agreed the dashboard would support the delivery of personalized care for residents. Almost all respondents (13/14) agreed or strongly agreed that the dashboard would assist with quality monitoring and improvement activities, and some pilot participants also made suggestions for incorporating the dashboard into those activities.

Conclusions: This study demonstrates the potential value of a co-designed dashboard to support the use of quality indicator data in residential aged care. Limitations of the current prototype include short pilot duration, convenience sampling, and reliance on manual quarterly data uploads, which constrain generalizability and scalability. Future work should explore long-term integration of the dashboard into routine quality improvement processes and evaluate its impact on resident outcomes and care quality over time.

Introduction

Quality indicators have become a common strategy in Australia and globally to support monitoring and improvement of quality in residential long-term care settings, including residential aged care facilities (also known as nursing homes) [1-6]. These metrics are quantitative measures for assessing care processes, structures, and outcomes to indicate how well care providers are performing in specific domains of care [7]. Indicators can facilitate the identification of care domains where quality is unacceptable or low and can enable tracking and comparison of quality at home/facility, organizational, regional, and national levels [1,7,8]. Indicators can also help identify top-performing services and enable the setting of evidence-based benchmarks to guide quality improvement efforts across long-term care settings [9].

Several countries use indicators for public reporting and comparing the performance of service providers [6]. In Australia, under the National Aged Care Mandatory Quality Indicator Program (QI Program), all government-subsidized service providers are required to report data on 14 indicators to the federal government every quarter of the financial year [10]. The program is designed to enable both the government and service providers to identify areas for improvement [10]. Five of the indicators also form a performance area used to determine a home's overall rating in the public star rating system for residential aged care homes in Australia. Providers collect individual resident data in each home/facility using government-issued quality indicator spreadsheet templates that aggregate the data prior to submission. Typically, these data are sourced from different software, including clinical information systems, and risk and medication management software.

Quality indicators and their associated data must be understandable and actionable to fulfill their function as quality improvement tools [11,12]. Health information technologies (HITs), particularly dashboards, can be a key facilitator for this goal. Health care dashboards aggregate and analyze data about care recipients and care processes from multiple sources and present the data using graphics and other visuals to facilitate decision-making for health care professionals [13-15]. Dashboards are ubiquitous in acute care [13,16-18] but are increasingly utilized in the aged care sector in high-income countries, including Australia [19-21]. Although software products are available for collecting and reporting QI Program data, there is no published evidence of dashboards designed to support the practical use of these data for quality monitoring and continuous improvement by providers. Likewise, the scientific literature lacks evidence of dashboards developed specifically for QI Program indicators or demonstrating that providers are actively using these data to guide continuous quality improvement, as intended by the program. The QI Program's quarterly collection of individual resident data presents an opportunity for providers to identify care domains requiring attention for each resident (ie, the indicators triggered) and to implement targeted care protocols accordingly. This resident-level approach not only has the potential to enhance outcomes for residents but also to improve overall provider performance within the QI Program. A dashboard would consolidate resident data into a single, accessible view and eliminate the need for providers to manually search across disparate software systems or navigate individual spreadsheets used for QI Program reporting.

Research shows that, like other HITs, involving end-users in the design and development of dashboards helps ensure the final product meets their specific needs. This collaborative approach also fosters a sense of ownership among end-users and other stakeholders, increasing the likelihood of adoption and long-term use [13,22-24].

The aim of this study was to develop and evaluate the usability of a dashboard to enable residential long-term care providers to use their mandated QI Program data to measure, monitor and improve the quality of resident care.

Methods

Study Design, Context, and Setting

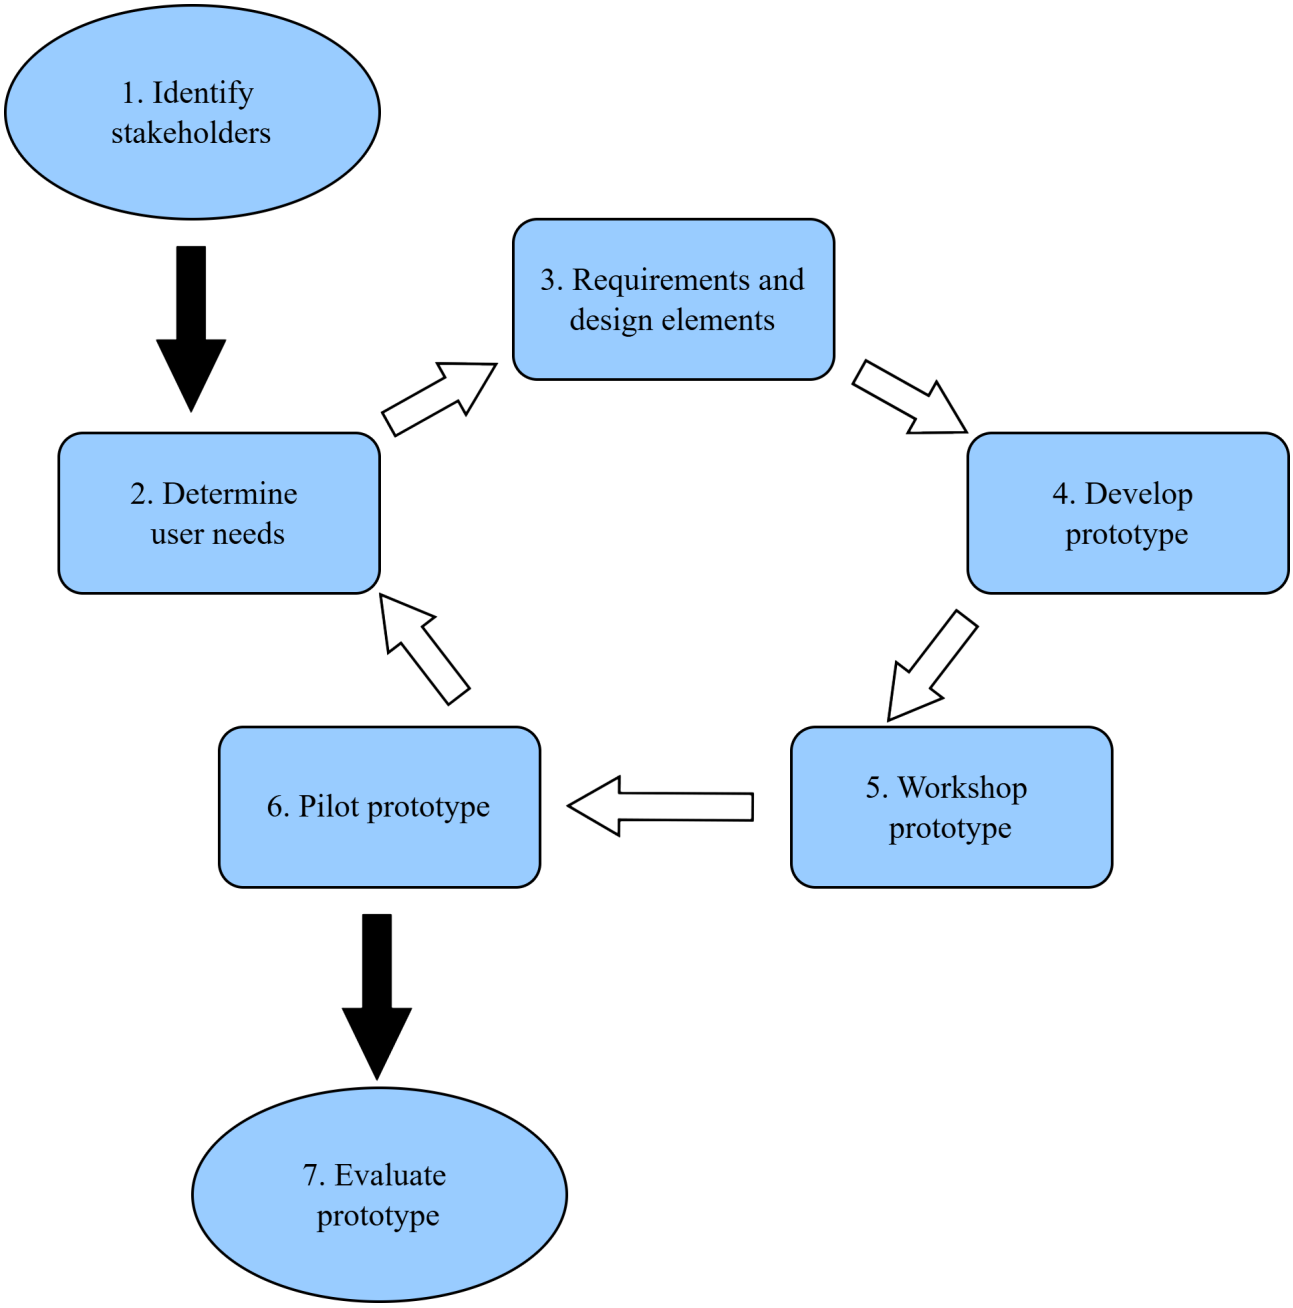
This was a mixed methods study that used different methodologies for the dashboard design and development, and evaluation of usability. The dashboard described in this study is a component of a larger project that aimed to develop various standards-based health data, digital tools, and strategies for quality improvement [25]. The industry partner was Regis Aged Care (Regis), one of Australia's largest aged care service providers [25].

Ethical Considerations

Ethical approval was provided by the University of Queensland Human Research Ethics Committee (ID: 2022/HE002362). After accepting invitations to participate in the project, participants were supplied with an information sheet summarizing the project and a consent form for signing prior to data collection. Furthermore, researchers began each workshop/interview by explaining the project aims, procedures, and ethical considerations, including participants' right to withdraw at any time. Participants were not compensated for participating in the project. All members of the research team adhered to institutional procedures governing research data storage, access, and privacy. Data were transcribed and deidentified using a commercial transcription service.

Iterative Co-Design Approach

Overview



We used a participatory design methodology to develop the dashboard. The core principle of this user-centered approach is the direct involvement of people for whom a product is being designed in a collaborative co-design process [26]. This approach has been successfully used in the design of health care dashboards in general [27-29] and specifically, aged care dashboards [20,28,29].

Figure 1 summarizes the design, development, and evaluation process [27,28,30]. The process was largely iterative and entirely collaborative. Stages 1 - 3 and 5 were conducted using a combination of in-person and online workshops to accommodate participants' availability and geographical locations. Except for

XSL•FO
RenderX

the first workshop, notes and outcomes of a prior workshop were reviewed at the beginning of each workshop to play these back, and confirm agreement of outcomes and decisions. We also leveraged fortnightly project committee meetings and email communications to expedite design decisions (all members of the project committee were participants in the co-design group).

Figure 1. Co-design and evaluation stages.

Data Collection and Analysis

Workshop notes, transcripts of workshop recordings, and feedback received via email constituted the qualitative data for the project. As mentioned, the qualitative data were transcribed and deidentified using a commercial transcription service. Content analysis [31] was conducted using NVivo software [32] to derive the data sought at each stage (ie, identifying stakeholders, user needs, and requirements for the dashboard).

Identifying Stakeholders

To kickstart the project, we established a project committee consisting of the research team and 4 Regis staff members. The project committee collaboratively identified individuals and groups within Regis in executive and operational management roles for whom data aggregation and interrogation of the care, needs, and outcomes of residents formed a significant part of their responsibilities (ie, stakeholders). The Regis staff on the project committee then invited specific individuals from each group to participate in the co-design (ie, co-design participants).

Determining User Needs, Developing Requirements, and Design Elements for the Dashboard

A discussion of user needs was initiated in the first workshop by seeking out answers to three broad questions:

1. What is the purpose of the dashboard?

XSL•FO
RenderX

2. How will end-users use the dashboard?
3. What would end-users expect to achieve by using the dashboard?

Data collected during the first workshop were analyzed as described above ("Data Collection and Analysis" section) to compile a list of feature and functional requirements for the dashboard. The requirements were discussed and collaboratively refined during the second workshop. The final requirements list was translated into design elements. Design elements refer to user interface components (eg, buttons, icons, and menus), user experience patterns (eg, navigation patterns, workflows, and interaction models), layout of visuals, information architecture (organization of content) and system design (data structure and back-end logic that supports the front-end interactions/visuals).

Developing and Workshopping a Prototype

The first step in building the dashboard prototype was drawing up wireframes for each prospective view/page based on the design elements. A wireframe is a simple schematic created in the early stages of designing a digital product to help designers to communicate and co-design participants to visualize user-interfaces of digital products (eg, web pages, mobile apps, dashboards) [33,34]. We used a free, web-based diagramming tool to create the wireframes [35], which were distributed to participants via email to gather feedback and input. Design details requiring in-depth discussions were deferred for consideration during workshops to obtain consensus. This approach facilitated feedback and confirmed acceptability without requiring time-intensive coding.

Following consensus on the wireframes, development of the dashboard commenced by building the back end (ie, data model, logic, and calculations). The lead author developed the dashboard using Microsoft Power BI software (Microsoft Inc) [36], with technical and professional support from a credentialed Microsoft services provider [37]. Data for the dashboard were sourced from Regis's quarterly QI Program data. Their national quality assurance manager, who was also a co-design participant, anonymized the residents using a unique code before supplying the data to the dashboard developer. The national quality assurance manager also supplied Regis's IT team with the master spreadsheet containing the resident name and anonymization code pairs. Upon completion of the development, the dashboard file was sent to the Regis IT team who uploaded the master spreadsheet into the dashboard files prior to publishing. This approach preserved the privacy of residents while allowing individual residents to be linked between quarters and to be re-identified by Regis staff within the dashboard.

Following completion of the first prototype, and each update thereafter, we conducted online or in-person workshops to demonstrate the dashboard's features and functions to the co-design group and gather feedback. During online workshops, the lead author guided participants through the dashboard workflow. During in-person workshops, participants were given hands-on access to the dashboard to explore and discuss its features and functionality. We employed the Think-Aloud method, an established approach for user interface evaluation in digital health [38], to gather real-time feedback. Participants were asked to verbalize their thoughts, observations, and opinions as they interacted with the dashboard. A member of the research team recorded these verbal responses and observations for subsequent analysis.

Pilot and Usability Evaluation

To evaluate the dashboard usability, we conducted a pilot study designed to assess usability and perceived usefulness of the prototype, rather than to evaluate impact on care quality outcomes (which would require a longer evaluation period). Pilot participants were a convenience sample of 30 end-users in 12 nursing homes, consisting of general managers, regional general managers, clinical care managers, and clinical care specialists. Pilot participants were granted unrestricted access to the dashboard and encouraged to explore it freely. However, to facilitate structured engagement, we provided a monthly task list suggesting specific areas for exploration. Throughout the pilot, we met with participants during their routine monthly quality review meetings to monitor task progression and address user queries or technical issues.

At the conclusion of the pilot, we assessed the dashboard's usability using the System Usability Scale (SUS) [39], a widely adopted, standardized instrument for evaluating perceived product usability, including HITs [40]. It comprises 10 items rated on a 5-point Likert scale, yielding an overall usability score between 0 and 100 [41,42]. SUS scores below 60 signal poor usability while scores in the 60 - 69 range signal fair usability, 70 - 79 signal good usability, 80 - 84 signal excellent usability, and 85 - 100 signal the best achievable usability [43]. In addition to the SUS items, the survey included questions assessing the perceived usefulness of the dashboard for person-centered care, its potential to support quality improvement, and suggestions for improvements. The survey was designed and administered using the Qualtrics platform.

Results

Co-Design and Iterative Approach

Overall, we conducted 5 workshops for Stages 1 - 5: the first 2 workshops for Stages 1 - 3 and the next 3 for Stages 2 - 5 (see Figure 1). The combination of hands-on exploration and the Think-Aloud approach during in-person workshops was effective at stimulating discussion among the co-design group and facilitating development of new ideas for further enhancement of the dashboard.

Identifying Stakeholders

Overall, 9 stakeholders were identified across three broad categories reflecting the clinical care hierarchy of Regis:

1. Organization level: executive general managers, clinical governance and care committees, regional general managers, regional quality and improvement managers, regional clinical care specialist managers, quality and improvement teams, and clinical care specialists
2. Home level: general managers and clinical care managers
3. Resident level: registered nurses

Identifying stakeholders enabled the co-design group to consider their specific needs during the design of the dashboard. The co-design group consisted of the following roles (Textbox 1).

XSL•FO
RenderX

Textbox 1. Roles of the co-design group.

Research

- Informatics
- Health services and quality improvement
- Geriatric medicine
- Research nurse

Regis aged care

- Executive general manager
- Group manager
- Regional quality and improvement manager
- National quality assurance manager
- Regional clinical care specialist manager
- Quality and improvement manager

User Needs, Dashboard Requirements, and Design Elements

The final list of requirements is provided below.

1. The dashboard must display all current clinical and consumer experience indicators [10], that is, all except the "Workforce" indicator.
2. Home-level and resident-level end-users should have ability to select a specific home and period (ie, the "financial year" and "quarter") whose indicators they intend to view.
3. Organization-level end-users should be able to select a group of homes and compare their performance for any indicator.
4. The dashboard must allow benchmarking against a national or organizational statistic (eg, average, median).
5. End-users should have the ability to drill-through the data and view details for each indicator per home. Drill-through is a term for functionality in dashboards that enables users to explore data at different levels of granularity by navigating from summary-level pages to detail-level pages. For example, navigating from an overview page showing all indicators for a specific home to a page showing details for the pressure injuries indicator (distribution of pressure injury stages, pressure injuries acquired outside the home, trends, etc).
6. The drill-through function must allow the viewing of individual residents, including the resident's status for each indicator with clear indication of triggered indicators.
7. Access to resident-level data must be constrained by user credentials (eg, a registered nurse should only be able to view residents in the home in which they work).
8. The dashboard should have functionality to export visualizations/reports into PDF documents.

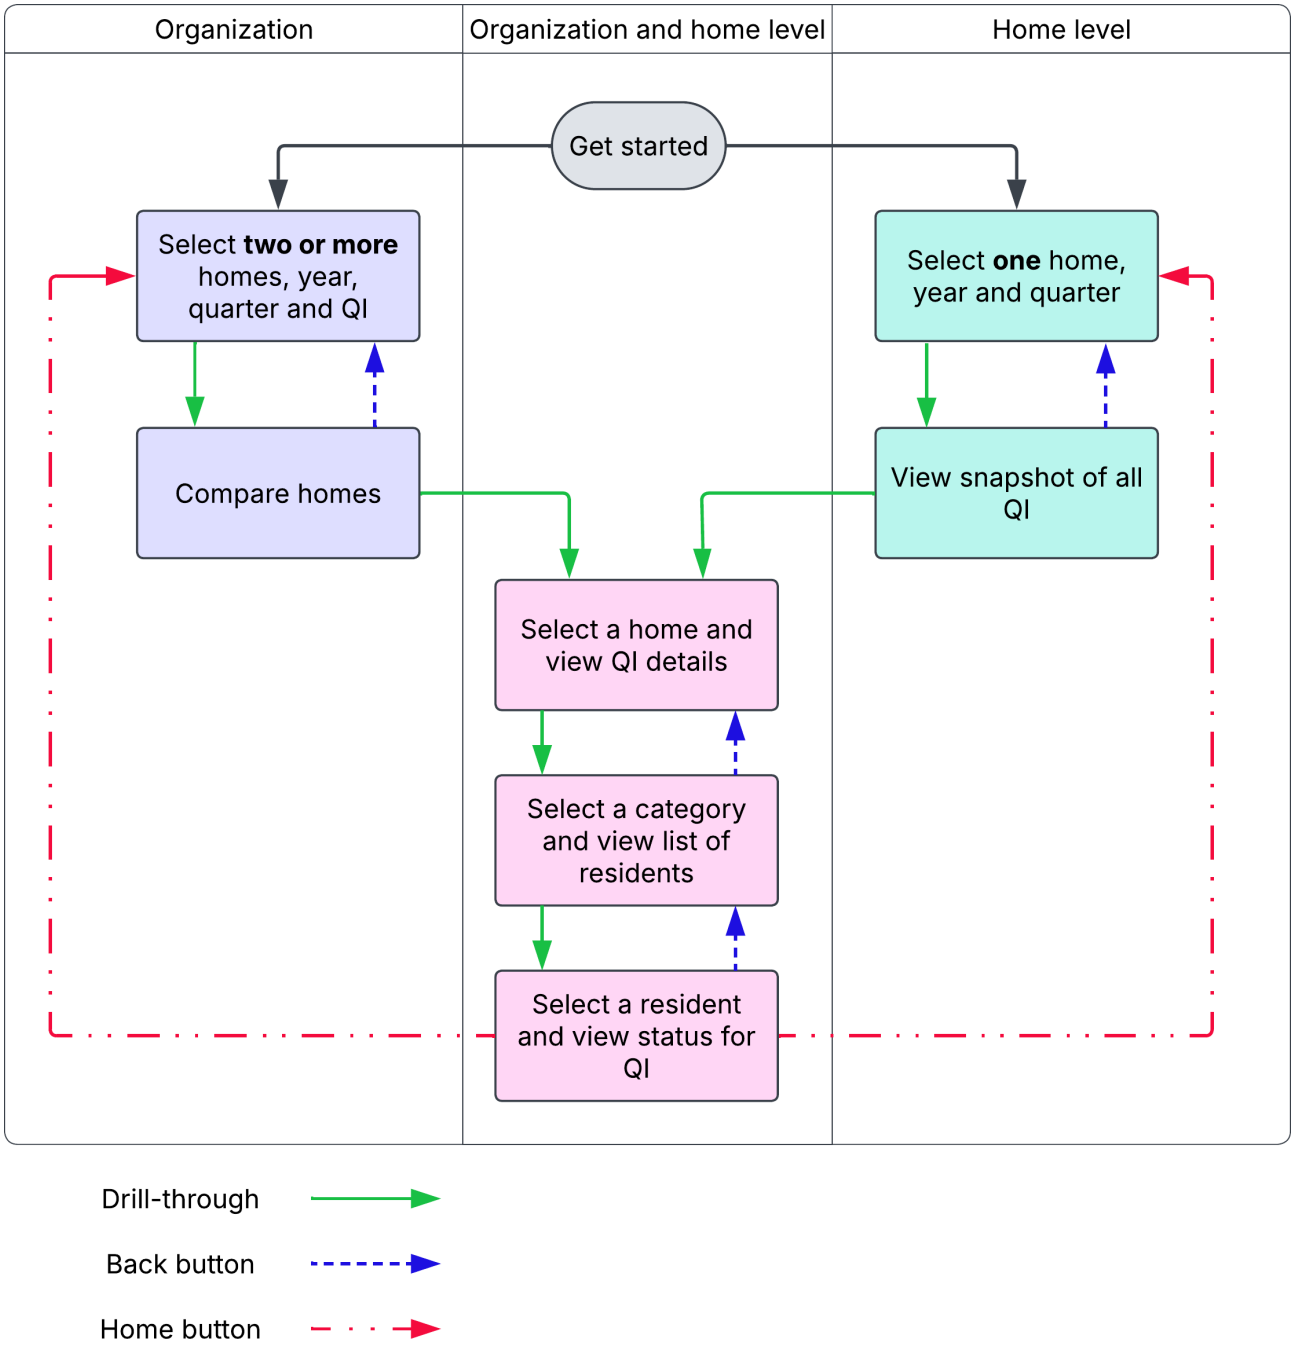
Design elements included drop-down lists for selecting variables to view (ie, homes, year, and quarter) and several combinations of "gauge," "card," and bar and line graph visuals in paginated views within the dashboard. Color was used extensively to convey key information visually—for example, to indicate a home's performance relative to benchmarks. Co-design participants emphasized the importance of designing the dashboard to meet the diverse needs of end-users.

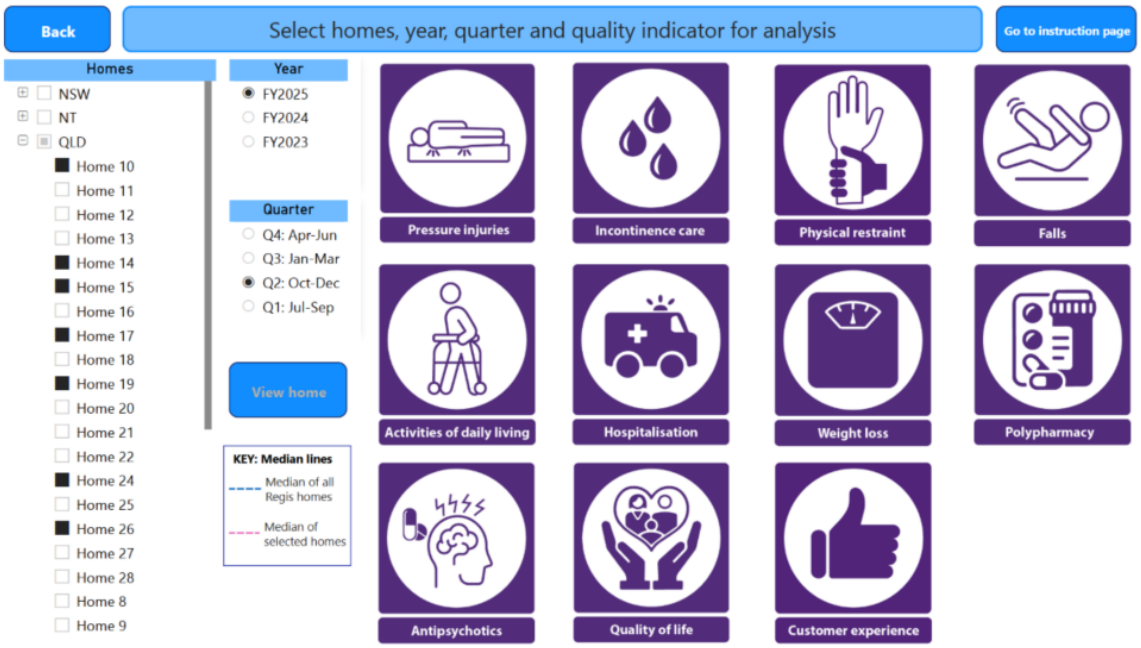
Developing and Workshopping a Prototype

The final prototype incorporates 2 workflows (Figure 2) to fulfill the different needs of end-users: a common technique for tailoring health care dashboards for multiple use-cases using the same data [18,44]. The "organization-level" workflow, for users in the organization-level category (see the "Identifying Stakeholders" section in the Results), allows users to select several homes, the period, and a specific indicator for comparison. The "home-level" workflow, for users in the home- and resident-level categories, allows the selection and viewing of all indicators for a single home for a given period. Figure 3 shows the landing page for the organization-level workflow and an example of the subsequent comparison page when an indicator is selected.

XSL•FO
RenderX

Figure 2. Organization-level and home-level workflows for the dashboard. QI: quality indicator.





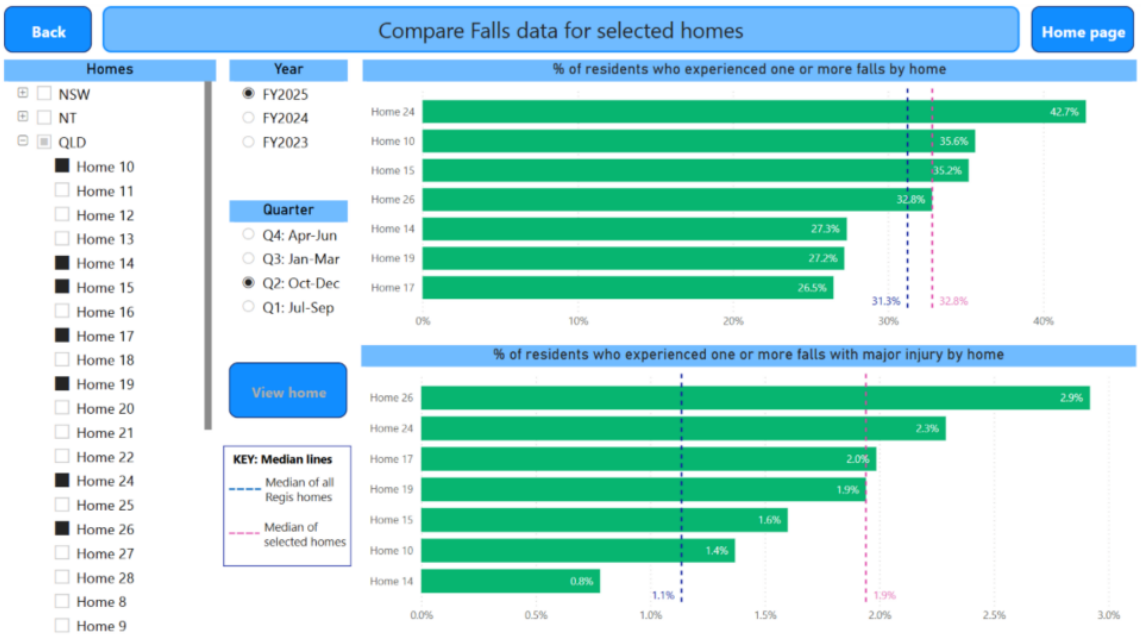


Figure 4 shows the landing page for the home-level workflow, which unlike the organization-level workflow, immediately displays an overview of all indicators after selection of a home and period. In this view, each home can be compared against a benchmark set for all homes in the organization. The benchmark was set as part of the co-design process to fulfill one of the requirements (see the "User Needs, Dashboard Requirements, and Design Elements" in the Results). It is indicated on the visual for each indicator by the dark line, and the actual value can be displayed by hovering the cursor over the line. The color scheme, also chosen during co-design, provides a visual indication of a home's performance relative to the benchmark, with the intensity of color (ie, brighter/darker) indicating the percentage increase away from benchmark, as follows: (1) green signals performance above the benchmark, (2) amber signals performance equal to the benchmark, and (3) red signals performance below the benchmark.

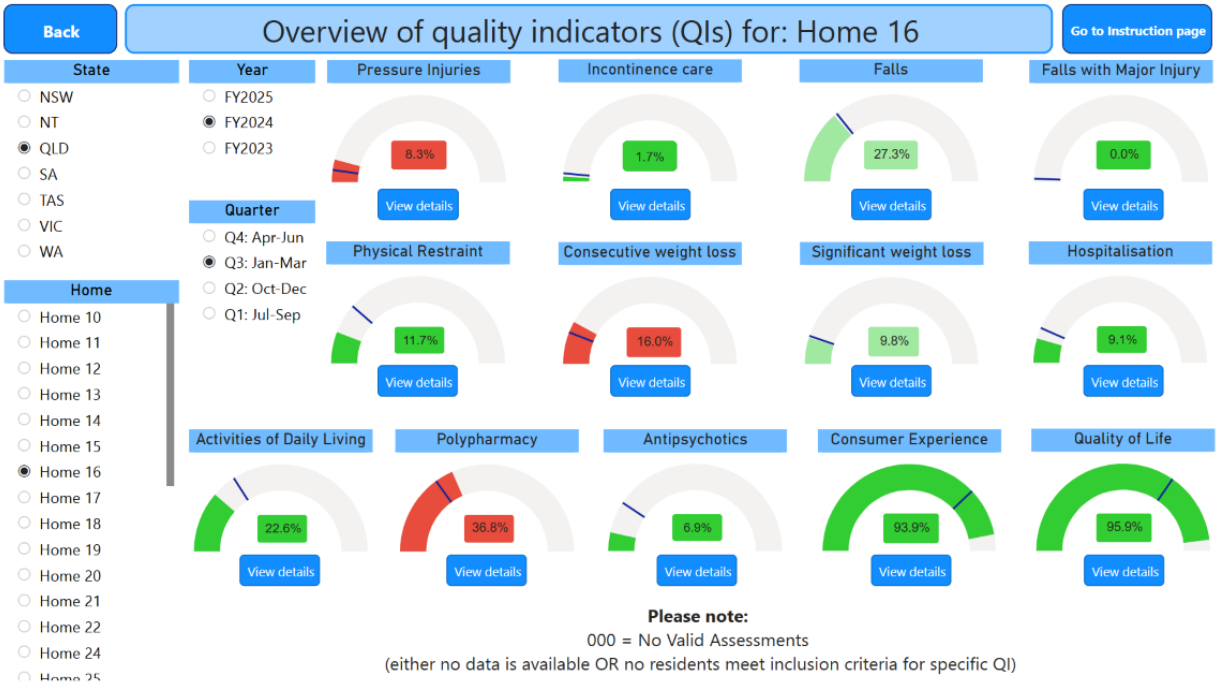
XSL•FO
RenderX

Figure 3. The (A) homepage for the organization-level version of the dashboard and (B) comparison of falls indicators. The names have been anonymized for illustrative purposes.

XSL•FO
RenderX

Figure 4. The homepage for the home-level version of the dashboard. The name of the selected home has been anonymized for illustrative purposes.



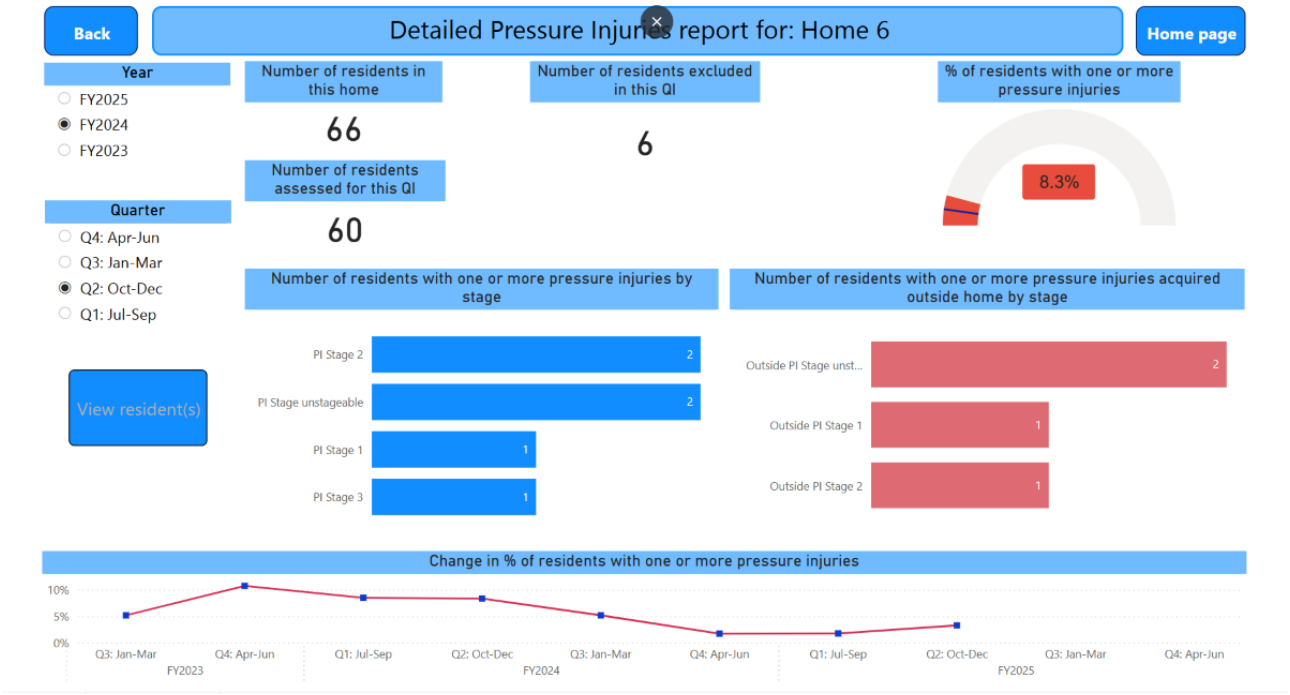


Figure 5 shows an example of a drill-through to an indicator detail page. The indicator detail page displays all the reporting items required by the QI Program for that indicator. Figure 6 shows the resident-level data where a color scheme for each quality indicator title indicates the resident's status as follows: (1) red signals that the resident has triggered the indicator (eg, the resident has a pressure injury), (2) green signals that the resident has not triggered the indicator (eg, the resident does not have a pressure injury), and (3) blue signals that the data for the indicator are not available (eg, the resident declined to be assessed for pressure injuries).

Figure 5. An example of a detailed QI (Pressure injuries) report for a specific home. The name of the home has been anonymized for illustrative purposes. QI: quality indicator.

XSL•FO
RenderX

Figure 6. An individual resident's QI status detail page. The resident's name and home have been anonymized for illustrative purposes. QI: quality indicator.

Dashboard Pilot and Evaluation

Of the 30 individuals invited to participate in the pilot, 29 participants accessed the dashboard at least once during the pilot period, and 16 opened the usability survey (53% response rate) and 14 completed the survey (87.5% completion rate). The average SUS score was 75.2 (SD 16.3), indicating end-users thought usability of the dashboard was good. Among the completed surveys, 85.7% (12/14) of respondents reported being likely or extremely likely to recommend the dashboard to a colleague. An equal proportion (12/14) believed the dashboard would support the delivery of personalized care for residents. Additionally, 92.8% (13/14) agreed or strongly agreed that the dashboard would assist with quality monitoring and improvement activities within Regis.

The drill-through to individual resident-level views was well-received, with participants noting it could help staff quickly identify and prioritize relevant care domains, thereby promoting more person-centered care. In response to a survey item on integrating the dashboard into routine workflows, pilot participants suggested it could be useful for preparing internal quarterly reviews. They also recommended refreshing the data monthly to enable exporting dashboard views for inclusion in monthly clinical quality reports. Participants offered several suggestions for further improvements. However, some of these were contradictory, reflecting differences in personal preferences. For example, while some users preferred listing homes alphabetically when comparing performance, others favored sorting by descending indicator value to highlight the best- or worst-performing homes.

Discussion

Principal Findings

This article describes the design, development, and preliminary evaluation of a dashboard for quality indicator data. To our knowledge, it is the first published study to describe a dashboard specifically designed to support the Australian QI Program in aged care. Workshops were the primary collaboration method in the co-design process, complemented by a flexible, multi-channel approach that maintained momentum by enabling the prompt resolution of minor issues between scheduled sessions.

The multi-level drill-through capability is a key feature of the dashboard, which allows users to explore data at progressively finer levels of detail. This functionality supports a broad range of users across executive, managerial, and clinical roles. By providing secure access to resident-level data, the dashboard supports data-driven personalized care, which is associated with better resident outcomes and higher satisfaction and quality of life [45]. In this way, quality indicator data can be used as an operational asset for continuous quality improvement, enabling a bottom-up approach in which targeted care at the individual resident level may cumulatively contribute to improved performance at both home and organizational levels.

The dashboard requirements that were not specific to our use-case, that is, those that can be generalized to most health care dashboards, were consistent with those in the existing literature [14]. Like participants in other co-designed health care dashboards, co-design participants required functionality for selecting specific data subsets (homes or groups of homes, years, and calendar quarters) to view/compare indicators and multi-level drill-through capability, to have the ability to benchmark homes against group statistics, and to have secure

XSL•FO
RenderX

access to resident-level data [14,19,46-48]. The design elements incorporated into the dashboard (radio buttons for navigation, color-coded visuals, line and bar charts, etc) were also consistent with existing literature [19]. The co-design and pilot participants found these design elements to be simple but powerful ways for conveying important details within the data as reported by users of other health care dashboards [19].

Study Strengths and Limitations

A key strength of this study is the participatory, iterative development approach involving stakeholders across organizational executives, managers, and nurses. This enabled the tailoring the dashboard for real-world quality monitoring workflows and to support both performance oversight and resident-level care planning. Another strength is that the pilot was conducted in an operational aged care setting, providing an initial indication of feasibility and usability in practice.

This study has several limitations. First, the pilot evaluation was conducted with a convenience sample within a single aged care provider organization, and only 14 of the 30 participants completed the post-pilot survey. This limits generalizability and introduces the possibility of response and selection bias. Second, the 3-month pilot duration may be insufficient to understand long-term adoption, workflow integration, and sustained use. Third, the evaluation focused on perceived usability and usefulness but not effectiveness; we did not directly measure changes in care quality, staff decision-making, or resident outcomes attributable to dashboard use. Fourth, the prototype relied on manual data uploads and did not include automated data pipelines, which may limit scalability and real-world implementation readiness. Fifth, the dashboard operated on QI Program data, which is collected quarterly and may be too infrequent for timely monitoring of emerging issues in resident care.

Implications for Practice and Future Development

Although the findings suggest potential for dashboards to make quality indicators more practical for monitoring care quality and supporting continuous improvement, broader implementation in practice will require technical and organizational development beyond this prototype stage. Future work should progress in 3 stages. First, implementation-ready infrastructure is needed, including a central data warehouse (or equivalent) and automated data pipelines from clinical information system sources. This would improve scalability, reduce manual workload, and enable stronger data quality controls (eg, completeness and timeliness checks). Second, dashboard functionality should be extended to support more frequent refreshes and enhanced analytics such as automated alerts and trend detection (improvements suggested by participants during this pilot). The divergent feedback on interface preferences during the pilot (eg, alphabetical vs performance-based sorting) suggests that usability in this context depends not only on simplicity, but also on flexibility. Future iterations should therefore include user-configurable interface features, such as selectable sort and display options, role-specific default views, and saved filters. These enhancements would better accommodate diverse workflows and user preferences across organizational, home-level, and clinical roles. Third, the dashboard should be evaluated in a larger, multi-site longitudinal study to measure not only usability and adoption but also the impact on quality improvement processes and resident outcomes. Organizations must establish robust governance strategies to mitigate the risk of “tunnel vision”—a phenomenon where attention becomes overly focused on the domains measured by implemented quality indicators at the expense of unmeasured aspects of care [49]. While this is a risk of using indicators for improvement more broadly [49], a dashboard with resident-level views may heighten the effect by directing clinical attention primarily toward the indicators presented on screen. Aged care organizations should also consider expanding the suite of dashboard quality indicators to complement the current QI Program and encompass a broader range of critical resident care domains.

Specific Lessons

This study holds several lessons for informatics and the aged care sector. A multi-channel collaboration approach helped us gather feedback faster than relying solely on the workshops. The aged care industry, especially in Australia, is highly regulated, and providers occasionally have to attend to short-notice site visits and requests for information from regulators, necessitating immediate and intense activity by executive and operational managers. For this reason, it was common for some co-design participants to suddenly become unavailable for scheduled co-design workshops; however, the fortnightly meeting and emails provided additional avenues and opportunities to capture feedback and contributions. While fortnightly meetings may not be feasible for others, less frequent timeframes may be sufficient (eg, monthly or bimonthly). The feedback gathered from co-design participants using the Think-Aloud technique when interacting with the dashboard during in-person workshops provided richer data than online workshops. The Think-Aloud technique, which has been successful applied in HIT co-design in aged care [50], was particularly effective at stimulating insightful discussions and generation of ideas among co-design participants.

Conclusion

In conclusion, dashboards co-designed with stakeholders have the potential to help aged care organizations operationalize quality indicator data for monitoring care quality and personalized care in residential aged care. Larger and longitudinal evaluations are required to determine their long-term impact on care quality and resident outcomes.

Abstract

Background: The increasing prevalence of cannabis use has motivated researchers to develop computational behavioral models that predict usage patterns and related health impacts in naturalistic environments. However, the opaque nature of many artificial intelligence (AI) systems limits users' ability to interpret outputs and undermines trust. Existing explainable artificial intelligence techniques often remain overly technical and do not account for the confusion or frustration clinicians may experience when interpreting complex model explanations.

Objective: We propose and evaluate an empathic clinical decision support system (empathic-CDSS) that integrates large language models (LLMs) with real-time emotion recognition and explainability modules. The goal is to provide transparent, adaptive, and emotionally attuned explanations that enhance interpretability, user confidence, and trust in AI-assisted clinical decision-making.

Methods: Our empathic-CDSS integrates explainable artificial intelligence, causal inference, and affective computing within an interactive LLM-driven framework. Users' affective states were inferred using the circumplex model of affect, which characterizes emotions along 2 dimensions: valence (the degree of pleasure or displeasure) and arousal (the level of physiological activation or energy). Based on the captured emotional signals, the system dynamically adjusts the tone, structure, style, and complexity of its explanations generated by a fine-tuned LLM, enabling personalized and plain-language explanations. A total of 33 participants with diverse medical and technical backgrounds engaged with the system through guided evaluation tasks and postsession assessments to evaluate 6 dimensions of user-centered questions: usability, personalization and relevance of insights, clarity and comprehensibility, system benefits, satisfaction, and trust and reliability.

Results: Our empathic-CDSS effectively generated personalized and transparent explanations that revealed the causal reasoning behind model predictions while enhancing users' emotional engagement and trust in the system's decision logic. Continuous, affect-based feedback enabled the system to dynamically adapt explanation delivery to individual user needs. Participants reported significantly improved usability, clarity, satisfaction, and trust compared with a baseline clinical decision support system without

XSL•FO
RenderX

emotion adaptation. Improvements were also observed across additional evaluation dimensions, including personalization and perceived system benefits, supporting the feasibility and added value of integrating empathy-aware communication into AI-driven clinical decision support.

Conclusions: This study introduces a transparent, trustworthy, and emotionally adaptive framework for AI-assisted prediction and clinical decision support. By uniting causal reasoning, affective sensing, and LLM-based natural-language explanations, the empathic-CDSS offers a novel direction for developing emotionally intelligent and user-centered AI systems, with potential applications in behavioral monitoring and personalized interventions, including cannabis use and related health domains.

Introduction

The integration of artificial intelligence (AI) and machine learning (ML) into health care has significantly advanced the development of clinical decision support systems (CDSSs) that can analyze complex health behaviors such as cannabis use. By combining multimodal data, including physiological, behavioral, and contextual information, AI models can provide real-time insights that assist clinicians in monitoring patient risks and treatment response. However, despite these advances, many existing CDSS systems still face challenges in terms of transparency and interpretability, and these issues remain key obstacles hindering their effective clinical application [1].

Given these limitations, explainable artificial intelligence (XAI) has been increasingly adopted to reveal how predictive models generate outputs (eg, feature-importance visualization, counterfactual explanations, and causal modeling). Yet, in practice, XAI outputs are often presented through technical plots, numeric weights, or attribution scores that clinicians without AI training may struggle to interpret. This can increase cognitive load and trigger negative affect, which paradoxically reduces trust in systems intended to improve transparency.

Despite rapid advances in XAI methods, a critical bottleneck persists in explanation delivery: how to convey model reasoning processes in practical clinical interpretation tasks in a manner that nontechnical clinicians can easily understand and use, rather than merely generating technically correct explanations. Cognitive factors such as mental workload and information complexity, as well as emotional factors such as trust, frustration, and confidence in AI recommendations, can significantly influence how clinicians interpret and rely on AI-generated insights.

Driven by the demand for more human-centered design, recent research has begun exploring how emotional and cognitive factors influence interactions between clinicians and AI systems. Several lines of research have attempted to improve human-AI interaction in CDSSs through better communication design and adaptive data presentation. For example, integrating sensor data from wearable and mobile devices has enhanced the ability of CDSSs to detect and predict patient health states in real time [1-4]. In parallel, advances in large language models (LLMs) have made it possible to process unstructured data and generate natural-language explanations [5-10]. Within the human-computer interaction community, LLM-driven conversational agents have been explored to improve medical reasoning, facilitate clinician-AI dialogue, and make AI-generated insights more accessible. However, despite their potential, most existing systems provide static, one-size-fits-all explanations that do not adapt to users' emotional or cognitive states. This limitation constrains their ability to sustain user engagement and trust, especially in emotionally demanding clinical contexts. Existing systems often treat interpretation as a fixed content generation process, underestimating health care professionals' tolerance for complexity and the dynamic shifts in emotional engagement and trust during moments of uncertainty, stress, or time pressure.

Emerging evidence from affective computing suggests that detecting and responding to users' emotions can substantially improve perceptions of system usability, reliability, and trustworthiness [11-14]. Negative emotions such as confusion or stress can reduce users' ability to comprehend complex outputs, whereas emotionally attuned interactions can promote engagement and confidence in AI systems. These dynamics are particularly relevant in health care, where clinicians must make rapid judgments under pressure and cognitive load. Complementary research in algorithmic empathy has shown that conversational LLMs can simulate empathetic dialogue. For instance, ChatGPT (OpenAI) has been observed to express empathy more often than physicians in patient-facing scenarios [15]. Nevertheless, such "synthetic empathy" can lack contextual awareness or amplify biases learned during training [16,17]. Moreover, most empathy-oriented AI systems rely solely on text-based sentiment analysis, overlooking multimodal affective signals such as valence (emotional pleasantness) and arousal (physiological activation) that form the foundation of real-time emotion modeling [18,19]. These limitations indicate a gap in developing CDSSs that dynamically adapt their communication based on clinicians' emotional states during AI interaction. To address these challenges, we developed the empathic clinical decision support system (empathic-CDSS), a novel framework that integrates XAI, affective computing, and LLMs to create an emotion-adaptive, explainable dialogue system for clinical decision-making. The system incorporates three core components: (1) a multimodal emotion-recognition module that analyzes facial behavior and linguistic sentiment to infer users' valence and arousal in real time, (2) an XAI engine that uses SHAP (Shapley Additive Explanations), causal reasoning, and

XSL•FO
RenderX

counterfactual analysis to generate transparent model explanations, and (3) an adaptive dialogue module powered by a fine-tuned LLM that dynamically adjusts the tone, complexity, and level of detail in its explanations based on the detected affective state. Through this integration, the empathic-CDSS aims to bridge the gap between technical explainability and emotional alignment, providing explanations that are both transparent and contextually sensitive to the user's experience. Based on this framework, this study aims to investigate whether such emotion-adaptive interpretability can enhance clinicians' trust, usability, and comprehension of AI-generated insights.

After developing the empathetic CDSS, we evaluated its impact on user perception and interaction experience. This study evaluates whether the empathic-CDSS enhances trust, usability, and interpretability among users with diverse clinical and technical backgrounds. Specifically, we asked: (1) How can real-time emotion recognition be integrated into an explainable dialogue system to guide adaptive responses during user-AI interaction? (2) How does emotion-adaptive explanation influence users' trust, satisfaction, and perceived reliability compared with a baseline CDSS? (3) How does the integration of personalized and real-time affective state awareness-based feedback impact the usability, interpretability, and accessibility of XAI for multidisciplinary users (clinicians and technical users)?

This study contributes to both the design and evaluation of emotion-adaptive XAI for clinical decision support. Specifically, it (1) introduces a novel framework (empathic-CDSS) that unites XAI, affective computing, and LLM-driven dialogue for empathic human-AI interaction; (2) demonstrates how valence-arousal emotion modeling can inform dynamic adaptation of AI explanations in real time; and (3) provides empirical evidence that emotion-adaptive explainability enhances trust, usability, and interpretability in clinical AI tools.

The remaining sections are organized as follows. The Methods section describes the empathic-CDSS architecture, participant recruitment, and evaluation procedure. The Results section reports quantitative and qualitative findings on usability, trust, and system satisfaction. The Discussion section interprets key results in the context of prior work and implications for empathic AI design, and the conclusions summarize contributions and directions for future research.

Methods

Study Design

We conducted a mixed-methods, within-subject experiment to evaluate the usability, trust, and explainability of two CDSS versions: (1) a baseline CDSS providing static explanations without emotion perception, and (2) an empathy-enhanced version integrating real-time emotion perception and adaptive explanation generation.

We designed and evaluated a novel CDSS named empathic-CDSS. The core functionality of empathic-CDSS integrates (1) analyses of multimodal patient data (eg, sensor data and self-report), with (2) real-time multimodal emotion recognition of the user who is using empathic-CDSS to deliver to the user, more transparent, empathic, and understandable explanations of the model's results.

For analyses of data provided by the "patient," the system is configured to analyze passive sensor data collected via smartphones and wearable devices to predict specific behavioral outcomes for the patient (eg, whether a cannabis user is in an "intoxicated" state). The system then uses multiple XAI techniques (including SHAP [20], causal analysis [21], and counterfactual reasoning) to provide explanations for these person-level predictions [22]. For further technical details on the model generation pipeline and the XAI-based interpretability results, please refer to Multimedia Appendix 1, particularly the sections titled Personalized Model Generation for Cannabis Users ("Patients") and Interpretability Analysis.

For the health care provider, or clinician or researcher who needs to interpret empathic-CDSS model outputs (ie, person-level prediction models), empathic-CDSS innovatively integrates, in real-time, multimodal emotion perception functionality as the user uses the system. Specifically, the system analyzes, in real time, users' facial expressions (extracting valence and arousal) and emotions from dialogue text entered in the system (eg, sentiment analysis), to capture users' emotional states. The system uses emotional insights from the user's facial expressions and dialogue text to dynamically adjust the style and complexity of the system's explanations of model outputs through a fine-tuned LLM, thereby providing a more empathetic and personalized interactive experience for the user (eg, the user using the system).

Participants

A total of 33 participants (P1-P33) took part in this study to represent the user who needs to interpret the empathic-CDSS model outputs. Participants were predominantly male (approximately 20/33, 70%), a majority aged 20-29 years, and most were highly educated (20 PhD students, 7 master's students, and several professionals such as physicians, nurses, and medical product managers). Participants were recruited through online advertisements and community networks. Eligibility criteria included adults aged 20 years and older. No age-based exclusion criteria were applied. Age distribution reflects voluntary enrollment during the recruitment period. Participants represented diverse disciplines, including engineering, computer science, psychology, and health care. Participants' experience in the medical field ranged from none to more than 20 years, providing a balanced mix of novice and expert perspectives for evaluating the explainable and emotion-aware AI system. This heterogeneous sample of system users was intentionally targeted to capture the interdisciplinary ecosystem in which clinical AI tools are typically developed and deployed, spanning both technically trained developers and nontechnical health care professionals. Including participants with varying levels of technical and clinical expertise allowed examination of differences across users in interpretability, emotional receptivity, and usability perceptions, thereby ensuring that the system's design and evaluation reflect real-world diversity among potential end users in clinical and decision-support contexts. Detailed demographic information about the participants is provided in Table 1.

Ethical Considerations

This study received approval from the Stevens Institute of Technology Institutional Review Board (2024-090 (N)) before recruitment and data collection began. Written informed consent was obtained from all participants. Participants who completed this study received a US $20 Amazon gift card as compensation.

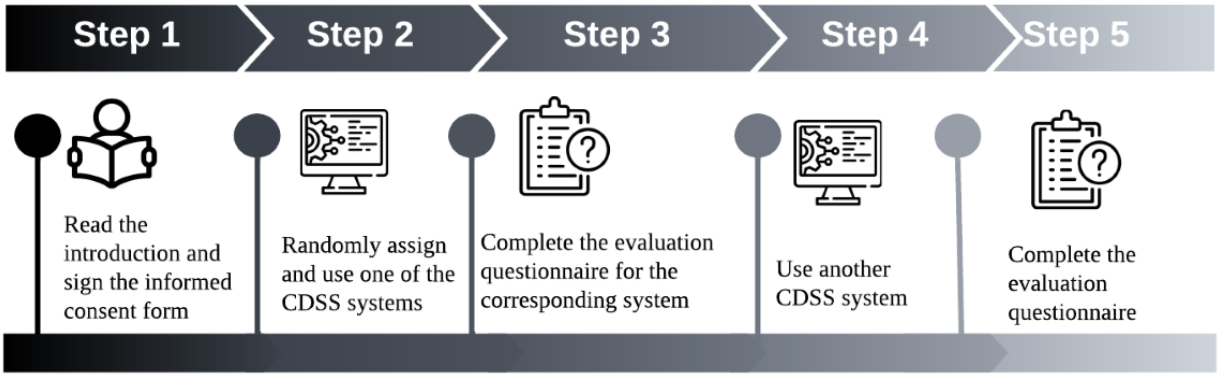
In accordance with IRB requirements, participation was entirely voluntary. Subjects were informed of their right to withdraw from the laboratory session at any point without any negative consequences, though full completion was required for the compensation.

To protect participant privacy, all collected data (including survey responses and system logs) were anonymized immediately after collection. Personal identifiers were replaced with unique alphanumeric codes (e.g., P01, P02).

All research data were stored on secure, password-protected servers within the laboratory. Access was restricted to the primary research team to ensure that no data would be disclosed to third parties or leaked outside the institution.

Study Setting and Procedure

This study used a within-subjects design, in which each participant interacted with both versions of the system to enable direct comparison. To mitigate potential learning or order effects, the presentation order of the 2 systems was counterbalanced: approximately half of the participants were randomly assigned to use the basic system first, while the other half used the advanced system first.



This study included 2 experimental conditions. The first was the basic-CDSS, which included the core study features, namely a personalized prediction model for cannabis intoxication and multiple XAI visualization charts (such as SHAP plots and causal diagrams). The dialogue interface was driven by a standard, not fine-tuned GPT-4 (OpenAI) model, and crucially, it did not possess any emotional perception capabilities, so its responses were purely information-oriented and did not adjust based on the user's emotional state. The second was the empathic-CDSS, which represents the complete empathic-CDSS proposed in this paper. Empathic-CDSS builds upon all the features of the basic-CDSS and integrates two core enhancement modules: (1) a multimodal emotion perception module for

XSL•FO
RenderX

real-time analysis of users' facial expressions and textual emotions; and (2) an empathy dialogue model, which has been fine-tuned on the motivational interviewing (MI) dataset [23] to generate emotion-adaptive responses.

Before any interaction with the system, participants were asked to review and complete an informed consent form that outlined this study's purpose, procedures, and their rights as participants. Participation was contingent upon signing this form. The participant then interacted with 1 of the 2 systems (randomly assigned). After completing their interaction with the system, the user filled out a comprehensive posttest questionnaire to evaluate their experience. The user then repeated the same process with the second system and filled out another evaluation questionnaire. At the end of the experiment, we asked participants to complete open-ended questions to collect qualitative feedback on the user experience for both systems. The user study procedure is illustrated in Figure 1.

Figure 1. User research tasks and questionnaire evaluation process. CDSS: clinical decision support system.

System Description: Empathic-CDSS Architecture and Processes

Basic-CDSS

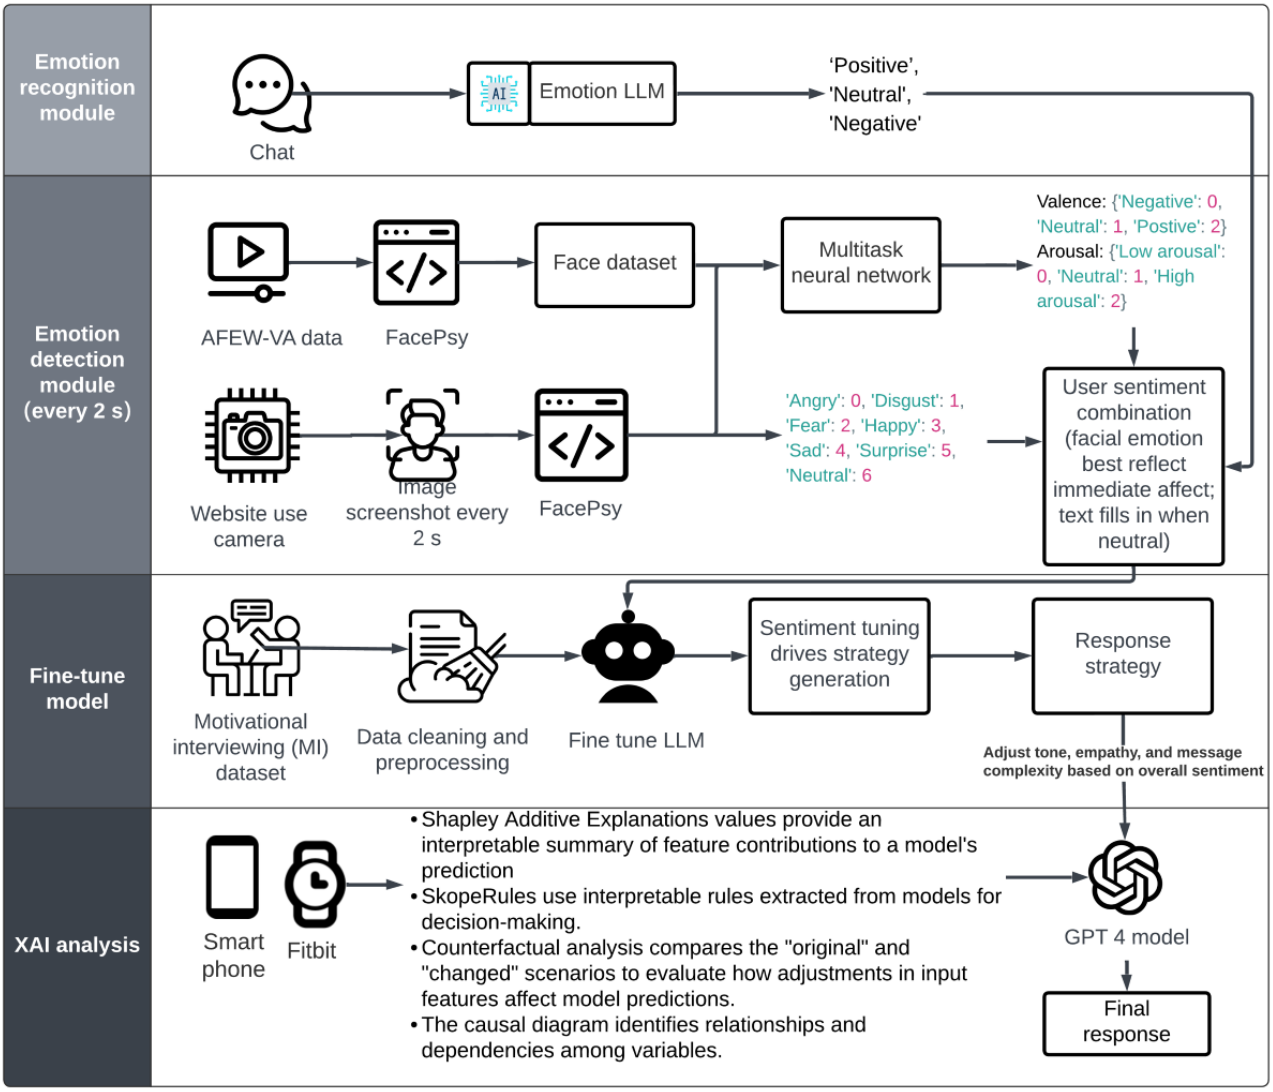
The basic CDSS in this study serves as a control system, which aims to provide a standard, data-driven clinical decision support platform. The system primarily relies on traditional explainable ML analysis workflows, including structured data processing, clinical feature extraction, and interpretable presentation of model prediction results. Basic-CDSS uses generic XAI methods to explain model outputs, enabling users to understand the key factors behind predictions and use this information to inform clinical judgments. Compared to the empathic-CDSS developed in this study, basic-CDSS does not incorporate emotion recognition modules (such as text sentiment analysis or facial expression recognition) and does not use model fine-tuning with emotional strategies. Consequently, system interaction uses a standardized, nonemotion-adaptive interface presentation. Nevertheless, the system retains core analytical capabilities, including clinical data processing, model execution, and visual presentation of interpretive results.

Empathic-CDSS

The empathic-CDSS developed in this study aims to provide users with an intelligent interactive platform that integrates emotional understanding with XAI analysis. To do this, empathic-CDSS combines XAI methods with emotion-aware interaction design. The system combines multimodal emotion recognition involving text sentiment analysis and facial expression recognition with personalized, explainable ML models. Through this architecture, the system not only generates accurate and transparent analytical results but also presents them through empathetic, emotionally adaptive conversational interactions. To generate and support strategies for empathic responding during the conversational interaction, an MI dataset [23] was cleaned and used for web-based fine-tuning. This approach enhances users' trust in the system and improves their overall interaction experience.

In order to enable real-time emotion recognition for users interacting with the system and to allow ML models to process facial expressions quantitatively, the raw video data must first be converted into structured numerical features. These numerical representations enable the system to capture facial movements and emotional signals in a format suitable for computational analysis and subsequent modeling of emotion-aware interactions.

For real-time emotion recognition of the person while they are using the system, we first decoded the video frame-by-frame to convert the video into a sequence of still images. Each decoded frame was processed individually using our FacePsy [24] code to extract facial action units, head pose parameters (yaw, pitch, and roll), confidence scores for 7 emotion categories (angry, disgust, fear, happy, sad, surprise, and neutral), and 68 facial landmarks [20]. Specifically, action units are a set of features defined by the Facial Action Coding System that are used to quantitatively describe the activity of facial muscles. In addition, we extracted the confidence distribution of 7 basic emotions from the image: angry, disgust, fear, happy, sad, surprise, and neutral. These emotion confidences are inferred directly from facial features using a deep learning model, reflecting the likelihood of multiple emotions in each frame. To describe the geometry of the face, we used standard facial landmarking techniques to extract 68 facial landmarks (landmark0 to landmark67). These landmarks cover the precise locations of facial boundaries, eyebrows, eyes, nose, mouth, etc, providing a basis for capturing expression and emotion changes. The numerical combination of these features forms a high-dimensional feature vector for further analysis and



XSL•FO
RenderX

modeling. Examples of facial behavior features are provided in Multimedia Appendix 2.

Figure 2 shows the overall architecture and data processing flow of this system. Using data from smartphone and wearable device (eg, Fitbit [Google LLC]) collected in a separate study from individuals who use cannabis [25], the system combined several explanatory AI models (eg, SHAP, SkopeRules, and counterfactual analysis) and causal analysis to generate the corresponding explanatory analysis [20-22,26]. The process involves user or clinician (hereafter: "clinician") input to the system (eg, asking the system a question), AI model processing, interpretable analysis generation, and finally, feedback provided to the user.

In order to keep track of the user's interaction history and analysis results, the system is designed with a data persistence mechanism. Each user input, system-generated response, and corresponding timestamp are recorded and stored. This not only supports the system's session retention function but also provides valuable historical data for subsequent data analysis and improvement.

Figure 2. Empathic-CDSS architecture and processes. AFEW-VA: Acted Facial Expressions in the Wild – Valence-Arousal (a publicly available dataset for affective computing); CDSS: clinical decision support system; LLM: large language model; MI: motivational interviewing; SHAP: Shapley Additive Explanations; XAI: explainable artificial intelligence.

Measures

Participants completed a structured evaluation comprising 6 dimensions: system usability [6], personalization and relevance [27], clarity and comprehensibility [5], system benefits [3], overall satisfaction [9,16], and trust and reliability [17,28]. Table 2 shows the constructs for each dimension. Each item was rated on a 10-point Likert scale (1=lowest, 10=highest). Example items include "How easy was it to interact with the system using natural language?" and "How clear and understandable were the explanations provided by the system?" The complete questionnaire is available in Table 2 and Multimedia Appendix 3.

XSL•FO
RenderX

Table 2. Survey constructs and example items.

Section	Construct measured	Example item (scale range: Likert 1-10)	References
System usability	Ease of interaction, intuitiveness, and satisfaction	"How easy was it to interact with the system using natural language?"	[6]
Personalization and relevance	Perceived individualization of system insights	"To what extent did you feel the insights were personalized to patient data?"	[27]
Clarity and comprehensibility	Understandability of explanations and visuals	"How clear and understandable were the explanations provided by the system?"	[5]
System benefits	Perceived usefulness and outcome impact	"How beneficial do you believe the insights were in improving understanding of patient health behaviors?"	[3]
User satisfaction	Satisfaction	"How satisfied are you with the overall quality of the insights and recommendations provided by the system?"	[9,16]
Trust and reliability	Trust and perceived reliability	"Please rate the perceived trustworthiness of this system in meeting your needs."	[17,28]

Data Collection

Cannabis Use Data from "Patients"

We used the AWARE framework app [29] to track cannabis users' smartphone sensor data, such as GPS and accelerometer, alongside Fitbit Charge 2 data for heart rate and step count. The data were analyzed to identify patterns of cannabis use, with physiological and behavioral data segmented into 5-minute intervals. Key statistics, such as heart rate and step count, were extracted to evaluate cannabis intoxication. Events were classified into "intoxicated" and "not intoxicated" to test the system's ability to predict and interpret behavioral outcomes from sensor inputs [25]. These ground truth labels were obtained through daily ecological momentary assessment reports, where participants self-reported their current intoxication status upon receiving a prompt on their smartphone. This dataset comprises passively collected smartphone and wearable device data linked to self-reported cannabis intoxication episodes. After preprocessing, the data were segmented into annotated samples representing intoxicated and nonintoxicated states. As the data was gathered in natural settings, the class distributions reflect real-world reporting patterns rather than artificially balanced designs. To ensure model training consistency and robustness, standard preprocessing steps were implemented, including normalization, missing value handling, and participant-level modeling.

User Chat Data With the CDSS

For the chat data, user interactions, and generated responses with the CDSS were logged in Google Sheets (Google LLC). The data were structured with fields for email, timestamp, role (clinician or CDSS assistant), and content [30]. This structure allows for persistent storage of conversation history, which can be retrieved and used to maintain context in the ongoing session.

Data Analysis

Quantitative

The quantitative data for this study were derived from clinical practitioners' ratings of the systems on a 1-10 Likert scale following their experience with both the baseline-CDSS and empathic-CDSS. The rating scale encompassed multiple dimensions, including system usability, personalization and relevance, clarity of explanations, system benefits, user satisfaction, and trust and reliability. As the same group of users evaluated both systems, paired *t* tests were conducted for each questionnaire item to assess differences between the empathic-CDSS and baseline-CDSS scores. For each item, the program automatically aligned valid paired samples across both systems, calculating the mean score, SD, *t* statistic, and *P* value for both empathic-CDSS and baseline-CDSS.

Qualitative

Open-ended questions in the questionnaire were collected under the empathic-CDSS condition to supplement users' subjective experiences and perceptions of the system. These responses to open-ended questions primarily serve a descriptive purpose and summarization, aiding discussions of quantitative findings by illustrating how users interpret the system's explanatory approaches, personalized presentations, and emotion-adaptive behaviors.

ML or System Evaluation

At the natural language processing and dialogue generation level, both systems support users posing questions to the CDSS using natural language. The system first performs semantic parsing of user input, mapping natural language into retrieval requests for backend models and data stores. It extracts intent categories and slot information related to patient timeframes and metric types. Empathic-CDSS further incorporates sentiment analysis and emotion-adaptive modules. It uses a sentiment classifier based on pretrained language models to identify emotions in input text, outputting sentiment polarity and coarse-grained emotion categories (eg, neutral, confused, and concerned) as additional conditions for dialogue planning. Subsequently, the dialogue generation module integrates backend ML predictions, XAI explanations (eg, SHAP feature contribution rankings, key curves, and temporal trend charts), and sentiment analysis signals to generate responses that align with model outputs while adapting to the user's current emotional state: when detecting higher uncertainty or stress, the system uses more step-by-step, detailed explanatory structures and a more supportive tone; while using more concise, summary-style answers during neutral or positive emotional states. Baseline-CDSS uses the same cannabis intoxication prediction and XAI pipeline but presents results in a uniform,

XSL•FO
RenderX

nonemotion-adaptive format, excluding sentiment analysis or linguistic style adaptation. XAI model reliability is evaluated by separating smoking session data, with a portion used for model testing and the remaining samples for model training. Predictions are validated within retained sessions to ensure stable personalized performance, thereby enabling interpretable generation for CDSS.

Model of Emotion Valence and Arousal

We constructed an efficient model training framework for multiclassification problems with dual labels. All samples in the dataset were labeled, and the objective was to improve the training efficiency and generalization ability of the model while ensuring classification performance. Due to the large size of the training set, using all samples directly may cause the model to be disturbed by redundant information during the learning process. Therefore, we systematically designed the model training process through cross-validation (5-fold cross-validation) and feature preprocessing to improve model performance and robustness.

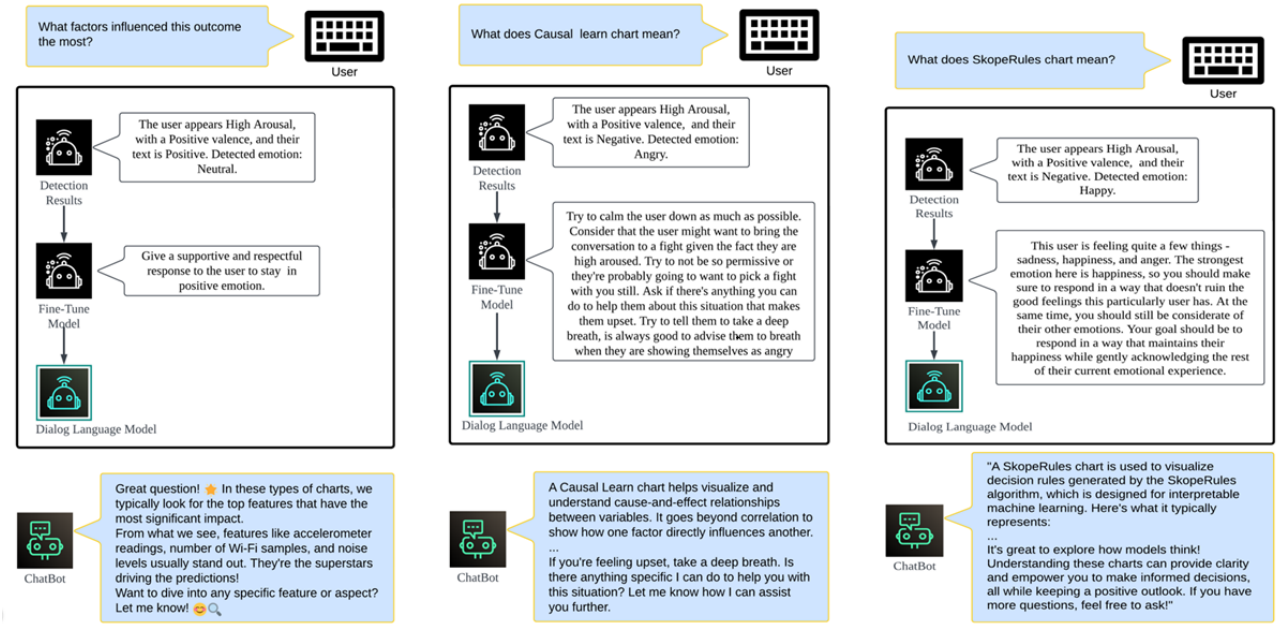
In the data preprocessing stage, we cleaned and converted missing values, nonnumeric fields, and coordinate-type features in the data. Coordinate information was parsed from string format into numeric vectors and expanded into separate feature columns. Subsequently, we standardized all input features to eliminate the influence of different units of measurement and ensure that the model had stable gradients and convergence speed during training.

This study used a multitask neural network (multitask neural network structure) [31] to simultaneously perform 3-class classification prediction for 2 emotion dimensions, valence (negative, neutral, and positive) and arousal (low arousal, neutral, and high arousal) [32]. This structure introduced shared hidden layers, enabling the model to share representation learning between 2 related tasks, thereby improving training efficiency and enhancing generalization ability.

The shared feature extraction part consists of 2 fully connected networks, combined with batch normalization, ReLU (rectified linear unit; an activation function commonly used in deep learning models, including facial recognition systems) activation functions, and dropout, which can effectively enhance the model's expressive ability while reducing the risk of overfitting [33]. The 2 output branches use independent fully connected layers to predict the arousal and valence labels, respectively.

During training, we used the cross-entropy loss function [34] to supervise each output branch. The final optimization objective was the weighted sum of the 2 losses, expressed as follows: $L=\lambda_1 L_{(Arousal)}+\lambda_2 L_{(Valence)}$, $L_{(Arousal)}$ and $L_{(Valence)}$ represent the cross-entropy losses for arousal and valence, respectively. This structure demonstrates robust performance and classification accuracy when handling 2 emotional label tasks simultaneously.

We used the Adam optimizer to minimize this loss function during training [35]. The model updates parameters through backpropagation and iteratively optimizes the performance of the 2 tasks. This structure demonstrates good efficiency and performance in multilabel multiclassification problems, capturing both shared information between tasks and task-specific discriminative features.



Fine-Tuning Model and Dual Language Model Architecture

To achieve more empathic and context-aware responses, the system uses a dual language model architecture that leverages both a standard GPT-4 model [36] and a fine-tuned GPT-4 model [37]. All LLM functionalities in this study, including standard GPT-4 calls and model fine-tuning, were implemented via the official application programming interfaces provided by OpenAI. This design ensures that the system combines XAI analysis with emotional context for a comprehensive and user-centered interaction. The first language model is the standard GPT-4, which is used to process the output generated by the XAI component. The model interprets the results of XAI analyses, such as feature importance, counterfactual reasoning, or causal inference graphs, and extracts key insights. The second language model is a fine-tuned GPT-4 that has been specifically trained using an MI dataset [23]. This MI dataset provides the basis for equipping the model with the ability to recognize and respond to users' emotional states. The fine-tuning process enables the model to generate responses that adhere to the principles of communicating empathy and support, based on the results of the sentiment analysis. This is crucial for building engagement into the interaction.

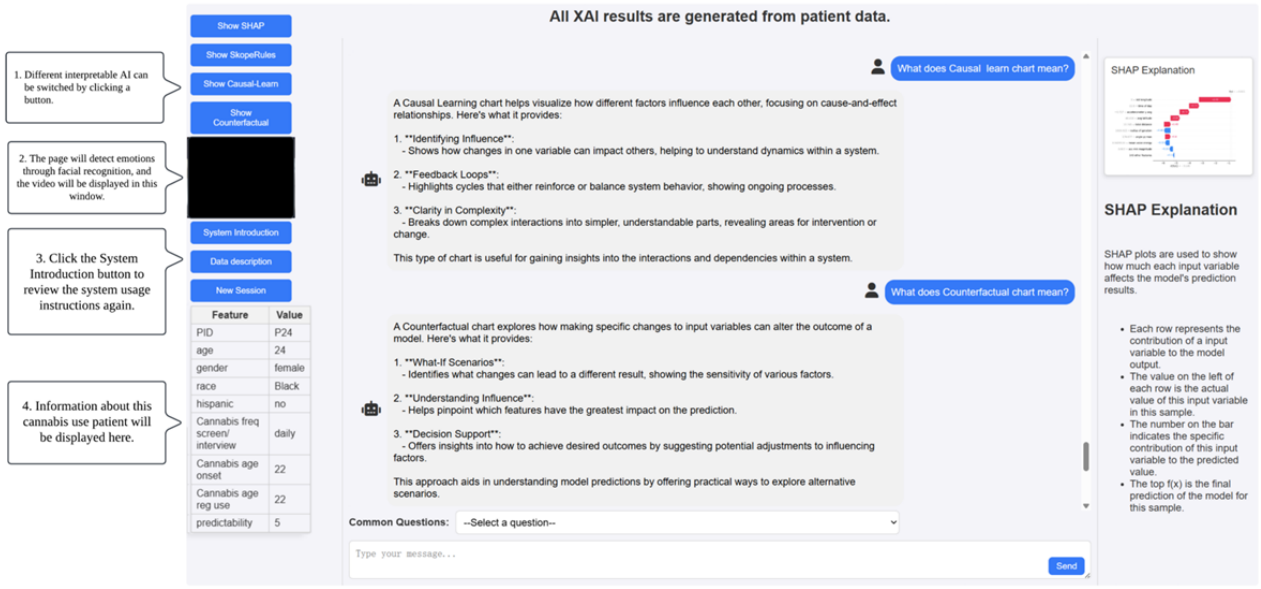
The fine-tuning process included preprocessing the dataset to ensure data quality and compatibility with the GPT architecture. Noise was eliminated, annotations of emotional states were aligned, and tokenization was optimized to preserve empathetic communication. These steps enabled the model to learn conversational patterns that emphasize understanding, validation, and support. Through this process, the model generates responses that match the user's psychological needs based on the emotional valence and arousal, as well as the sentiment of the user's text. The fine-tuning process focuses on enabling the model to recognize subtle emotional cues in user input and generate responses that adhere to the principles of empathy and support. By incorporating real-world patterns of conversation from the MI dataset, the system learns to address the user's concerns in a compassionate manner, which promotes engagement. This fine-tuning approach enhances the system's ability to dynamically adapt to different emotional contexts, ensuring that the user not only receives accurate explanations, but also emotionally resonant responses that make interactions more human-centered. Fine-tuned by integrating a corpus of MI data, the system now strikes a good balance between empathetic communication and clear explanations. This approach not only improves the user's experience but also reinforces the trustworthiness of the system as an XAI interaction. The system integrates multiple high-level components, including emotion recognition and natural language processing models, to achieve its core functionality. One model detects the user's emotional state through a combination of text sentiment analysis and facial expression recognition. Then, another model generates personalized and context-aware responses based on the detected emotion, as shown in Figure 3.

XSL•FO
RenderX

Figure 3. Examples of emotion detection language model.

Dialog System

The system provides an intuitive way to present complex data analyses directly to the user. Data tables are presented visually in the interface, eliminating unnecessary navigation steps. To facilitate understanding, the contents of these tables are displayed immediately without additional manipulation. The system automatically converts the analyzed data into visualizations such as SHAP plots, cause-effect plots, and rule interpretation plots. These graphical outputs greatly enhance the clarity of the information, while the images are encoded in base64 and embedded in the web page to enrich the visual experience [38]. Each table is accompanied by a detailed explanation, including the names of the features and their respective importance or influence. In addition, the system can seamlessly convert the XAI results in the data table into images and embed them in the user interface. This approach not only improves the readability of the data, but also helps the user understand the analysis results in a more intuitive way. The system interface is shown in Figure 4.



The system allows users to interact via a natural language interface, and each message is subject to a multistep sentiment analysis. The system uses 3 different mechanisms to assess the emotional state of the user. First, the sentiment of the input text is analyzed and classified as positive, negative, or neutral. At the same time, when the camera is active under the empathic-CDSS condition, facial expression recognition is used to assess the visible emotions of the user. In addition, indicators of emotional valence and arousal are calculated to capture the intensity and type of emotion, providing a comprehensive understanding of the user's emotional context.

We use a dual model architecture to process the results of 3 sentiment analysis methods (text sentiment, facial expression recognition, and value arousal indicators). The fine-tuned model only receives the sentimental results and generates preliminary analysis and corresponding response guidance based on these results. This response guidance is then passed to the GPT model, which takes the user's question and analysis results as input to generate the final response. This step-by-step approach ensures that the generated response is not only consistent with the sentiment context, but also effectively explains the XAI output in a user-friendly and sentiment-intelligent manner.

To improve the quality of the interaction, the system keeps a detailed dialog history and ensures that the conversation is consistent. The system can adapt its responses based on previous exchanges, making the interaction more personalized and meaningful. Finally, the system presents feedback through a combination of text, visuals, and emotion summaries. These outputs not only provide explanations for the model's decisions but also include explanatory images or diagrams to help the user understand the system's behavior intuitively. By integrating text sentiment analysis, facial expression recognition, and value arousal metrics, the system can respond in a user-centered manner.

Results

Performance of Personalized Models for Predicting Cannabis Intoxication

We first assessed the performance of the personalized predictive model designed to estimate cannabis intoxication. To approximate real-world prediction conditions, we used a personalized evaluation strategy in which self-reported cannabis intoxication from selected individuals served as the prediction target. A total of 3 representative cannabis users were selected, and an individualized model was trained and evaluated for each user. For each model, 1 day of self-reported "cannabis use" was used as the test set, while all remaining historical data served as the training set.

Across all 3 users, the personalized models demonstrated strong predictive capability, achieving F_1-scores exceeding 70% in independent tests. These results indicate that the models effectively captured individual behavioral patterns and generated reliable predictions of future intoxication states. The prediction outputs and corresponding XAI explanations from these tests were subsequently incorporated into the CDSS interface presented to users during the comparative evaluation of the basic and empathic systems.

Affective Sensing Model Performance

We next evaluated the performance of the emotion-perception component of the system. Using the AFEW-VA (Acted Facial Expressions in the Wild – Valence-Arousal [a publicly available dataset for affective computing]) dataset [39], we conducted 5-fold cross-validation to assess arousal and valence prediction accuracy. As summarized in Table 3, the model achieved strong overall performance across folds. For arousal prediction, the model achieved an average F_1-score of 0.75 (SD 0.0086) and an accuracy of 88.16% (SD 0.0020). For valence prediction, the average F_1-score was 0.70 (SD 0.1173), with an accuracy of 74.39% (SD 0.0075).

To deploy the affective sensing module within the empathic-CDSS, we selected the best-performing model fold based on overall cross-validation metrics. The detailed performance of this selected fold is presented in Table 4.

As shown in Table 4, the selected model achieved an F_1-score of 0.75 with an accuracy of 88.03% for arousal prediction, and an F_1-score of 0.71 with an accuracy of 74.78% for valence prediction. These metrics confirm the effectiveness and reliability of the affective sensing module integrated into our empathic-CDSS.

Table 3. Average performance metrics of the affective sensing model.

Metrics	Arousal	Valence	Average (SD)
F_1-score	0.75	0.70	0.73 (0.035)
Precision	0.82	0.74	0.78 (0.057)
Recall	0.70	0.68	0.69 (0.014)

Recall	0.71	0.70	0.71 (0.007)
AUC[a]	0.93	0.87	0.90 (0.042)
Accuracy (%)	88.03	74.78	81.41 (9.37)

[a]AUC: area under the curve.

Overall System Performance

We systematically evaluated our emotion-aware approach, which integrates continuous valence-arousal modeling with LLM-based dialog generation. The results indicate that the use of continuous affective representations substantially improves the system's ability to detect, interpret, and respond to subtle user sentiments during real-time interactions. Compared with traditional classification-based models, our approach enabled more contextually appropriate, emotionally consistent, and empathetic responses.

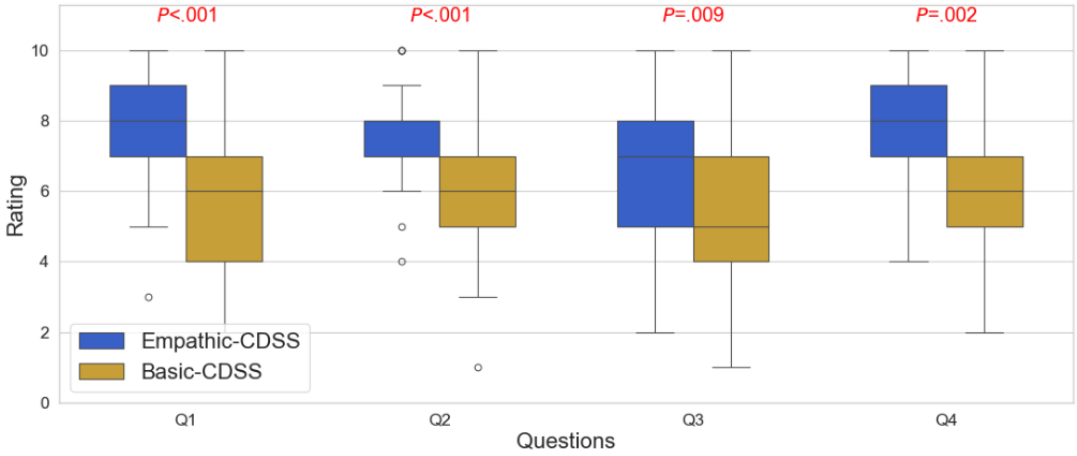
User feedback also confirmed smoother conversational flow, fewer emotionally inconsistent replies, and improved alignment with user intent. Unlike conventional affective models that depend on fixed emotion categories, our system adapts dynamically to changes in user emotional state, leading to more natural and personalized interactions.

Quantitative Comparison Between Systems

Multimedia Appendix 3 outlines the evaluation areas included in this study. To quantify differences between the empathic-CDSS and the basic CDSS, we conducted paired-sample *t* tests for all questionnaire items, reflecting within-participant comparisons between the 2 system conditions (Table 5).

XSL•FO
RenderX

Table 5. Comparative results across usability and perception metrics between the empathic- and basic-CDSS conditions. All *P* values follow JMIR formatting guidelines; *P*<.001 denotes highly significant differences at the α=.05 level.



Dimension and question	Empathic mean (SD)	Basic mean (SD)	*t (32)*	*P* value
System usability				
Q1	8.00 (1.64)	6.12 (2.25)	4.178	<.001
Q2	7.73 (1.38)	5.88 (2.07)	4.245	<.001
Q3	6.67 (2.35)	5.21 (2.32)	2.784	.009

User satisfaction				
Q1	7.76 (1.20)	5.85 (2.00)	4.357	<.001
Q2	7.64 (1.43)	6.06 (2.00)	3.859	<.001
Trust and reliability				
Q1	7.85 (1.20)	5.91 (1.59)	5.329	<.001
Q2	7.79 (1.17)	6.12 (1.62)	5.133	<.001

System Usability

As shown in Figure 5, the empathic-CDSS demonstrated significantly higher usability across all items. For example, users rated the ability to “interact with the system using natural language” higher for the empathic-CDSS (mean 8.00, SD 1.64) compared with the baseline system (mean 6.12, SD 2.25; *P*<.001). Significant improvements were also observed for interface intuitiveness (Q2), response time satisfaction (Q3), and accurate data interpretation (Q4; all *P*<.05). These findings suggest that incorporating emotional-perception feedback results in smoother, more natural clinician-AI interactions.

XSL•FO
RenderX

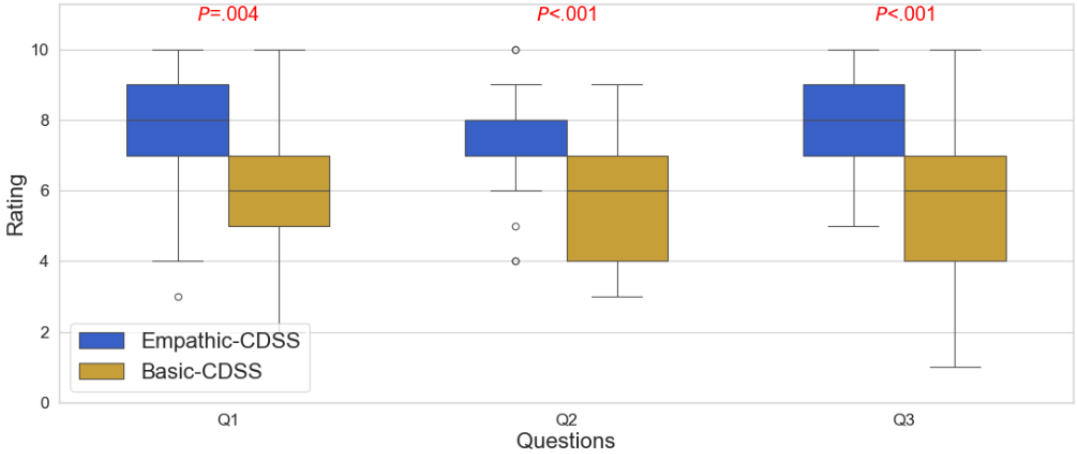

Figure 5. Comparative results across system usability. CDSS: clinical decision support system.

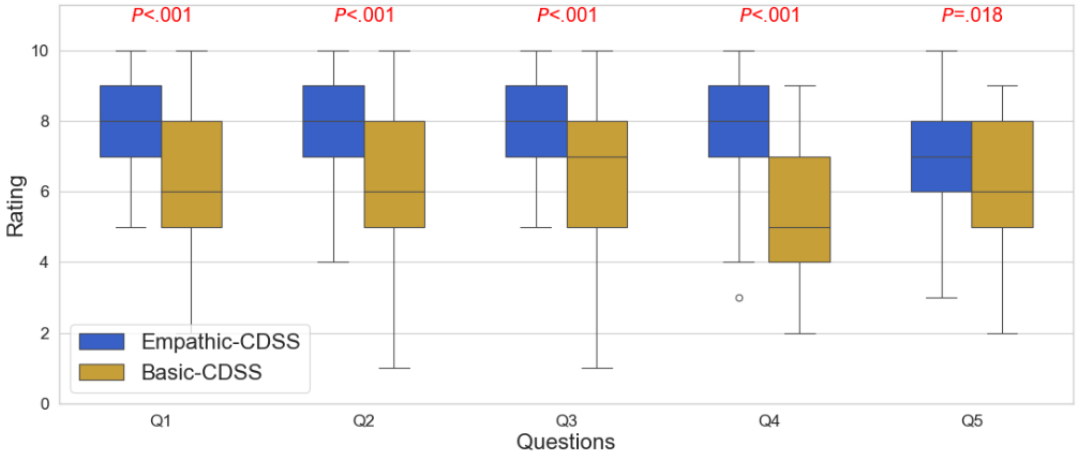
Personalization and Relevance of Insights

The empathic-CDSS also outperformed the baseline system in personalization and relevance (Figure 6). For example, users rated the system's ability to consider the patient's current condition significantly higher (mean 7.64, SD 1.41 vs 5.73, SD 1.97; *P*<.001). The empathic-CDSS also showed superior performance in handling missing information and referencing appropriate individual-level data (eg, Q5: 7.15 vs 6.12; *P*=.02). These results highlight improved adaptability to patient-specific information and more accurate context-aware responses.

Figure 6. Comparative results across personalization and relevance. CDSS: clinical decision support system.



Clarity and Comprehensibility of Explanations

The empathic-CDSS achieved significantly higher scores (overall mean 7.77, SD 0.49 vs 6.19, SD 0.41) in clarity and comprehensibility compared to the baseline (Figure 7). Participants rated the clarity of explanations provided by the system significantly higher (mean 8.09, SD 1.53, vs 6.39, SD 2.00; *P*<.001). Specifically, the transition from raw technical SHAP data to LLM-generated plain-language narratives helped clinicians better grasp the causal reasoning behind the model's predictions.

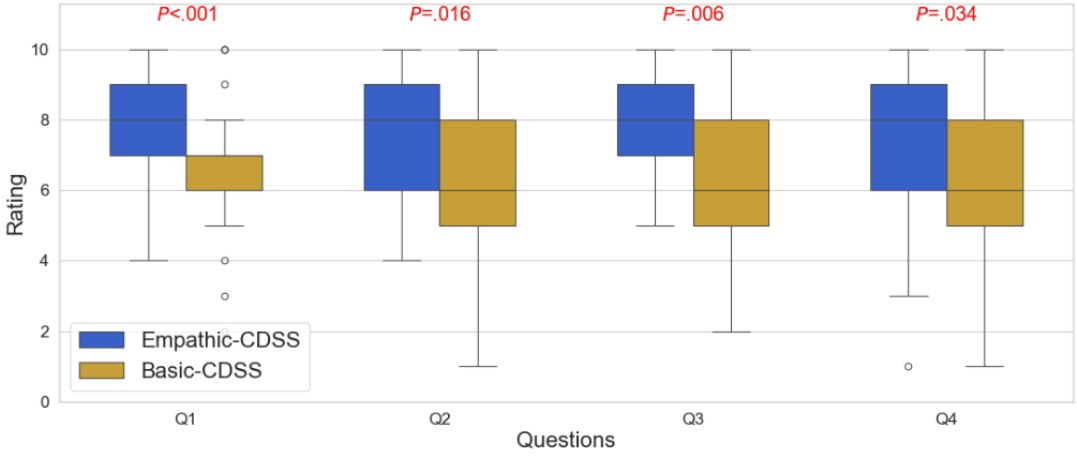

Figure 7. Comparative results across clarity and comprehensibility. CDSS: clinical decision support system.

System Benefits

As shown in Figure 8, the optimized model showed significant advantages across all 4 benefit-related metrics. Participants rated the system as more helpful for understanding patient health behaviors (Q1: mean 8.03, SD 1.38, vs 6.61, SD 1.78; *P*<.001). They were also more likely to recommend the system to others (Q3; *P*=.006). The optimized system further reduced misinformation (Q4), reflecting improvements in output accuracy and clarity.

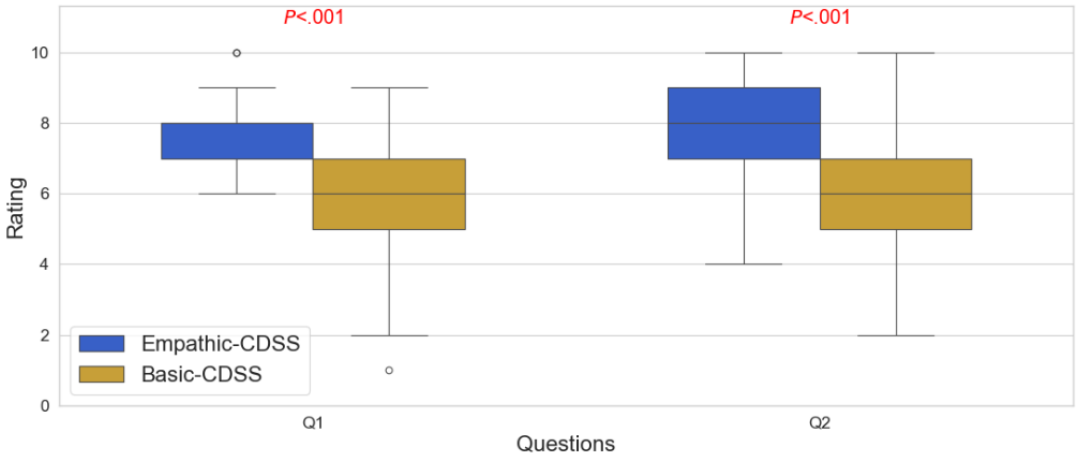
Figure 8. Comparative results across system benefits. CDSS: clinical decision support system.

User Satisfaction, Trust, and Reliability

The empathic-CDSS consistently achieved higher satisfaction, trust, and reliability scores (Figures 9 and 10). All satisfaction-related differences were statistically significant (all *P*<.001). For example, users reported a higher likelihood of continued system use (mean 7.76, SD 1.20, vs 5.58, SD 2.00). Trust-related items also favored the empathic-CDSS, with scores above 7.7 on trustworthiness and overall reliability, compared with approximately 6.1 for the baseline model.

XSL•FO
RenderX

Figure 9. Comparative results across user satisfaction. CDSS: clinical decision support system.



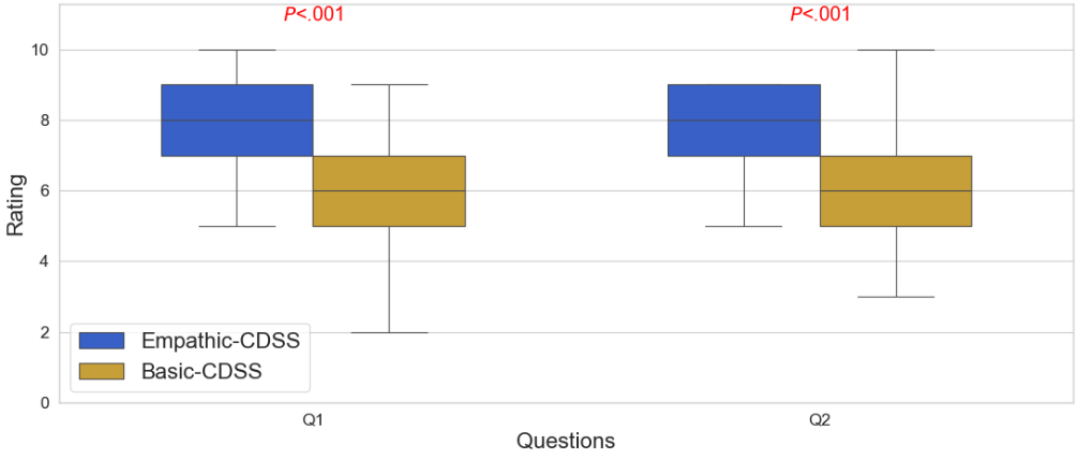


Figure 10. Comparative results across trust and reliability. CDSS: clinical decision support system.

Summary of Findings

Overall, results demonstrate that the empathic-CDSS substantially outperforms the baseline system in usability, interpretability, personalization, trustworthiness, and perceived usefulness. The combination of multimodal sentiment recognition, MI-informed fine-tuning, and XAI-driven decision support significantly enhanced user experience and increased acceptance of the system. These findings emphasize the importance of human-centered AI design and highlight the value of adaptive, affective, and context-aware interactions in improving clinical decision-support performance.

System Impact on User Emotion and Stress

To assess the systems' impact on users' emotional states, we compared self-reported emotion and stress levels before and after interaction with the basic-CDSS and the empathic-CDSS. Most participants reported neutral emotions in both conditions. A small number of mood changes were observed: after using the empathic-CDSS, 1 participant (P14) reported a shift from neutral to happiness, whereas after using the basic-CDSS, 1 participant (P21) reported a shift from happiness to neutral. This same participant showed no mood change when using the empathic-CDSS.

Stress levels also showed modest differences across conditions. Under the basic-CDSS, stress increased for several participants (for example, P21 increased from 2 to 4, and P12 increased from 4 to 6). In contrast, stress levels remained stable or decreased for most participants when using the empathic-CDSS (for example, P22 decreased from 6 to 5, and P31 decreased from 4 to 3). Overall, the basic-CDSS was associated with stress increases in 4 participants and decreases in 7 participants (mean change –0.76, SD 1.51). The empathic-CDSS produced only 1 stress increase, with a similar mean reduction (–0.84, SD 1.73), and stress remained unchanged for most participants.

Summary of Qualitative Feedback

Users provided generally positive feedback regarding the system's interactivity, natural language capabilities, and clarity of explanations. Many participants highlighted the system's ability to support conversational flexibility and deliver rapid, data-driven insights. For instance, P10 praised the system's natural dialog style, noting: "Any question can be asked, and the system appears to understand." Similarly, P11 commented that the system "can provide clear and data-driven insights based on the user's question," emphasizing trust in its analytical outputs.

Despite this positive reception, users also identified limitations related to explanation depth and interpretability. P11 remarked

XSL•FO
RenderX

that "the explanations are not very detailed," and P13 noted that "the decision path is a bit confusing," suggesting that the clarity of complex decision pathways could be enhanced. Additionally, P14 observed that "the sentiment seems to affect the output by a large margin," indicating that the weighting of the sentiment module may at times overly influence the system's responses, an important design consideration for future refinement.

Participants also suggested specific interface and usability improvements. For example, P12 recommended adjusting button colors for better visibility, while P13 expressed a desire for a more readable output structure to improve comprehension of results. Despite these suggestions, users consistently recognized the system's potential value. P11 highlighted that the empathic-CDSS's "step-by-step recommendations" offer clear guidance, and P10 suggested that the system "may assist in improving care for a patient." Regarding the XAI component, P14 stated: "The ability to understand how the model makes a decision is helpful for patients and doctors." This feedback reflects users' cautious optimism—while acknowledging areas for improvement, they recognize the importance and usefulness of transparent explanation in clinical decision support.

Discussion

Principal Findings

This study shows that the proposed empathic-CDSS, which integrates multimodal emotion perception with adaptive empathic response generation, outperformed the baseline CDSS that lacked emotion-awareness of the system's user. The empathic-CDSS produced higher scores in usability, clarity, personalization, trust, and user satisfaction. These improvements are consistent with prior research indicating that emotionally adaptive technologies can reduce cognitive load, improve comprehension, and enhance trust in AI systems [40-44].

Our findings confirm that empathetic adaptation significantly enhances system credibility, reliability, and user satisfaction. When systems recognize user emotional states, users report higher levels of system confidence—aligning with the need for more human-centered clinical AI. The integration of real-time emotion perception significantly enhances system usability, clarity, and comprehensibility while boosting the personalization and relevance of insights generated by the system. By dynamically aligning explanation complexity with user emotional states, the system successfully translates technical XAI outputs into interpretable, plain-language clinical insights.

Higher scores in clarity and comprehensibility (mean 8.09, SD 1.53, vs 6.39, SD 2.00, $P<.001$), with a large effect size, demonstrate the substantial impact of this approach on user understanding. This represents a meaningful improvement in clinicians' comprehension of model predictions rather than a marginal gain. These findings indicate that adaptive explanations with emotional perception not only enhance subjective satisfaction but also improve clinicians' ability to interpret AI predictions. By integrating causal reasoning outputs with plain-language explanations generated by LLMs, the system facilitates a clearer understanding of predictive logic and enhances the interpretability of AI-assisted decision-making. LLMs serve as a bridge, translating complex SHAP feature weights and technical causal graphs into narrative lay summaries, making them more accessible to clinicians without deep AI expertise. This shift from static technical visualizations to dynamic empathetic dialogue effectively mitigates the "black box" nature of clinical AI, thereby enhancing trust and reliability. Prior work, consistent with our observations, indicates that emotion-adaptive explanation strategies can improve user engagement, reduce frustration, and lower perceived cognitive load during complex analytical interactions [45-48].

This study's results are consistent with studies showing that empathic responses can stabilize emotional states and reduce interactional friction during demanding tasks [49]. Participants in our study frequently described the empathic-CDSS (vs basic system) as clearer, easier to engage with, and more understanding. These perceptions likely contributed to the significantly higher ratings of trustworthiness and reliability. Trust is widely recognized as a crucial factor for clinical adoption of AI systems [41,43].

Comparison With Prior Work

Most existing CDSS and XAI frameworks focus on improving algorithmic transparency while paying little attention to how explanations are communicated to clinicians or system users [50-52]. In many systems, explanation generation is treated as a static process that delivers identical information regardless of user context or emotional state [51,53]. Our findings challenge this assumption. Consistent with recent work in affective computing and empathy-aware conversational agents [40-42], our study demonstrates that dynamically adapting the communication style of explanations can significantly improve user comprehension and interaction quality.

Unlike earlier empathic-CDSS prototypes that relied on rule-based or predefined text responses, our innovative system incorporates real-time arousal and valence detection. These signals allow the LLM to adjust explanation complexity, tone, and pacing in response to subtle emotional changes during interaction. This novel feature addresses a key limitation of static XAI approaches, which do not respond to users' evolving cognitive or emotional states. Our findings also extend prior research by applying empathy-aware interaction to the problem of helping nontechnical users interpret machine-learning explanations, which represents a new and challenging scenario.

In addition, integrating XAI technology with emotion-aware LLM-driven communication enables more effective transmission of model reasoning processes to users. Real-time detection of emotional valence and arousal allows the system to dynamically adapt the level of detail, tone, and complexity of explanations to better match users' cognitive and emotional states. This real-time adaptive explanation strategy enhances the clarity and comprehensibility of model outputs, as reflected in higher user ratings and qualitative feedback, and facilitates smoother and more effective clinical decision support interactions. Furthermore, the strong performance of the affect recognition module supports the reliability of emotion-adaptive explanation delivery.

XSL•FO
RenderX

As a result, a key contribution of this work is demonstrating that the delivery method of explanations is as important as the content itself. This contribution provides a concrete example of how multimodal emotion perception, XAI techniques, and LLM-based communication can work together to improve user understanding.

Implications for LLM-Based Clinical Decision Support

This study also highlights a new role for LLMs in health care. LLMs can function as empathetic mediators between complex AI models and users. In addition to translating technical XAI outputs into natural language, the empathic-CDSS incorporates the user's emotional state into the explanation process. This advance aligns with emerging evidence that emotionally intelligent conversational agents can enhance trust, adherence, and perceived clarity even when system users lack technical expertise [42-44].

Our results point toward a new model of clinician-AI collaboration. In this model, intelligent systems do not merely present information but actively sense cognitive or emotional load and adjust the way information is delivered. This creates opportunities for more effective and supportive interactions, particularly in high-stakes clinical environments.

By improving interpretability, reducing interaction difficulty, and providing emotionally aligned explanations, empathic XAI frameworks such as empathic-CDSS may help lower barriers to adoption of AI tools in behavioral health monitoring and intervention settings. By enhancing trust, usability, and perceived usefulness, these systems facilitate greater acceptance among clinicians who may otherwise be hesitant to adopt complex AI-driven decision support tools.

Limitations and Future Work

Although this study achieved positive results, several limitations remain that need to be addressed in future work. First, the participant sample of system users consisted primarily of younger adults with high educational attainment, many of whom had limited or no real clinical experience. This demographic profile may not fully reflect practicing users who routinely engage with clinical decision support tools. Future studies should involve a more diverse user population, including physicians, nurses, and allied health professionals, in real-world clinical environments to evaluate performance, workload impact, and long-term adoption of CDSS. The age distribution in our sample was uneven, with no participants in the 40-49 years age group. Although no age-based exclusion criteria were applied, this gap likely reflects sampling variability given the modest sample size (N=33). As a result, findings may not fully generalize to midlife adults within this age range. Future studies with larger and more stratified samples are needed to examine potential age-related differences more comprehensively.

Second, the current system relies on commercial OpenAI application programming interfaces for emotion-adaptive response generation. Although effective for prototyping, this dependency raises concerns about response latency, the cost of large-scale deployment, and data privacy. Transmitting facial expressions and conversational content to external servers poses potential confidentiality risks even when anonymization is applied. To support future clinical translation, deployment using locally hosted or HIPAA (Health Insurance Portability and Accountability Act)-compliant open-source LLMs should be explored, along with on-device or edge-based emotion processing.

Third, while the emotion-perception module improved the clarity and smoothness of interactions overall, several users reported that empathic adjustments sometimes altered the specificity or focus of the explanations. For instance, some responses became overly supportive at the expense of addressing the clinical question directly. This suggests the need for finer control over the strength and timing of empathic behaviors. Future designs may include adjustable empathy levels, task-sensitive modes, or guardrails that ensure explanation fidelity is maintained.

Finally, emotional perception in the current system is based on facial arousal and valence estimation captured through the webcam. This approach may miss important cues such as vocal tone, hesitations, or physiological signals that often reflect cognitive load or frustration. Integrating multimodal data (for example, voice features or wearable sensor data) and developing reinforcement learning mechanisms that adapt emotion recognition based on user feedback could substantially improve model accuracy and the appropriateness of empathic responses.

Overall, these findings demonstrate both the potential benefits and limitations of integrating empathetic communication into AI-driven CDSSs. Key advantages include improved trust, enhanced understanding of model reasoning, and more effective user interaction. At the same time, these systems present important limitations, including potential variability in emotion recognition accuracy and the need to ensure that emotional adaptation does not compromise clinical precision or decision clarity in high-risk medical contexts. Future work should further refine these systems to better balance emotional responsiveness, interpretability, and clinical reliability.

Conclusions

This study introduced an empathic-CDSS that integrates a continuous valence-arousal emotion model with LLMs to support affect-aware interaction in clinical decision support. By using real-time emotional cues to guide response generation, the system is able to detect subtle affective shifts and deliver explanations that are more contextually appropriate and emotionally aligned with the clinician's affective state.

Our findings demonstrate the feasibility and value of combining emotion perception with LLM-based explanation generation. Participants rated the empathic-CDSS higher than the basic system across usability, clarity, personalization, trust, and satisfaction, highlighting the importance of emotion-aware communication in facilitating effective human-AI collaboration. This work suggests that the delivery and adaptation of explanations are as critical as their informational content, particularly when clinicians must interpret complex AI outputs under possible situations of high cognitive load and time pressure.

Overall, this research provides early evidence that emotionally intelligent conversational systems can enhance the clinician experience in AI-assisted decision-making. The integration of

XSL•FO
RenderX

valence-arousal modeling with LLMs offers a promising direction for future emotionally aware clinical AI tools, and it lays the groundwork for designing more supportive, intuitive, and human-centered conversational interfaces in health care.

Abstract

Background: Chronic obstructive pulmonary disease (COPD) is characterized by acute exacerbations that frequently result in hospitalization, highlighting the need for improved follow-up care. Hybrid care incorporates digital health strategies such as remote patient monitoring (RPM). This could offer the opportunity to detect early signs of disease worsening by remotely tracking selected health indicators. However, it is unknown how RPM can effectively be integrated into current practice.

Objective: This study aims to cocreate a theoretical hybrid COPD care pathway integrating RPM into the existing care trajectory, considering the expertise of participating care pathway stakeholders.

Methods: This 2-phase study was conducted between May and August 2025. At first, semistructured interviews were conducted with stakeholders (ie, patients and health care professionals [HCPs]) involved in COPD care to map the existing care pathway in a single tertiary care hospital in Belgium. Patients were approached during hospitalization based on predefined eligibility criteria, whereas HCPs were recruited through convenience sampling. In phase 2, patient representatives and HCPs were recruited through patient-organization networks and professional referral, respectively, using convenience sampling, and participated in separate interactive workshops. These workshops reviewed existing care pathway phases and HCP roles and explored the integration of RPM, including timing, duration, implementation, data monitoring, and follow-up responsibilities, to codevelop a theoretical hybrid care pathway. Interview and workshop data were independently reviewed by 2 researchers to extract information on care pathway elements, stakeholder roles, limitations, and proposed adaptations. Findings were organized according to the relevant care pathway phase, independently summarized and compared, with discrepancies resolved through discussion and consensus. Interview findings informed the development of an initial infographic representing the existing care pathway, which was subsequently adapted based on workshop findings to represent the proposed cocreated theoretical hybrid care pathway.

Results: In total, 10 stakeholders participated in the interviews (5 patients and 5 HCPs), and 6 stakeholders participated in the workshops (3 patient representatives and 3 HCPs). The existing COPD care pathway involves multiple stakeholders whose activities can be organized into 5 functional domains: support, treatment, medical advice, patient education, and monitoring. Stakeholders can be divided into hospital-based, community-based, or cross-setting. The workshop participants identified the need for a stakeholder dedicated to RPM activities in order to integrate RPM strategies into the care pathway. This individual could be responsible for all RPM-related activities (ie, RPM device installation, providing RPM-related education, data review, alert management, and RPM discontinuation) and could serve as the bridge between patients and physicians, ensuring close communication.

XSL•FO
RenderX

Conclusions: This study resulted in a cocreated theoretical hybrid COPD care pathway. Stakeholders highlighted the potential value of a dedicated RPM role to coordinate and deliver RPM activities as part of the COPD care pathway. Further research is needed to assess its feasibility and clinical applicability.

KEYWORDS

care pathway; chronic obstructive pulmonary disease; COPD; digital health; hybrid care; remote patient monitoring

Introduction

Chronic obstructive pulmonary disease (COPD) is a progressive respiratory condition characterized by recurrent episodes of acute symptom worsening, known as acute exacerbations of COPD (AECOPD) [1]. These are defined as "an event in the natural course of the disease characterized by a change in the patient's baseline dyspnea, cough, and/or sputum that is beyond normal day-to-day variations, is acute in onset, and may warrant a change in regular medication in a patient with underlying COPD" [1]. While approximately 18% to 33% of patients with COPD Global Initiative for Chronic Obstructive Lung Disease stage 3 or 4 are hospitalized at least once per year, rehospitalizations represent an even greater challenge [2]. A large cohort study of 15,191 patients with AECOPD reported that 35.1% of patients hospitalized for AECOPD were readmitted within 90 days [3]. AECOPD is not only a leading cause of costly emergency room (ER) visits and hospitalizations but is also associated with poor quality of life [4].

Effective management of COPD, especially during and after AECOPD events, requires coordination across multiple care settings, patient engagement, and timely intervention. Care pathways represent a potential organizational strategy for achieving these aims [5]. A care pathway can be defined as a complex intervention for the mutual decision-making and organization of a care process for a well-defined group of patients during a well-defined period [5]. Their use offers the advantages of standardizing best practice, streamlining care processes, and providing a structural framework for collaboration between care pathway stakeholders [6]. Additionally, in COPD, care pathways have shown the potential to reduce complications, readmissions, and length of stay [7]. Given that no globally established guidelines exist for structured COPD care, clinical practice differs between centers and countries [8].

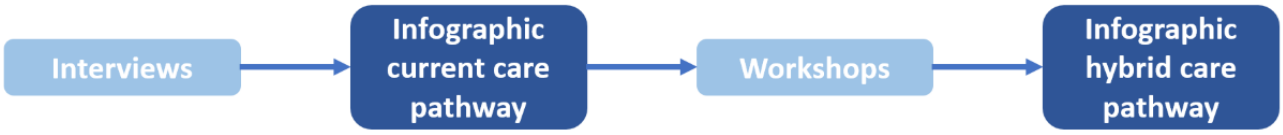
Hybrid care, which combines traditional in-person care with digital health modalities such as remote patient monitoring (RPM), is being increasingly adopted across various health care domains. Evidence suggests that hybrid approaches can enhance access, patient engagement, and continuity of care, particularly in the management of chronic diseases [9-11]. In addition, they may offer a scalable solution to reduce ER visits and exacerbation-related readmissions in patients with COPD [12]. Despite the growing adoption of hybrid care models, evidence on how to effectively integrate hybrid care components into existing care pathways remains limited. Furthermore, it is unclear how these pathways should be adapted to ensure that quality, safety, and coordination are maintained [11].

The aim of this descriptive co-design study was to (1) map the current COPD care pathway, including stakeholder role delineation and perceived bottlenecks, and (2) cocreate a theoretical hybrid care pathway for patients with COPD after an AECOPD event, incorporating digital health strategies based on stakeholder perspectives.

Methods

Study Design: 2-Phase Design

A 2-phase descriptive co-design approach was used to develop a theoretical hybrid COPD care pathway incorporating digital health strategies. Semistructured interviews and interactive workshops were conducted with patients with COPD, patient representatives of COPD, and health care professionals (HCPs) involved in COPD care at a tertiary care center and its regional care network in Belgium. The study specifically targeted people who experience COPD exacerbations, defined as individuals experiencing AECOPD who required hospitalization.



Data collection occurred in consecutive phases. Recruitment continued until sufficient information had been obtained to support the mapping of the care pathway. Information sufficiency was assessed at the level of the overall care pathway rather than within each individual stakeholder group. Recruitment continued until the interviews consistently confirmed previously identified care pathway elements and did not substantially contribute new information relevant to the study's focus. For stakeholder groups represented by multiple participants, consistency of information across interviews was considered when assessing whether additional interviews were likely to contribute new pathway elements. Groups represented by a single individual were considered specific informants because of their distinct roles and expertise in COPD care or hybrid care. In these interviews, information sufficiency could therefore not be assessed through within-group repetition. Instead, their contributions were assessed in relation to the broader pathway information obtained from other participants and their specific relevance to the pathway components with which they were involved.

Both interviews and workshops were conducted by a postdoctoral researcher (FW) with a PhD in Biomedical Sciences, accompanied by a second researcher (RK), who took field notes and digitally recorded the sessions. Both researchers had a background in digital health research. They had no direct clinical care relationship with the participants. Sessions were audio-recorded with participant consent, and recordings were destroyed following manual, clean verbatim transcription. Participant checking was not performed.

XSL•FO
RenderX

In the first phase, semistructured interviews were conducted to gather the perspectives of both patients and care pathway stakeholders on the existing COPD care pathway. Insights from these interviews informed the visual representation of the care pathway in the form of an infographic. In the second phase, this infographic was used as a guide during the workshops. A new theoretical hybrid care pathway was developed, informed by stakeholder expertise. This new hybrid care pathway was again visualized in the form of an infographic (Figure 1).

Figure 1. Study design.

This study adhered to the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines [13]. The COREQ checklist is provided in Multimedia Appendix 1.

Phase 1: Interviews

Recruitment

Eligible interview participants included patients hospitalized due to AECOPD and HCPs involved in COPD management or RPM. Patient selection was based on predefined inclusion and exclusion criteria. All patients had a confirmed diagnosis of COPD by spirometry (Tiffeneau index <0.7) and a history of multiple AECOPD events, including hospitalization due to AECOPD within the preceding year. Patients hospitalized due to AECOPD at Ziekenhuis Oost-Limburg were screened for eligibility by DR. Eligible patients were approached in order of hospital admission. HCPs were eligible if they were actively involved in the care of patients with COPD and had at least 2 years of experience in COPD care. HCPs were identified based on their active involvement in COPD care and selected to represent different professional roles in the COPD care pathway. Potential participants were identified through professional contacts within the clinical networks and contacted by email with an invitation to participate. Recruitment therefore followed a convenience sampling approach based on the accessibility and willingness of eligible HCPs to participate. Eligible HCPs included all professionals actively involved in the care of patients with COPD (ie, pulmonologists, physiotherapists, occupational therapists, and a dedicated COPD nurse) and did not have to be associated with Ziekenhuis Oost-Limburg. To support the development of a hybrid care pathway, an additional interview was conducted with a telemonitoring nurse from Ziekenhuis Oost-Limburg who had extensive experience in implementing hybrid care in the Cardiology department.

Interview Procedures

Semistructured, face-to-face, one-on-one interviews were conducted to explore the perceptions of patients and HCPs regarding the current COPD care pathway. All interviews were carried out by the same researcher to ensure consistency. Interview guides were developed by FW by first identifying the information required from each participant group to map the existing COPD care pathway. Questions were then formulated to address the relevant experiences, roles, and perspectives of each group. Separate guides were developed for patients, physicians, occupational therapists and physiotherapists, the COPD nurse, and the RPM nurse. The guides consisted of open-ended questions covering relevant aspects of COPD care and were tailored to the specific roles and experiences of each participant group. Because the study involved RPM using digital technology, additional questions were asked to evaluate participants' digital literacy. The interview guides for patients, physicians, occupational therapists and physiotherapists, COPD nurses, and RPM nurses are provided in Multimedia Appendices 2-6, respectively.

Prior to each interview, patients were informed that the purpose of the study was to explore their experiences and perceptions of the care they received following previous hospitalizations. For HCPs, the goal was to gain insights into their professional roles and perspectives on the COPD care pathway. Interviews used open-ended questions organized into categories, including postdischarge treatment, follow-up, perceived bottlenecks, symptoms, involvement of informal caregivers, and potential areas for improvement in care. All interviews were conducted at the tertiary care center Ziekenhuis Oost-Limburg in Genk, Belgium.

Data Analysis

Interview transcripts and accompanying field notes were reviewed independently by FW and RK. Each researcher reviewed the transcripts and notes to identify information relevant to the existing COPD care pathway at Ziekenhuis Oost-Limburg, focusing on (1) the different phases of care, (2) the stakeholders involved in each phase, (3) the actions and responsibilities of each stakeholder, (4) perceived limitations or bottlenecks in the current care pathway, and (5) suggestions for improving current care processes. Formal qualitative coding was not performed; instead, relevant information was systematically extracted and organized according to the corresponding phase of the care pathway. Each researcher subsequently developed an independent summary of the identified care pathway elements and stakeholder perspectives. These summaries were compared to identify areas of agreement and discrepancy. Discrepancies were discussed by FW and RK until consensus was reached. The resulting synthesis was used to construct the initial infographic representing the existing COPD care pathway, including different phases, involved stakeholders, and their respective actions and responsibilities. Illustrative quotes were selected to reflect the identified perspectives and provide examples of the findings.

Phase 2: Workshops

Recruitment

Eligible workshop participants included Dutch-speaking representatives of patients with COPD, informal caregivers of

XSL•FO
RenderX

patients with COPD, and HCPs. Patient representatives were selected over hospitalized patients to provide perspectives informed by broader experiences with COPD and health care services, rather than experiences based solely on individual clinical status or hospitalization history. In addition, through their ongoing activities and interactions with other people living with COPD, they are exposed to a variety of patient experiences and perspectives beyond their own. Patient representatives were members of COPD vzw, a Flemish organization representing patients with COPD. Representatives were contacted by email and invited to participate in the workshop. Workshop HCPs were eligible if they were actively involved in the care of patients with COPD and had at least 2 years of experience in COPD care. HCPs were identified based on their active involvement in COPD care and selected to represent different professional roles in the COPD care pathway. Participants were invited by email and recruited using a convenience sampling approach. To maximize data richness and encourage honesty about challenges, separate workshops were organized for patient-side stakeholders and HCPs.

Workshop Procedures

Each workshop was an interactive, semistructured session designed to engage participants in collaboratively considering the implementation of digital health solutions within the current COPD care pathway. After the study objectives were introduced, participants reviewed and verified care pathway phases and HCP roles. Next, participants discussed the infographic representing the current care pathway and explored transitions toward a hybrid model. In this hybrid model, RPM was introduced by the researchers as a nonintrusive wearable device (eg, a smartwatch) capable of measuring multiple vital parameters. Specific devices, parameters, and alert protocols were not further explored. Discussion topics included role delineation, stakeholder responsibilities, the period of remote monitoring, the integration of remote monitoring into routine COPD care, and potential hurdles to implementation. The workshop guides for HCPs and patient representatives are provided in Multimedia Appendix 7.

Data Analysis

Workshop transcripts and notes were independently reviewed by FW and RK using a descriptive approach similar to that used with the interviews. The analysis focused on proposed changes to the existing care pathway and the integration of RPM and other digital health strategies, including (1) changes in stakeholder roles and responsibilities, (2) communication and follow-up processes, (3) monitoring activities, and (4) points of interaction between stakeholders. Formal qualitative coding was not performed; instead, relevant information was systematically extracted and organized according to the corresponding phase of the care pathway. FW and RK independently developed descriptive summaries of the proposed adaptations and compared their findings. Discrepancies were discussed and resolved through consensus. The agreed findings were then mapped onto the initial infographic to identify which components of the existing pathway should be retained, modified, added, or removed. This iterative process resulted in a second infographic representing the proposed theoretical hybrid COPD care pathway. Illustrative quotes were selected to reflect the identified perspectives and provide examples of the findings.

Statistical Analysis

Data processing and statistical analysis were performed using R (version 4.6.0; R Foundation for Statistical Computing, Vienna, Austria). Descriptive statistics are presented as mean (SD) or number (%), as appropriate.

Ethical Considerations

The study protocol complied with the principles of the Declaration of Helsinki and was approved by the medical ethics committee (ie, Ziekenhuis Oost-Limburg, Genk, Belgium; B3712025000001). Written informed consent was obtained from all participants prior to data collection.

Results

Participant Characteristics

Participants were recruited between May and August 2025. A total of 5 patients with COPD and 5 care pathway stakeholders were approached for the interviews. As no participants declined the invitation, 5 patients with COPD and 5 care pathway stakeholders participated in the interviews (Table 1). The interviews with patients lasted 11.8 (range 8.0-32.3) minutes, and those with stakeholders lasted 23.2 (range 15.3-45.3) minutes. For the workshops, 3 patient representatives and 3 HCPs were invited. No participants declined the invitation. Workshops with patient representatives lasted 1 hour 38 minutes, and workshops with HCPs lasted 1 hour 28 minutes. One patient representative was also active as an informal caregiver. None of the interviewees took part in the workshops. All HCPs reported daily internet use, and 4 out of 5 reported daily smartphone use, compared with 2 out of 5 and 1 out of 5 patients, respectively. Only 1 HCP received data from wearables or remote monitoring, whereas none of the patients did.

Table 1. Characteristics of the interview and workshop participants.

Characteristic	Interview		Workshop	
	Patient (n=5)	HCP[a] (n=5)	Patient representative (n=3)	HCP (n=3)
Age (years), mean (SD)	65.0 (4.1)	38.6 (14.5)	71.7 (3.1)	53.3 (14.2)
Male, n (%)	3 (60)	2 (40)	2 (66.7)	2 (66.7)
Experience[b] (years), mean (SD)	N/A[c]	6.7 (6.2)	10.7 (8.1)	24.0 (4.9)
Time since diagnosis (years), mean (SD)	7.6 (4.3)	N/A	N/A	N/A

[a]HCP: health care professional.

[b]Number of years of experience is calculated as the number of years a patient representative has participated as a representative of patients with COPD or an HCP has worked in COPD-related care.

[c]N/A: not applicable.

Care Path Overview

HCP participants indicated that the current care pathway for people who experience COPD exacerbations can be set out in general terms. However, they emphasized that individual adjustments are necessary depending on patients' medical history, pulmonary function test results, and individual illness experience.

Overall, the interviews indicated that patients may either have been formally diagnosed with COPD before their first AECOPD event or encounter the disease for the first time in the context of an AECOPD hospitalization. While mild AECOPD events can often be managed in primary care, severe cases often require hospital admission. After a period of hospitalization, the patient stabilizes and is discharged from the hospital. In the care pathway described by participants, the discharge decision is based on a clinical evaluation that includes infectious parameters, general blood work, and the need for supplemental oxygen. If necessary, the patient may be discharged with temporary supplemental oxygen at home. However, this clinically determined point of discharge did not always correspond to patients' perceived readiness to return home. Several patients described feeling insufficiently prepared for discharge, highlighting a gap between clinical stability and perceived readiness for home recovery (quote 1 in Textbox 1).

Textbox 1. Illustrative quotes from interviews and workshops with patients, patient representatives, and health care professionals.

Quote 1: patient 4 (interview)

- For me, it (being discharged) was mentally very challenging. I continually questioned myself whether I was ready for it.

Quote 2: patient representative (workshop)

- The pharmacist is actually someone who is just as close to the patient as the GP. That's where you go for your medication, and that's where your partner goes for their medication.

Quote 3: health care professional (workshop)

- Wherever a home care nurse visits, education can be provided, but we still miss a group of patients we never reach. All patients, however, visit the pharmacist. Not all physicians know that they must write a prescription for inhalation-therapy education. The pharmacist needs that prescription to be compensated.

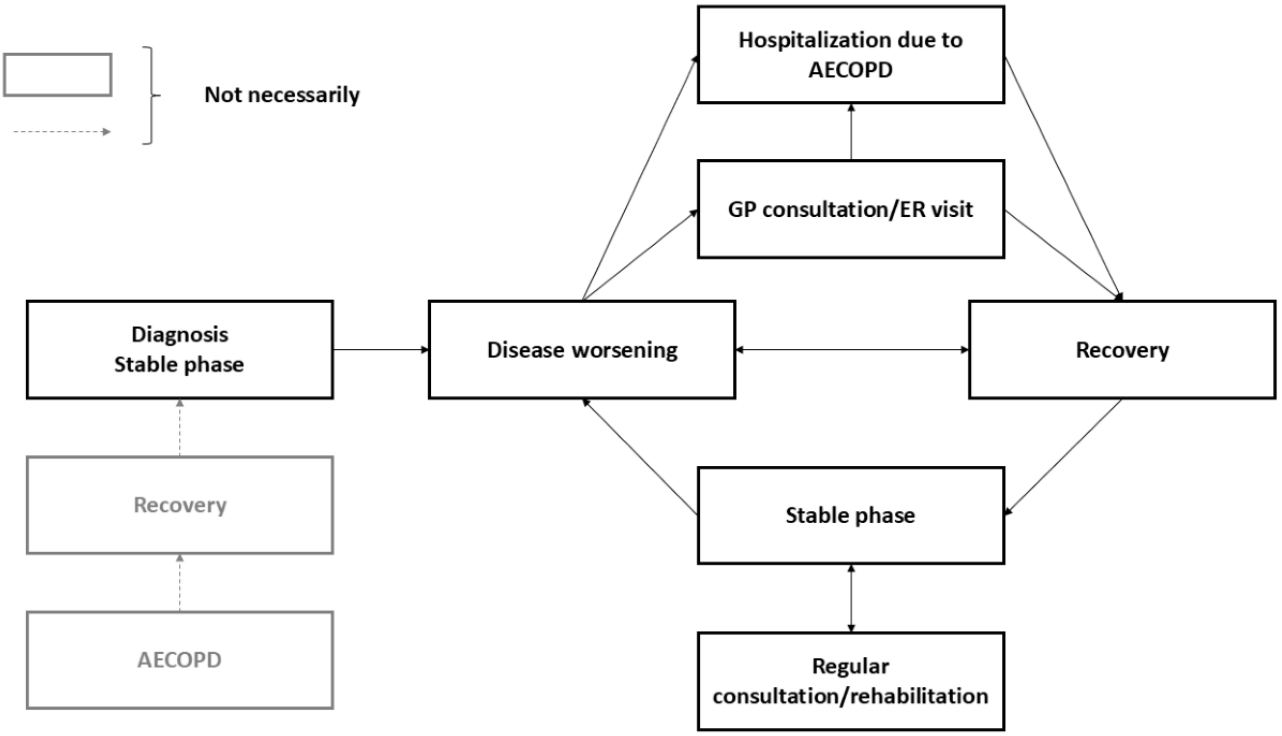
Quote 4: home nurse (workshop)

- The required level of monitoring vital signs should be determined on an individual basis. However, a challenge is that many patients do not receive home nursing care, particularly when no technical nursing or hygiene-related support is required. In these cases, home nurses are often not involved. This creates a gap regarding patient education and support, as these activities are not reimbursed as home nursing services. From the patient's perspective, charging €10 per day for this may represent a considerable financial burden, even though a daily cost ceiling applies. At the same time, this fee would not cover the involvement of a home nurse. This creates a challenge, despite the fact that such support could be highly valuable for patient follow-up.

Quote 5: patient representative (workshop)

- When you leave the hospital, it feels like something hits you on the head. You only remember that you won't be able to manage for a while, and everything else is gone. If someone else is with you, they can put things into perspective and remember the details. But as a patient, you're told so much that you simply can't take it all in anymore.

Quote 6: pulmonologist (interview)



- In case of disease worsening, we always advise patients to see a physician. In most cases, this is their GP, but long waiting times can allow their condition to worsen. Having a way to monitor patients remotely, without adding excessive medical burden or cost, could be crucial.

XSL•FO
RenderX

Besides feeling unprepared, patients reported experiencing a lack of information, guidance, and follow-up after hospitalization for AECOPD. In the local care setting, discharge letters typically contain the necessary clinical details and are provided to patients or transmitted electronically to their general practitioner (GP). However, patients reported that the information they received was largely limited to their current pharmacological regimen. Moreover, they noted a lack of guidance regarding potential postdischarge symptoms, appropriate self-management strategies, and clear instructions on whom to contact in the event of clinical deterioration.

Although the exact point at which recovery begins is not always clear, 2 possible scenarios were identified during this phase. In the first, the disease suddenly worsens, often resulting in a new visit to a GP or ER, with potential hospitalization. In the second scenario, recovery progresses into a stable phase, during which patients should receive at least 1 annual outpatient follow-up that includes a pulmonology consultation and pulmonary function testing. Depending on individual needs, certain components of the care pathway may be added or omitted (Figure 2).

Figure 2. General clinical trajectory of a patient experiencing an acute exacerbation of chronic obstructive pulmonary disease (AECOPD). GP: general practitioner; ER: emergency room.

Care Pathway Stakeholders

The care pathway for patients who frequently experience COPD exacerbations can be represented by the vicious circle in the general clinical COPD trajectory (Figure 2). Across this pathway, 10 key stakeholders were identified, which can be categorized into 3 groups based on their primary setting of interaction: hospital-based, community-based, and cross-setting (Multimedia Appendix 8). The stakeholder roles described reflect responsibilities, activities, and interactions reported by study participants in relation to the existing COPD care pathway. These descriptions therefore reflect participants' experiences and perceptions of how local care was organized in practice and are not intended to define the formal scope of practice of each profession.

Hospital-Based Stakeholders

The pulmonologist is primarily responsible for patient treatment, including prescribing medication and interpreting spirometry results. Additionally, participants reported that the pulmonologist plays a critical role in patient education, discussing lifestyle modifications and pulmonary rehabilitation.

While most hospital-based interactions occur during periods of hospitalization, annual ambulatory follow-ups were reported to be recommended to assess medication efficacy and lung function progression.

The hospital nurse was mentioned as contributing both during hospitalization and in ambulatory follow-up. During hospitalization, the hospital nurse provides direct patient care and education. During outpatient visits, participants described the primary task of the nurse as performing spirometry testing.

The dietitian was mentioned as providing dietary counseling, particularly for patients experiencing unintentional weight loss or gain, thereby supporting nutritional optimization as part of COPD management.

According to interviewed participants, the social worker evaluates the patient's living environment, supports discharge planning, and offers psychosocial support when needed.

Cross-Setting Stakeholders

Although their role may appear self-evident, pharmacists were recognized by both patients and HCPs as essential contributors

XSL•FO
RenderX

to the COPD care pathway. Beyond supplying prescribed therapies, pharmacists were reported to be well-positioned to guide patients and informal caregivers in the correct use of inhalers and other respiratory treatments. Their frequent and accessible contact with patients allows them to reinforce key aspects of disease management and support adherence to therapy (quote 2 in Textbox 1). Notably, a participating HCP mentioned that, in Belgium, these educational services may be eligible for reimbursement when appropriately prescribed by the patient's treating physician (quote 3 in Textbox 1).

Another important stakeholder who can be present in both hospital-based and community-based settings is the physiotherapist. In the hospital, the role of the physiotherapist was described as focusing on patient mobilization, physiotherapy-related education, inhaler use, and general disease management. After hospital discharge, according to participants, the physiotherapist is responsible for guiding the patient through pulmonary rehabilitation.

The physiotherapist primarily focuses on restoring mobility, physical performance, and overall body function. The occupational therapist, in contrast, was described by participants as supporting patients in regaining or maintaining independence in activities of daily living (ADL). In addition to ADL training, participants mentioned that the occupational therapist may provide education on energy preservation, breathing techniques, and relaxation methods. For patients at increased risk of falls, targeted preventive interventions are also implemented.

Community-Based Stakeholders

During daily life, ongoing medical management was described by participants as being primarily coordinated by the GP. As the patient's primary point of access to health care, the GP was described as providing comprehensive and ongoing care, addressing both acute issues and long-term conditions. Participants indicated that the GP's role includes discussing lifestyle modifications, educating patients on medication use and symptom monitoring, and supporting overall disease control. Participants also highlighted that, when patients experience worsening respiratory symptoms, Belgian local practice allows the GP to perform diagnostic tests, such as a C-reactive protein test, to help identify potential infectious exacerbations.

Alongside the GP, the home care nurse was described by participants as playing a key role in supporting patients in their own homes. Within the care pathway described by participants, home care nurses were reported to provide professional nursing care, play a role in therapy- and lifestyle-related education, and assist with symptom management and overall disease management. Participants also indicated that home care nurses may monitor vital signs and other clinical indicators, enabling early detection of potential deterioration and timely intervention. However, participants noted that their involvement is generally limited to situations in which patients present with additional care needs, most commonly due to comorbid conditions that require home care nursing services (quote 4 in Textbox 1).

The final stakeholder in the COPD care pathway is the informal caregiver. Although participants noted that not all patients have access to unpaid, nonprofessional support, multiple stakeholders recognized the important role informal caregivers often play in daily life management. Participants described their responsibilities as varying according to the patient's needs and the nature of their relationship, potentially including personal care, emotional support, assistance with household tasks, and monitoring of the patient's health status. Study participants reported that the contributions of informal caregivers are often underrecognized by health care professionals. In particular, they highlighted that patients may feel overwhelmed during hospital visits and struggle to retain important information. For instance, participants described the presence of an informal caregiver or family member during the initial diagnosis, often perceived as life-altering, as helping patients better understand and remember key instructions and explanations provided by the pulmonologist (quote 5 in Textbox 1).

While most stakeholders are continuously present, certain stakeholder roles were mentioned as being embedded only as needed, such as those of the dietitian, social worker, home care nurse, and informal caregiver. Although these stakeholders play valuable roles, their involvement depends on the patient's personal circumstances, preferences, and individual care needs.

Limitations of the Current Care Pathway

Stakeholders identified several organizational and communication challenges within the current COPD pathway. These included the insufficient or time-limited involvement of physiotherapists and occupational therapists during and after hospitalization, inadequate patient and informal caregiver education, and a lack of structured follow-up at home, commonly referred to as the "black box" phase of postdischarge care. Both patients and professionals emphasized that education provided during acute hospitalization is often forgotten due to emotional strain and should therefore be repeated and reinforced during follow-up visits. In addition, physicians noted that referrals to physiotherapists and dietitians are not based on clearly defined criteria; instead, they largely depend on clinical judgment and physician preference. As a result, physiotherapy, particularly outpatient physiotherapy, is often initiated too late, even though earlier referral and intervention might be beneficial for patient outcomes. Moreover, communication between primary and secondary care has several limitations. Information is often lost or repeatedly requested, and relevant clinical details are not consistently transferred across care settings because different electronic health systems are unable to exchange data effectively. On the other hand, disease deterioration is often accompanied by patient anxiety and hesitation to seek help, sometimes reinforced by a perceived sense of failure when symptoms cannot be managed independently. This uncertainty may delay timely action, underscoring the need for objective RPM to support patients in recognizing clinically significant changes and responding appropriately (quote 6 in Textbox 1).

Development of a Hybrid COPD Care Pathway

This new theoretical hybrid care pathway focuses on patients who experience hospitalization due to AECOPD, as they place the greatest burden on the COPD care system. Stakeholders across primary and secondary care agreed that RPM strategies should be initiated and coordinated within secondary care, where clinical expertise and data interpretation capacity are

XSL•FO
RenderX

concentrated. Follow-up was considered most effective when led by a dedicated hospital-based nurse (eg, a COPD coach), who serves as the primary individual responsible for all RPM-related activities (quote 7 in Textbox 2). In addition, this individual could act as the first point of contact for patients experiencing worsening COPD-related symptoms, including those who are not enrolled in an RPM program (quote 8 in Textbox 3). RPM-related activities include installing the RPM devices, providing RPM-related education, reviewing RPM data, managing alerts, and discontinuing RPM when appropriate. While the COPD coach handles the practical aspects, close collaboration with the treating physician and regular communication with the GP remain essential. In addition to RPM management, the COPD coach can also play a key role in enhancing disease- and medication-related education and serve as a key contact person for both patients and their informal caregivers (Multimedia Appendix 8).

Textbox 2. Quote 7: health care professional (workshop).

Interviewer: Who should be responsible for reviewing the RPM-generated alerts?

Pulmonologist: Initially, this would be a nurse, who then reports back to the physicians (pulmonologists).

General practitioner: In our setting as well, especially if multiple conditions were being monitored, it would be a practice nurse who would perform the initial triage of alerts.

Home nurse: With telemonitoring, we are currently considering having an on-call nurse review the data once per day and escalate issues as needed.

Pulmonologist: I think it would be easier for our (pulmonology) department to assign someone to this task rather than shifting it to you in primary care.

General practitioner: Yes, we cannot hire someone for every pathology.

Pulmonologist: We want to reduce your workload. That already starts with a COPD exacerbation, so inclusion in RPM happens in the hospital. Therefore, it seems logical for this responsibility to remain with us (the hospital).

Textbox 3. Quote 8: health care professional (workshop).

Interviewer: Who should be the first point of contact for the patient?

Pulmonologist: A study nurse or a reference nurse, like we have in our oncology department (onco-coach). In case the patient experiences any issues, the patients contacts the nurse, who tries to solve the problem or contacts us in case of a medical issue.

Workshop participants emphasized that RPM should be considered a complementary tool rather than a replacement for direct patient contact. Although physiological parameters provide valuable insights, they do not fully capture the patient's clinical condition. Participants highlighted the importance of maintaining telephone or face-to-face interactions, as communication allows HCPs to assess additional aspects, such as the patient's breathing, speech, and overall presentation, which are essential for interpreting the clinical relevance of monitored parameters (quote 9 in Textbox 4).

Textbox 4. Quote 9: health care professional (workshop).

Pulmonologist: Is telephone consultation included somewhere in the infographic? We receive many phone calls from patients, and based on these conversations, we assess whether a patient should come in for a consultation or whether, for example, a short course of medication is appropriate if we know the patient well.

Interviewer: Could this be replaced by increased RPM?

Pulmonologist: No, home monitoring would complement this or provide an initial indication, but when you speak to a patient by phone, you also hear many relevant aspects: how they talk, how they breathe, and they can explain their situation.

Home nurse: Parameters are important, but they do not tell the whole story. With telemonitoring, when a parameter suggests that something may be wrong, it remains important to see or hear the patient directly to assess whether that value is clinically meaningful. RPM can serve as a supportive tool.

Primary care providers, particularly home care nurses, were viewed as having a supportive role, assisting with device troubleshooting or connectivity issues and communicating with the hospital nurse when necessary. As not all patients receive home care nursing, direct access to the COPD coach was considered essential.

GPs preferred to remain informed of their patients' participation in an RPM program but did not wish to interpret continuous data streams. Instead, they favored receiving periodic summary reports, with stakeholders specifically suggesting a one-page summary (quote 10 in Textbox 5) offering an overview of the patient's clinical status. HCP workshop participants reached a consensus that, within the proposed pathway, RPM data and alerts would therefore be reviewed and triaged by the designated in-hospital RPM team, with clinically relevant findings escalated to the appropriate pulmonologist (quote 7 in Textbox 2). This approach facilitates information sharing and continuity of care.

XSL•FO
RenderX

Textbox 5. Quote 10: health care professional (workshop).

I think those data should be available when the patient sits in front of you during a consultation, so you can integrate the data with everything else. When you're with the patient, you want to see it: that little graph of the oxygen saturation or breathing rate. There should already be an A4 sheet ready with those data on it.

Currently, RPM is not embedded in the daily management of patients with COPD at our care center, but it is likely to be more beneficial for those with severe disease or multiple comorbidities. However, participants indicated that patients without multiple comorbidities could also benefit from closer monitoring, representing a significant opportunity for improved care. Educating patients to enable self-monitoring is essential, and monthly follow-up for more stable patients would be desirable to ensure continuity and early detection of potential issues.

The hybrid COPD care pathway is presented as an infographic (Multimedia Appendix 8). It is organized into the main phases of the care pathway (ie, hospitalization, recovery, stable phase, and disease worsening), mirroring the circular trajectory shown in Figure 2. For each phase, the infographic summarizes the key activities of all stakeholders, grouped into 5 functional domains: support, treatment, medical advice, patient education, and monitoring. Changes from the current care pathway to the hybrid model are indicated with an asterisk.

Potential Barriers to RPM Implementation

Several potential barriers to RPM implementation were identified during the workshops, including low digital literacy, limited disease awareness, and affordability. Low digital literacy was highlighted as an important consideration in this population (quote 11 in Textbox 6). However, participants discussed that RPM could remain feasible if the system were designed to be as simple and user-friendly as possible, requiring minimal effort from patients. Limited disease awareness was also identified as a potential challenge, as some patients may be reluctant to engage in monitoring or to be continuously confronted with their disease status (quote 12 in Textbox 7). Furthermore, participants emphasized that alerts generated by the RPM system should be minimized and, where possible, should not be directly visible to or burdensome for patients.

Textbox 6. Quote 11: health care professional (workshop).

Interviewer: What are potential barriers for patients to use RPM?

Home nurse: I think the main challenge is digital illiteracy.

Pulmonologist: Yes, but perhaps patients should not have to do much themselves?

General practitioner: If it is a watch that performs many tasks automatically, this should not cause many problems.

Textbox 7. Quote 12: health care professional (workshop).

Home nurse: Another potential barrier is disease awareness. Patients may be reluctant to be monitored in this way. Similar to what we currently observe, some patients do not seek care from their general practitioner or hospital because they do not want to know how severe their disease is. RPM may confront them with their condition more directly.

Interviewer: So, they may feel that they are being confronted too much with the reality of their disease?

General practitioner and home nurse: Yes, indeed.

Discussion

Principal Findings

This study mapped the current COPD care pathway, delineated stakeholder roles, and developed a stakeholder-informed theoretical hybrid COPD care pathway incorporating RPM, while identifying key considerations for its integration into routine COPD care. Stakeholders were defined as individuals involved in the organization, delivery, or governance of COPD care. While internationally established guidelines exist for the management of COPD, there is no globally standardized COPD care pathway. Nevertheless, these guidelines recommend common principles that should underpin COPD care, including appropriate pharmacological treatment, smoking cessation, and annual vaccination. In addition, individualized assessment of nutritional status and mobility, encouragement of pulmonary rehabilitation, and evaluation of the need for home supplemental oxygen therapy should be performed [1]. However, the organization and implementation of these principles within care pathways often rely on the clinical judgment of physicians or locally developed internal hospital guidelines [8]. Consequently, substantial variation may occur between patient trajectories, depending on the country, available resources, and health system organization [8].

Although there are often no clear guidelines for COPD trajectories, evidence suggests that structured care pathways can improve care and outcomes for patients, as well as reduce unnecessary resource use and associated costs for health care providers [14,15]. The proposed theoretical hybrid care pathway is based on the COPD care pathway at a tertiary care hospital with an academic character (ie, Ziekenhuis Oost-Limburg, Genk) in Belgium and may differ from practices in other clinical institutions. Nevertheless, many of the general insights obtained remain relevant. In particular, the overarching responsibilities and the role of the COPD coach within the proposed theoretical hybrid care pathway may provide a useful starting point for consideration in other care settings and may inform the future development of similar care pathways. However, the specific

XSL•FO
RenderX

delineation of this role, including task allocation, integration within existing care teams, and organizational arrangements, is highly context- and institution-specific. As these aspects were beyond the scope of the workshops, they should be further defined and adapted by individual health care institutions during local implementation.

In the development of the hybrid care pathway, the researchers specified that RPM would be performed using a wearable device capable of measuring multiple vital parameters, without further specifications. The proposed hybrid care pathway should therefore be understood as an organizational framework for integrating RPM into COPD care rather than a device-specific protocol. It does not prescribe or evaluate specific devices, monitored parameters, alert thresholds, or escalation protocols, which should be defined and evaluated in subsequent research. Given that various hybrid RPM approaches have been evaluated in the literature, with varying results, further research should specify the components and structure of RPM in COPD [16]. Nevertheless, the integration of RPM into chronic care pathways is not a mere technical add-on but necessitates a reconfiguration of roles, responsibilities, and interactions within the care team. Previous literature on real-world implementations showed that it requires a fundamental reorganization of clinical workflows, staffing, and coordination structures [17,18]. For instance, in a multicenter European oncology program covering 33 cancer centers in France and Belgium, a remote symptom-monitoring pathway based on weekly patient-reported outcomes was successfully deployed after explicit roles were defined, alert-management workflows were established, and the RPM process was embedded into routine care using implementation science methods [19]. Similarly, in chronic heart failure care, surveys found that more than 80% of cardiology departments created dedicated RPM teams after implementing RPM, adjusting human resource allocation, and establishing new consultation workflows for handling alerts [20]. These findings support the broader concept that implementing RPM may require dedicated roles and adaptations to existing care processes.

In line with these insights, the proposed theoretical hybrid care pathway differs from the current care pathway by introducing a new stakeholder, the COPD coach, to support the integration of RPM into COPD care. While the name given to this new stakeholder is purely arbitrary, the role itself was proposed by workshop participants as a potential coordinating function for RPM-related activities. The COPD coach could be responsible for all RPM-related activities, including device installation, providing information on device use, following up on alerts, and discontinuing RPM. The COPD coach could perform these tasks in close collaboration with the treating pulmonologist and be responsible for reporting escalation outcomes to the treating GP.

Another stakeholder potentially involved in RPM activities is the informal caregiver, whose role in supporting patients throughout the disease trajectory has been repeatedly underscored by workshop participants but remains frequently underestimated [8]. Within the care pathway, the involvement of informal caregivers varies across phases of disease management but typically includes assisting with activities of daily living, medication management, emotional support, and coordination with HCPs [21]. Importantly, informal caregivers could also play an important role in the successful integration of RPM into the pathway. They may help patients operate monitoring devices, interpret and track generated health data, and liaise with the COPD care team (eg, the COPD coach) when alerts or issues arise. Empirical studies suggest that patients with engaged informal caregivers demonstrate improved symptom management, higher adherence to prescribed therapies, and more effective participation in self-management activities [22,23]. Consequently, informal caregivers act as an essential link between the patient, the RPM system, and the multidisciplinary care team, ensuring continuity, accuracy, and responsiveness throughout the proposed hybrid COPD care pathway.

While the COPD coach and informal caregiver play important roles in the proposed theoretical hybrid COPD care pathway, other stakeholders may also play significant roles. During the RPM follow-up period, initial triage and coordination are handled by the COPD coach, but the treating pulmonologist retains overall responsibility for the patient's clinical management when RPM alerts are generated. In some cases, the GP may adjust medical treatment during a scheduled visit based on RPM data trends or clinician-initiated recommendations. When an informal caregiver is absent, home care nurses may support the patient in operating RPM devices or help interpret monitoring data. They may serve as the interface between the patient, caregiver, and physician, ensuring device use and reporting. Thus, RPM becomes embedded within a multistakeholder care model in which multiple stakeholders jointly contribute to surveillance, triage, and therapeutic decision-making [17].

Although this study did not focus on a specific RPM strategy, implementing RPM requires several considerations. First, a reliable device must be used to collect patient data, which may take the form of a dedicated physical device or an application installed on the patient's smartphone. Second, data must be transmitted and stored automatically and securely, ensuring accessibility for authorized health care professionals. Where appropriate, algorithms for data processing and alert generation should be used to facilitate timely clinical decision-making. Third, the collected information should be presented in a meaningful and actionable manner for clinicians, ideally through integration with the electronic health record or other existing clinical systems [18]. Finally, patients must have sufficient digital literacy to participate effectively in an RPM program. Further research is needed to determine the level of digital literacy required for successful engagement [24].

In addition to RPM strategies, mobile health solutions can play a meaningful role in addressing educational needs. Mobile apps can provide structured, accessible, and on-demand educational content that reinforces disease knowledge, enhances understanding of treatment plans, and supports appropriate responses to changes in health status, potentially leading to reduced hospitalizations and improved quality of life [25,26]. Such digital tools may therefore complement traditional education, help overcome information loss after hospitalization, and strengthen patients' self-management capacities [27].

XSL•FO
RenderX

Future Perspectives

Future research should address several aspects related to the practical implementation of this theoretical framework. While previous research has demonstrated the feasibility and potential value of RPM using wearable devices in other care settings, further research is necessary to determine its impact on clinically relevant patient outcomes [28]. In addition, the influence of digital literacy and socioeconomic status on patients' ability to participate in RPM programs should be further explored, as these factors have previously been identified as important considerations and potential barriers to the implementation of digital health technologies in clinical care [29]. Cognitive burden should also be further investigated, particularly in relation to patients' ability and willingness to engage with RPM programs. Likewise, the influence of language proficiency and the availability and role of caregiver support should be explored, particularly among patients who may require additional support to engage with and use digital technologies.

Beyond the monitoring technology itself, future studies should further define strategies for alert management, as these are likely to influence the workload of the HCPs involved. The COPD coach role also requires further specification, including qualifications, training, workload, and patient-to-coach ratios, as well as clear procedures for alert escalation and clinical decision-making. In addition, practical and organizational considerations, including after-hours coverage, alert triage, reimbursement, and medicolegal responsibilities, need to be addressed before the role can be implemented in routine COPD care. Furthermore, the integration and communication of RPM data within existing health care networks, particularly between hospital-based and community-based care providers, should be evaluated in the context of local care structures. Finally, financial, organizational, and legal considerations require further investigation at the institutional and national levels. As these aspects are highly context-specific, they were beyond the scope of the current study.

Study Limitations

This study has several limitations. First, the sample size was relatively small, and all participants were recruited from a limited geographical region in Belgium, which may limit the transferability of the findings to other settings. Second, patients who participated in the interviews had very low daily smartphone use (1 out of 5), potentially negatively influencing their opinions on the added value of RPM. As the digital literacy of the patient representatives in the workshops is unknown, there might be bias regarding the use of this technology in this patient population. Third, the use of convenience sampling of HCPs may have introduced selection bias. Fourth, only 1 informal caregiver (who also served as a patient representative) was included in the workshops. Further research is necessary on how informal caregivers can contribute to hybrid care for patients with COPD. Fifth, RPM was introduced as a wearable device, such as a smartwatch, during the workshops, which may have influenced participant views. Despite these limitations, this study offers valuable, in-depth insights into the perspectives of key stakeholders, providing a meaningful foundation for future research on the development of hybrid care pathways.

Conclusion

This user-centered design study developed a theoretical hybrid COPD care pathway through interviews and workshops with stakeholders involved in COPD care. To facilitate the integration of RPM, stakeholders identified the need for a new role, namely, the COPD coach. This individual could be responsible for all RPM-related activities, including device installation, patient instruction, monitoring and triaging alerts, and managing the discontinuation of RPM services. A dedicated RPM role may support the coordination and integration of RPM into routine COPD care, as stakeholders highlighted that a digital tool alone may not be sufficient to achieve this. As the proposed pathway is purely a conceptual model, further research is necessary to evaluate long-term adherence in real-world clinical settings before implementation.

Acknowledgments

The authors thank all patients and health care professionals (HCPs) involved in the interviews and workshops and the delegates of the Flanders COPD association, COPD vzw, for their valuable contributions. Without their expertise, this paper could never have been written.

Funding

This research project was cofunded by the European Union (ERDF) via the Interreg Meuse-Rhine (NL-BE-DE) program (grant ID IMR6-00019).

Abstract

Background: Inclusive physical education (PE) plays a vital role in promoting participation and development among students with different abilities. However, many teachers do not have adequate tools to modify PE activities to meet these diverse needs. In addition, parents are essential partners, as their involvement helps reinforce strategies and provide useful information about their children. While online platforms provide a practical way to deliver such solutions, only a few have been intentionally created to support both teachers and parents in implementing inclusive PE learning. To address this gap, we codeveloped an online platform with adapted PE experts that digitizes an inclusion screening tool and delivers personalized, evidence-based inclusion strategies and resources to teachers and parents.

Objective: This study aimed to develop an online platform that provides inclusion strategies for PE teachers and to examine how teachers and parents perceived its usability, acceptability, and overall usefulness using a mixed methods approach.

Methods: A mixed methods design was used to evaluate the platform between September 2024 and March 2025. PE teachers (n=8) and parents of children with disabilities (n=8) were recruited through convenience sampling via national social media outreach and completed individual usability testing sessions via Zoom. Usability was assessed using the System Usability Scale (SUS), the Questionnaire for User Interaction Satisfaction (QUIS), and task performance metrics. Semistructured interviews were conducted to explore user experiences. Quantitative data were analyzed descriptively, while qualitative data were analyzed using codebook thematic analysis, with findings integrated using joint display analysis.

Results: All participants successfully completed the assigned tasks, with a few instances of minor difficulty (14 total errors across 136 task attempts). Participants completed both usability testing and semistructured interviews. Usability and satisfaction scores were high across both groups (SUS: mean 85.63, SD 9.14 for teachers and mean 84.69, SD 12.50 for parents; QUIS: mean 8.52, SD 0.82 for teachers and mean 8.00, SD 1.31 for parents, out of 9). Mixed methods integration showed convergence between positive usability ratings and perceived professional value, while also identifying challenges related to navigation, terminology, learning for first-time users, and mobile interface design.

Conclusions: The online platform provides strong usability and high satisfaction among PE teachers and parents. Future work will involve improving implementation and evaluating its impact on students' participation outcomes.

Introduction

Inclusive physical education (PE) aims to ensure that all students, regardless of ability, can participate and benefit. This is especially critical given persistent disparities in physical activity. Children with disabilities consistently engage in less physical activity than their typically developing peers and face higher rates of obesity and health-related complications [1]. National guidelines from the US Department of Health and Human Services (2018) recommend that children engage in at least 60 minutes of physical activity daily to support their physical, mental, and emotional well-being. However, a recent study in Canada found that 91% of children and adolescents with disabilities did not meet daily physical activity guidelines, compared to far lower proportions among their typically developing peers [2]. This inactivity has clear negative consequences for physical, mental, and emotional health, and underscores a critical need for inclusive PE practices that ensure equitable access to physical activity opportunities for all students during the school day.

At the same time, simply placing students with disabilities into general PE classes does not automatically yield positive outcomes. Recent research highlights that inclusive experiences depend on intentional practices and support [3]. Traditional, ableist approaches where ability is measured by performative criteria continue to marginalize students with disabilities and limit participation for all learners [4]. Haegele et al [3] surveyed 99 adapted PE specialists and identified 460 distinct barriers and 473 facilitators to inclusion, spanning seven thematic categories. Notably, they found that teacher-related factors were the most commonly cited barriers, more so than environmental or policy factors. This suggests that the attitudes, training, and strategies of PE teachers largely determine whether an "integrated" class truly feels inclusive. Other researchers have also questioned whether typical integrated PE settings, without additional supports, provide meaningful inclusion [5]. However, Universal Design for Learning (UDL) has been identified as a proactive framework for addressing learner variability in PE. By embedding UDL principles, educators can design lessons that minimize barriers for all students, rather than relying on individual modifications after challenges arise [6]. Research shows that UDL-based approaches not only support students with disabilities but also enhance engagement and outcomes for their peers without disabilities [7,8]. In short, inclusive PE is a complex challenge: it offers clear benefits for students (social interaction, improved fitness, and enhanced well-being), but achieving those benefits requires overcoming significant practical barriers in day-to-day instruction [9].

Unfortunately, many general PE teachers report feeling underprepared to effectively include students with disabilities in their classes. A lack of formal training, limited experience, and insufficient resources contribute to significant barriers in delivering high-quality, inclusive PE [10]. This is consistent with broader findings that many PE teachers feel underprepared to implement inclusive pedagogies, often due to limited exposure to effective strategies and insufficient professional development [11]. Teacher-specific practices such as offering a variety of instructional strategies, adapting equipment and rules, and collaborating with support personnel are essential for reducing environmental barriers and fostering meaningful participation [12]. Teachers frequently cite inadequate support, limited professional development opportunities, and a lack of practical tools as major obstacles to fostering inclusive environments. Alarmingly, over half (54%) of PE teachers report receiving no professional development related to inclusive practices from their school districts [10]. This issue is highlighted in research by Polat et al [13], who conducted a needs analysis with 133 teachers: they concluded that teachers' knowledge regarding special education students is often insufficient, and educators overwhelmingly desire more training and support to teach inclusively. This lack of professional preparation has been identified as a widespread issue that must be addressed to improve educational outcomes for students with disabilities [14,15], indicating a pressing need to support PE teachers through better training, resources, and peer support.

Current approaches to preparing PE teachers for inclusive practice include preservice coursework, continuing professional development workshops, consultation with adapted PE specialists, and instructional frameworks such as UDL [12,16]. While these approaches provide important foundational knowledge, access is often inconsistent, time-limited, and may not provide ongoing, just-in-time support for teachers managing real-world classroom inclusion challenges [10]. Digital platforms offer an opportunity to extend professional learning by providing scalable, accessible, and on-demand support, particularly for educators who may lack regular access to specialized training resources [13].

In response to this need, the Lieberman/Brian Inclusion Rating Scale for Physical Education (LIRSPE) was developed as a 27-item instrument designed to assess the extent to which PE teachers implement inclusive practices for all students, including those with disabilities, in their programs. The LIRSPE has demonstrated strong reliability and validity [17], making it a valuable tool for evaluating inclusive practices in PE settings. The tool was developed primarily as a practice-oriented self-assessment instrument to support educators in reflecting on and improving their inclusive teaching practices, rather than solely as a research measure. The lack of digital integration constrains data collection, limits opportunities for sharing successful strategies, and reduces its potential as a tool for ongoing professional development. Although the LIRSPE is valuable for assessing inclusive PE practices and identifying areas for improvement, its original static format does not provide embedded implementation guidance or tailored training resources. This is important given evidence that PE teachers often require practical professional development support to effectively implement inclusive practices [16,18]. As digital technologies continue to transform educational practice, there is an opportunity to adapt the LIRSPE into a more accessible and interactive format. A digital platform could enhance its use by supporting real-time feedback, facilitating resource sharing, and promoting sustained improvements in inclusive teaching practices across varied educational contexts.

Parents are important stakeholders in inclusive PE, as they provide valuable insight into their child's needs, support participation beyond the school environment, and often advocate

XSL•FO
RenderX

for appropriate inclusion and accommodations [19]. However, like PE teachers, parents often face similar barriers in accessing clear, actionable guidance for supporting inclusive PE at home and in the community. Including parents in the evaluation of the platform was therefore important to ensure that the resources and recommendations were understandable, relevant, and supportive of collaborative efforts between families and educators to promote inclusive PE participation.

To address these limitations, the present project developed a web-based platform to expand the use of the LIRSPE in supporting inclusive practices in PE. A mobile-friendly digital version of the LIRSPE, accessible via smartphones and tablets, was created, with a self-evaluation interface for teachers and para-PE teachers. In addition, the platform integrated a library of evidence-based solutions to support inclusive instruction. The design of the proposed platform was further informed by UDL, which emphasizes reducing barriers through multiple means of engagement, representation, and action and expression [7-9]. Consistent with these principles, the platform provides inclusion resources in multiple formats, including videos, downloadable documents, and interactive discussion forums, allowing users to access information in ways that align with their needs and preferences. In addition, tailored recommendations generated from users' LIRSPE responses provide individualized support, aligning the platform with the UDL goal of addressing learner variability and promoting inclusive participation [7-9]. This project followed a 2-phase design. Phase 1 involved the development of the platform, including the digitization of the LIRSPE and the integration of evidence-based inclusion resources, and phase 2 involved a usability evaluation of the platform with PE teachers and parents of children with disabilities. The present paper reports directly on phase 2. Accordingly, this study aimed to examine PE teachers' and parents' perceptions of the platform's usability, acceptability, and overall usefulness using a mixed methods approach.

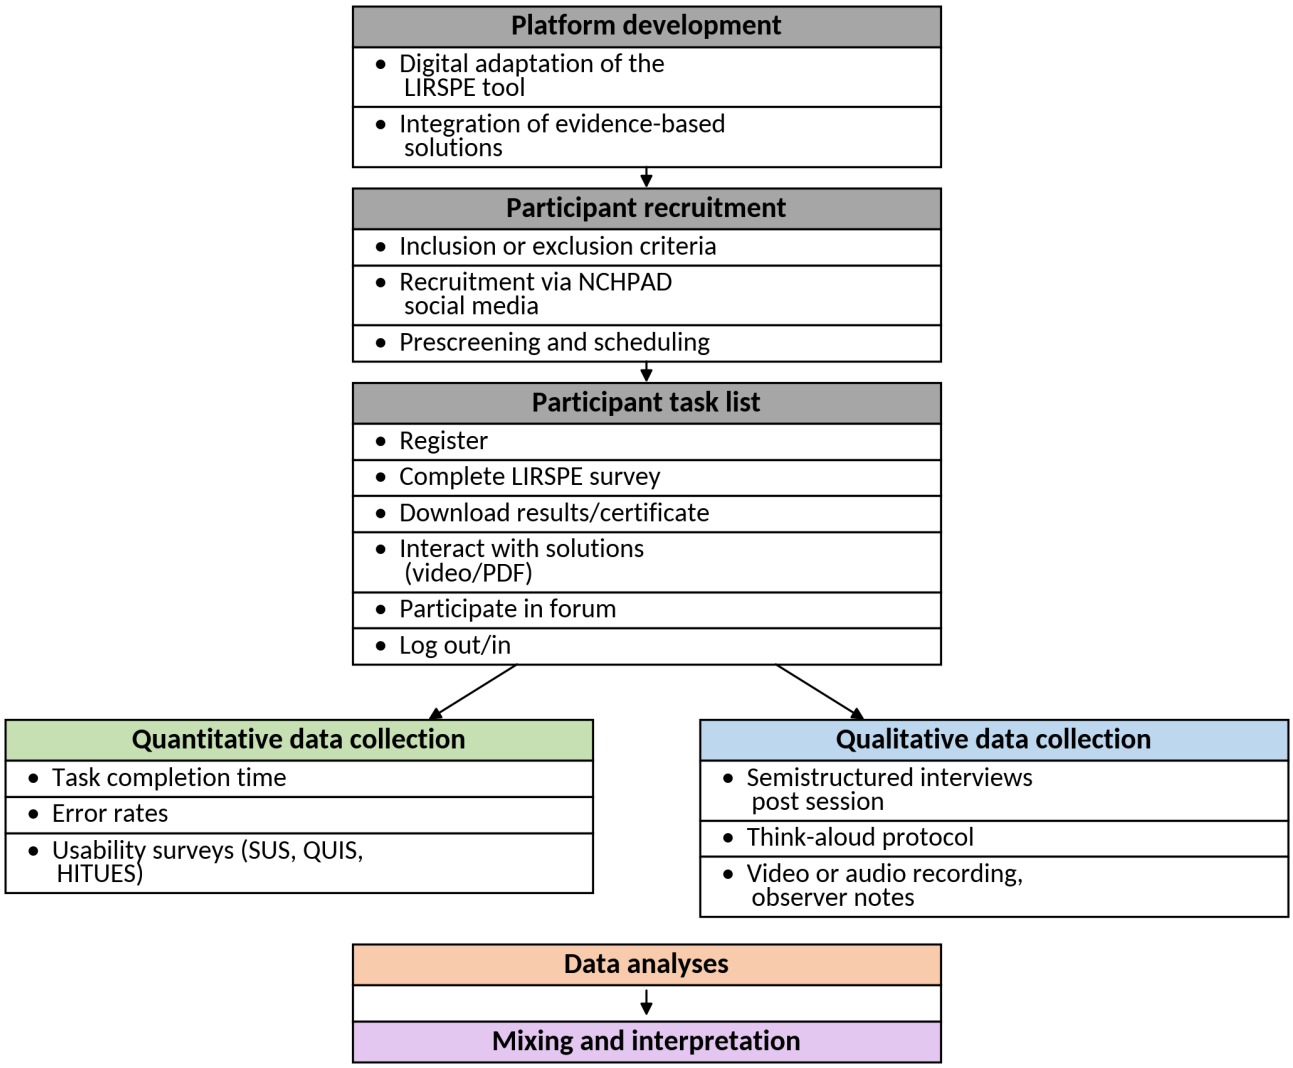
Methods

Development of the System

The web-based platform was built on WordPress, chosen for its robust content management capabilities and flexibility for nontechnical users. To digitize the LIRSPE, a custom software plug-in was developed to create a dynamic survey interface. This feature adapts to the specific user, loading distinct questions for teachers, parents, or students, and using automated logic to calculate scores and assign credits immediately upon submission. Based on these scores, the system triggers the Adapted PE Decision Support Tool, delivering personalized, evidence-based inclusion solutions and recommended resources to the user. Users can also generate and download PDF summaries of their results and completion certificates directly from the dashboard.

To support ongoing professional development and peer interaction, the platform integrates a discussion forum (powered by bbPress) with automated email notifications to alert users of new replies. User access, registration, and role management are handled through a secure interface (Ultimate Member). The visual design used the Divi theme, which was customized to ensure a consistent, accessible layout across devices, enabling intuitive navigation between the survey, results, and resource libraries. Finally, a custom administrative dashboard was built to facilitate data management, enabling the research team to monitor submission dates, analyze demographic trends, and export data for reporting.

Development of Inclusion Solutions



To develop the recommended solutions provided to participants upon completion of the online LIRSPE, 2 long-standing experts in adapted PE conducted a comprehensive resource review. This process involved a comprehensive search of relevant literature and online content, including YouTube instructional videos, Google searches, and materials from professional organizations such as SHAPE America and Human Kinetics. The experts also incorporated resources they had previously developed and, where gaps were identified, created new materials to address specific areas of need. The platform was designed to identify barriers to inclusive PE and provide personalized, evidence-based solutions and practical resources to improve knowledge, support decision-making, and increase confidence in implementing inclusive practices. This multisource approach ensured that the recommended solutions were both evidence-informed and practically applicable for PE teachers seeking to improve the inclusion of students with disabilities.

Mixed Methods Research Design

This study examined the strengths and weaknesses of the PE inclusion solutions platform using the International Organization for Standardization (ISO) usability criteria of effectiveness, efficiency, and satisfaction [20]. Acceptability was reflected in participants' perceptions of the platform's appropriateness and willingness to engage with or recommend its use, while usefulness referred to the perceived practical value of the platform in supporting inclusive PE decision-making and resource access. A mixed methods approach was used to provide a comprehensive assessment by integrating quantitative and qualitative insights. Specifically, we used the iterative convergent mixed methods design described by Alwashmi et al [21], which involves multiple cycles of concurrent data collection and analysis. This design allowed us to identify and address usability concerns in real time and ensured alignment between research objectives, data generation, analysis, and interpretation. The iterative process involved integrating quantitative usability metrics (task completion time, errors, and questionnaire scores) with qualitative findings from the think-aloud protocol and semistructured interviews. Following each participant session, the research team reviewed the findings, and any technical glitches identified were addressed before the next participant completed testing. More substantial refinements based on recurring feedback are described in the "Results" section. Figure 1 presents the procedural steps followed in this process [21].

XSL•FO
RenderX

Figure 1. Procedural flow of a mixed methods design for user testing of an online platform to deliver school-based physical education (PE) inclusion solutions. HITUES: Health Information Technology Usability Evaluation Scale; LIRSPE: Lieberman/Brian Inclusion Rating Scale for Physical Education; NCHPAD: The National Center on Health, Physical Activity & Disability; QUIS: Questionnaire for User Interaction Satisfaction; SUS: System Usability Scale.

Participants

The PE inclusion solutions platform is designed for use by PE teachers and parents of children with disabilities. Therefore, iterative user testing was conducted with a mix of parents and PE teachers. Participants were recruited nationally through the National Center on Health, Physical Activity & Disability (NCHPAD)'s social media site via public posts that included promotional videos and a flyer describing the study; no direct messaging or individualized outreach was used beyond these public posts. Inclusion criteria were the following: (1) aged 18 years or older, (2) fluent in English, (3) able to use a tablet computer, and (4) parent of a child with a disability or working as a PE professional. Recruitment and data collection were conducted between September 2024 and March 2025. A total of 25 individuals were reached during recruitment. Recruitment continued until the target sample of 16 eligible participants (8 PE teachers and 8 parents) was achieved, consistent with recommendations for iterative usability testing [9,22]. Eligibility screening was conducted by a member of the research team (SM). Individuals who did not meet these criteria were excluded. Eligible participants were provided with the study information and scheduled for a 1-hour individual Zoom session. Participants who did not meet the eligibility criteria or declined participation after screening were not enrolled in the study.

Ethical Considerations

The study was approved by the University of Alabama at Birmingham Institutional Review Board (IRB-300010295). All participants provided informed consent prior to participation. For the online component, oral informed consent was obtained before participants accessed the platform or completed study activities. Participation was voluntary, and all data were deidentified and stored securely to protect participant privacy and confidentiality. Participants received a US $25 gift card upon completion of the study session.

Data Collection

Data were collected through one-on-one user testing sessions with each participant conducted via Zoom. During those sessions, the researcher provided additional details about the testing process and reiterated that participation was voluntary. The session included navigating various web pages and testing features or functions. The testing session was video recorded

XSL•FO
RenderX

(computer screen only) and audio recorded. A research staff member took written notes from their observations of participants during the usability tasks. Participants were asked to complete the following tasks:

- Task 1: register as a PE professional or a parent.
- Task 2: complete the LIRSPE survey and find a solution or recommendation on how to include a child with a disability (imaginary in case they do not have one) in PE activities. Download the results copy and the certificate.
- Task 3a: download the results copy.
- Task 3b: download the certificate.
- Task 4a: from your results, check a solution that needs to be improved and comment on a video.
- Task 4b: from your results, check a solution that needs to be improved and comment on a PDF. Download or print the specific PDF.
- Task 5a: forum—post a response to the existing post "this is a test" and create a new post.
- Task 5b: forum—create a new post.
- Task 6: log out and log in.

The testing involved a "think-aloud protocol" while participants navigated the system [23]. Participants were asked to spontaneously report everything that went through their minds while performing a set of specific tasks. During testing, the system's efficiency was assessed by task completion time, and its effectiveness was evaluated based on the errors encountered while performing the tasks. System satisfaction was measured using three validated questionnaires: the System Usability Scale (SUS), a 10-item instrument with a 5-point Likert scale assessing overall usability [24]; the Questionnaire for User Interface Satisfaction (QUIS), which evaluates user satisfaction across multiple interface domains using 9-point rating scales [25]; and the Health Information Technology Usability Evaluation Scale (HITUES), a 20-item instrument with 5-point Likert response options assessing impact, usefulness, ease of use, and user control. All 3 questionnaires were self-administered electronically, with participants completing them independently via a Qualtrics survey link shared during the same Zoom session immediately after the usability tasks, rather than having items read aloud by the researcher or completed on paper. Internal consistency for these instruments has been reported as good to excellent in previous validation studies [26]. After completing the surveys, participants took part in a semistructured interview conducted by a member of the research team (SM). The interviews followed a preplanned interview guide (Multimedia Appendix 1) that explored participants' experiences, perceptions, opinions, and suggestions regarding the platform while allowing flexibility to discuss issues they considered important. Interviews lasted approximately 10 minutes. All recordings were transcribed for qualitative analysis.

Data Analysis

Qualitative data (think-aloud and interviews) were transcribed using Zoom and cleaned manually for accuracy before being imported into NVivo (Lumivero) for analysis. Data were analyzed using a codebook thematic analysis approach [27,28]. Two researchers (SA and SM) independently coded the transcripts using a shared codebook. The codebook was developed using a hybrid approach: core coding domains (platform navigation, screen layout, terminology, and learning) were derived deductively from the structured usability evaluation framework assessed by the quantitative instruments (SUS, QUIS, and HITUES) and the interview guide, while additional domains, for example, suggestions for the future, were added inductively as they emerged from the transcripts. SA and SM met iteratively to compare codes, resolve discrepancies, and reach consensus on the final coding structure. Rigor was addressed through these study-specific procedures [28]: credibility was supported by dual coding and a consensus process; transferability was supported by detailing the sample (8 PE teachers and 8 parents recruited via NCHPAD), the Zoom-based testing context, and study procedures; dependability was supported by documenting coding decisions and codebook revisions in NVivo; and confirmability was supported by SA and SM checking each code against its source (transcripts). Descriptive analysis (mean, SD and median, IQR) of quantitative data was conducted.

Iterative Platform Refinement During User Testing

Throughout user testing, the platform was refined iteratively as usability sessions progressed. After each participant session, the research team reviewed the observed usability issues, technical glitches, and participant feedback. Technical problems that affected task completion (eg, navigation errors, delayed system responses, and duplicated forum posts) were corrected before the next participant completed testing whenever feasible. This approach ensured that subsequently identified issues reflected new usability concerns rather than previously recognized technical faults.

Results

Participants Demographics

Participants in the PE teacher (n=8) and parent (n=8) groups underwent user testing. Table 1 provides the demographics of the teachers, including their age (mean 41, SD 14 y), job role, grade level taught, highest education level, state of current employment, and years of work experience. Table 2 provides the demographics of the parents of a child with a disability. Iterative modifications to the platform were made throughout testing in response to observed usability issues and participant feedback, as described in the *Methods* section and summarized in Multimedia Appendix 2.

Multimedia Appendix 3 summarizes task completion outcomes, observed difficulties, and errors encountered by PE teachers and parents during usability testing of the PE inclusion solutions platform.

Effectiveness

Errors during task performance and task completion were used to assess system effectiveness. Overall, both PE teachers and parents were able to complete most assigned tasks with minimal errors (Multimedia Appendix 3). Among PE teachers, the majority of errors occurred during forum interactions, with 4 participants encountering difficulties when responding to existing posts and 2 participants experiencing issues when creating new posts, mainly due to navigation delays or duplicate submissions. Parents similarly completed most tasks successfully, with only isolated difficulties observed in account creation, logging in and out, and commenting on existing forum posts. These findings suggest that the platform effectively supports core tasks, with minor challenges concentrated around interactive navigation features.

Efficiency

The efficiency of teachers and parents in completing the various tasks is shown in Table 3.

Table . Time taken for completing the tasks in seconds for physical education (PE) teachers and parents[a].

Task	PE teachers, mean (SD)	PE teachers, median (IQR)	Parents, mean (SD)	Parents, median (IQR)
Account creation and login	138.75 (87.85)	113.5 (87.8-145.3)	114.63 (66.44)	92.5 (70.5-135.3)
LIRSPE[b] survey	786.00 (429.47)	805.0 (547.0-923.3)	635.88 (247.71)	636.0 (508.5-870.3)
Download result copy	22.75 (46.46)	6.5 (4.5-9.0)	37.17 (50.26)	15.0 (11.3-30.0)
Download certificate	4.25 (1.92)	4.0 (3.0-5.0)	N/A[c]	N/A
Solution PDF interaction	84.00 (54.79)	70.0 (41.5-105.5)	103.75 (123.30)	38.0 (27.8-133.5)
Video interaction	70.50 (42.54)	58.0 (36.3-86.3)	110.63 (83.15)	111.0 (56.8-140.5)
Forum: comment on existing post	56.13 (27.85)	48.5 (34.5-77.0)	84.50 (75.90)	60.5 (37.5-92.8)
Forum: create new post	81.13 (19.42)	76.5 (72.3-81.8)	63.63 (25.80)	60.0 (45.3-71.8)
Logout and login	25.63 (11.28)	24.5 (21.8-27.0)	29.88 (18.84)	22.5 (15.8-39.0)

[a]All time measured in seconds.

[b]LIRSPE: Lieberman/Brian Inclusion Rating Scale for Physical Education.

[c]N/A: not applicable.

XSL•FO
RenderX

Task completion times during usability testing were used to assess system efficiency. Table 3 presents the task completion times (in seconds) for PE teachers and parents, including both mean (SD) and median (IQR) values to facilitate comparison.

During the think-aloud process, some participants deviated from assigned tasks to provide additional feedback, which may have influenced completion times. Overall, both PE teachers and parents completed simpler tasks efficiently, while more complex tasks requiring interpretation or multiple steps, such as survey completion (PE teachers: mean 786.00, SD 429.47 s and median 805.0, IQR 547.0-923.3 s; parents: mean 635.88, SD 247.71 s and median 636.0, IQR 508.5-870.3 s) and account creation/log-in (PE teachers: mean 138.75, SD 87.85 s and median 113.5, IQR 87.8-145.3 s; parents: mean 114.63, SD 66.44 s and median 92.5, IQR 70.5-135.3 s), took longer. Parents also spent more time on video interaction (mean 110.63, SD 83.15 s and median 111.0, IQR 56.8-140.5 s), suggesting additional navigation demands.

Satisfaction

Satisfaction scores, as seen in Table 4, were assessed using 3 validated instruments: SUS, HITUES, and QUIS.

Table . Usability survey scores for teachers and parents.

Instrument	PE teachers, mean (SD)	Parents, mean (SD)
SUS[a]		
Total	85.63 (9.14)	84.69 (12.50)
HI-TUES[b]		
Total	4.60 (0.38)	4.69 (0.23)
Impact	4.83 (0.31)	4.92 (0.24)
Perceived usefulness	4.50 (0.51)	4.76 (0.35)
Perceived ease of use	4.80 (0.35)	4.78 (0.27)
User control	4.33 (0.76)	4.08 (0.79)
QUIS[c]		
Total	8.52 (0.82)	8.00 (1.31)
Overall reaction to software	8.03 (1.59)	8.13 (1.06)
Screen	8.35 (1.08)	7.80 (1.66)
Terminology and system information	8.03 (2.68)	8.10 (1.36)
Learning	9.69 (0.40)	8.63 (1.57)
System capabilities	9.06 (1.24)	6.69 (2.25)

[a]SUS: System Usability Scale.

[b]HI-TUES: Health Information Technology Usability Evaluation Scale.

[c]QUIS: Questionnaire for User Interaction Satisfaction.

PE teachers and parents reported high usability and satisfaction. SUS scores were high for both PE teachers (85.63) and parents (84.69), exceeding the benchmark score of 68. On the HITUES, PE teachers and parents reported similarly high overall scores (4.60 and 4.69, respectively), with the highest ratings in impact (4.83 and 4.92) and perceived ease of use (4.80 and 4.78), while user control received comparatively lower ratings (4.33 and 4.08). QUIS findings also reflected positive satisfaction, with overall mean scores of 8.52 for PE teachers and 8.00 for parents, particularly in learning (9.69 and 8.63), although parents reported lower ratings for system capabilities (6.69), suggesting opportunities for functional refinement.

Qualitative Findings

Qualitative findings were organized into structured usability evaluation domains derived from the study's codebook, including platform navigation, screen layout, terminology and learning factors, overall experience with the system, and suggestions for the future.

Platform Navigation

Many PE educators and guardians commended the system's intuitive nature for solution retrieval. A professional participant characterized the survey's organization as "logical and well-categorized." Nonetheless, some parents advised simplifying access to critical resources, such as survey results or video libraries, to minimize clicks. While certain parents accepted the scrolling, others deemed it excessive. Another participant suggested that "collapsible headings for grouping solutions would mitigate overwhelm." There was a prevalent request for reducing scroll length through content reorganization or the inclusion of a "jump to" feature.

Both demographic groups experienced challenges in navigating the forums. A participant noted that the platform lacked intuitiveness for posting forum inquiries. One recommendation was to reposition the "Create New Topic" button to the top of the page.

XSL•FO
RenderX

Screen Layout

A PE instructor observed that disorganized mobile layouts hindered content readability (PE7). Although many parents valued the material's organization, some raised issues about the text size in PDF formats. Recommendations for enhancement included expanding white space; increasing font size, or text enlargement and screen reading compatibility; adding visual indicators to improve readability and lessen cognitive burden; and more diverse images of kids with disabilities.

Terminology and Learning Factors

Some PE teachers valued the formal tone while parents appreciated clear language, yet others found the survey wording too complex. An educator criticized the use of advanced terminology, suggesting it alienated nonexperts: "The survey questions used '$50 words' when '$5 words' would do….it felt like it was designed by PhDs for PhDs" (PE1). A parent expressed the need for simpler language, indicating a desire for clarity. Multiple parents recommended adding definitions or tooltips to enhance understanding and accessibility.

Overall Experience and Suggestions for the Future

Overview

Parents acknowledged the system's value while expressing minor concerns. One parent rated it positively but had doubts about its correctness. Another parent strongly recommended it as transformative for advocacy. When asked for the most favorite feature, all parents mentioned the detailed solutions provided. The PE teachers regarded the platform as a valuable resource for inclusive education. Participants recognized its promise but requested enhancements for better efficiency. Recommendations for improvement included the addition of progress tracking and clearer error messaging to improve user experience. Participants also suggested the following in the future version of the system: resources to buy adaptive equipment, federal laws for each state, a checklist for para-PE teachers, and search options to find solutions without going through the survey.

Joint Display

The joint display provides a visual depiction of the integrated qualitative and quantitative (QUIS score) data (Tables 5 and 6).

Table . Joint display of quantitative and qualitative findings from the Questionnaire for User Interaction Satisfaction (QUIS) among physical education (PE) teachers.

Domain	QUIS, mean (SD)	Qualitative findings	Representative quote	Integration
Overall reaction	8.03 (1.59)	Valuable resource; most PE teachers would recommend the system.	"I'd be more inclined to use this during my prep periods. if I present at a State convention, I would probably use this resource." (PE6)	High score converges with perceived professional value and willingness to recommend.
Screen	8.35 (1.08)	Layout was generally easy to navigate, but spacing was an issue on mobile.	"Everything was labeled really nicely. The dropdown menus made a lot of sense." (PE5)	High score converges with positive desktop layout feedback.
Terminology	8.03 (2.68)	Mostly easy to understand, though some wording was viewed as too technical.	"Discussion boards used simple, precise wording anyone could understand." (PE2)	Qualitative data complements the score.
Learning	9.69 (0.40)	Mixed experiences on user-friendliness and efficient access to PE solutions.	"It's easy to find and look through things to find stuff." (PE2)	High score mostly converges with positive learning feedback, though workflow efficiency can improve.
System capabilities	9.06 (1.24)	Content was viewed as reliable; navigation was mostly easy, but forum speed was slow.	"Navigation, it was pretty smooth, pretty easy." (PE8)	High score converges with content reliability and navigation, with minor technical issues noted.

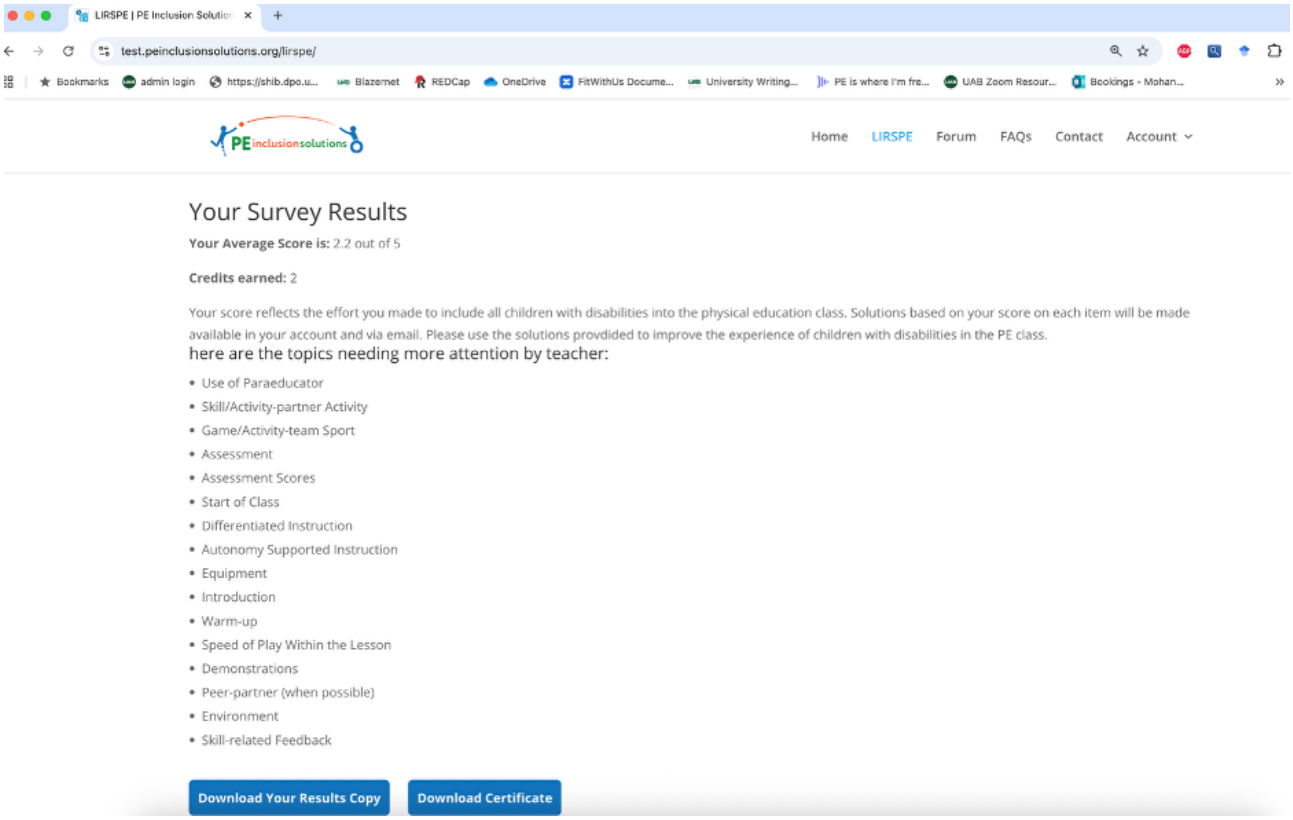
RenderX

Table . Joint display of quantitative and qualitative findings from the Questionnaire for User Interaction Satisfaction (QUIS) among parents of children with disabilities.

Domain	QUIS, mean (SD)	Qualitative findings	Representative quote	Integration
Overall reaction	8.13 (1.06)	Beneficial and supportive; parents would recommend the system.	"The whole idea itself is commendable." (P3)	High score converges with perceived value and recommendation of the system.
Screen	7.80 (1.66)	Mixed reviews on layout; some found the content visually overwhelming.	"The layout is well-organized, with clear sections and headings." (P7)	Qualitative findings expand on the lower quantitative score.
Terminology	8.10 (1.36)	Mixed reviews; language was generally clear but may need simplification for some parents.	"The language used in the system is clear and understandable." (P7)	Qualitative themes expand the score.
Learning	8.63 (1.57)	Mixed experiences on user-friendliness; some users felt unsure during tasks.	"It was very user friendly, easy, not overly complicated." (P8)	High score converges with positive feedback while leaving room for improvement.
System capabilities	6.69 (2.25)	Mixed reviews on navigation, with suggestions to improve features and speed.	"After submitting a comment, it was difficult to return to the survey results; adding a back button would be helpful." (P2)	Lower score aligns with navigation and feature-related concerns.

Overall satisfaction was high for both PE teachers (8.03) and parents (8.13), a finding that converges with the universal theme of the system being a "valuable resource." This high rating is expanded by the qualitative data, indicating satisfaction is rooted in the system's mission and purpose. Furthermore, both groups found the system exceptionally quick to master (learning between 9.69 and 8.63), yet this still diverges with "mixed experiences" due to functional flaws and complex language.



The most critical finding was the divergence in the system capabilities domain. PE teachers reported a 9.06 score for system capabilities converging with expert-level content trust. In sharp contrast, the parent group scored significantly lower (6.69), which was complemented by qualitative data detailing specific functional failures and navigation. While the PE teachers scored well (8.35) in the screen domain, the parents group scoring lower (7.80) was expanded by complaints of visual clutter that acted as a barrier for the nonexpert group. Regarding the terminologies, for PE teachers, the qualitative data complements the score, confirming that terms are generally appropriate for experts but showing inconsistency (high SD) for a few. For the parents group, the qualitative themes expanded the score, emphasizing the need for simplification and lower reading levels.

Explanation of Sections

Participants requested additional information on what to expect before starting the survey (Multimedia Appendix 4), details on what the score means to be moved closer to the score. P5 said, "When directly results show, it is confusing" (Figure 2). The explanation of scoring is provided before the start of the survey. Participants also requested an explanation for the different terms and expansion of abbreviations used in the demographic forms as different jargon is used in different states.

XSL•FO
RenderX

Figure 2. Screenshot of the Lieberman/Brian Inclusion Rating Scale for Physical Education (LIRSPE) survey results display interface. PE: physical education.

Forum

Overall, most of the participants in both groups had difficulty with the system speed while performing tasks in the forum. There was confusion in finding the add new topic button. PE1 said, “To add new topic, it takes time to scroll down and find the place to add new topic or difficult to find it.”

Demographic Form

Participants had confusion with password setup as the requirements for the password were not provided ahead. Similarly, some of them had difficulty using the DOB (date of birth) calendar option provided.

System Refinements Following User Testing

During iterative user testing, several system modifications were made to enhance platform usability (Multimedia Appendix 5); these changes are summarized in Multimedia Appendix 2.

Discussion

User Experience: Parents vs Teachers

The study findings suggest that the PE inclusion solution is usable and acceptable for both PE teachers and parents of children with disabilities. Both groups completed simple tasks with ease, while complex, multistep tasks were more difficult for both groups, particularly for parents. This difference across task types suggests that task complexity, rather than the platform’s overall design, was the main source of user difficulty. Furthermore, both groups struggled with tasks involving videos, PDFs, or the downloading of results, suggesting that navigation for resource-based activities is not intuitive. The reason for the difference between groups could be their level of familiarity with PE class activities and the terminology used in the surveys, since PE teachers work with this content regularly while parents typically do not. Some participants also deviated from the tasks, especially during the survey portion of the think-aloud process, and engaged in longer discussions, which may reflect their interest in the content rather than difficulty using the platform. Usability challenges were primarily observed in tasks involving complex navigation and access to platform resources, suggesting targeted rather than widespread issues. This pattern indicates that the platform supports core functionality but would benefit from refinement in more cognitively demanding workflows. This is consistent with established benchmarks indicating that scores above 80 reflect excellent usability.

It is important to note that the LIRSPE survey was originally developed as an assessment tool for PE teachers, with terminology and constructs tailored to professional practice [18]. When digitized for this platform, the tool was extended to parent users without a corresponding adaptation of its content or validation for this new group, and parent-specific use does not appear to have been a formal design consideration during digitization. As a result, some parents in this study expressed confusion or uncertainty regarding specific terms and survey items, which is understandable given the tool’s educator-focused design and may partly explain parents’ comparatively lower system-capability ratings. This suggests that fully meeting parent users’ needs may require a parent-adapted tool that is designed with parent input, rather than the current teacher-focused instrument. This expert-novice gap reflects a well-documented expertise reversal effect, in which design elements that support

XSL•FO
RenderX

less experienced users can be redundant or even burdensome for domain experts, and vice versa [29]. It is also consistent with the broader literature on parental involvement in physical education, which highlights that parents engage with PE content and terminology differently than PE professionals given their differing roles and familiarity with the subject [19].

The divergence between positive quantitative ratings and qualitative reports of confusion may reflect differences in what the evaluation measures captured. Standardized usability and usefulness measures assessed participants' overall perceptions of the platform, whereas qualitative feedback captured specific task-level challenges encountered during direct interaction. Participants may also have valued the platform's perceived relevance and learning potential despite difficulties with navigation or unfamiliar terminology. This discrepancy is itself a notable finding: parents' SUS scores were close to those of PE teachers and well above the accepted usability benchmark, yet qualitative data indicated that parents struggled to understand and navigate core survey content. This suggests that standardized usability scales, while useful for benchmarking overall ease of use, may not capture comprehension-level barriers faced by lay users of a tool originally designed for domain professionals. For future dual-audience digital tools, this points to a substantive design implication: usability and comprehension should be treated as distinct constructs and evaluated separately, since a high SUS score alone can mask meaningful gaps in understanding for nonexpert users.

Overall, the platform supports basic tasks but becomes less efficient when workflows require multiple steps or interpretation. Streamlining navigation and simplifying complex tasks would improve efficiency for both groups, with the largest gains for parents. The slow speed of the system could have resulted in errors, especially in the forum.

These findings are consistent with prior research showing that usability, clear navigation, and understandable terminology are important for the adoption of digital educational tools, particularly among users with different levels of expertise [13,21]. While digital platforms can improve access to training and support, design complexity and professional terminology may reduce usability for nonexpert users such as parents. This is consistent with established SUS benchmarks indicating that scores above 80 reflect excellent usability [24], suggesting the platform performs well overall despite the specific challenges noted above.

These findings also align with prior research showing that PE teachers often require additional support and training to implement inclusive practices effectively, and that educational technology adoption is influenced by usability, perceived relevance, and user confidence. The challenges observed among parent users further highlight the importance of designing inclusive digital tools that accommodate users with differing levels of expertise and familiarity with educational terminology [14,15].

This study contributes to the literature by extending LIRSPE beyond assessment into a digital platform that provides tailored inclusion solutions and practical resources. Including both PE teachers and parents also offers insight into how different stakeholder groups engage with inclusive digital tools. This platform may serve as a scalable resource for supporting inclusive PE, particularly where in-person training or specialist guidance is limited. These findings also underscore the importance of designing accessible educational technology for users with varying levels of professional expertise [13].

Future Research

Future research should evaluate the platform in larger and more diverse populations and assess its effect on inclusive PE knowledge and practice over time. Studies should also examine implementation in real-world school settings, including potential barriers to adoption, teacher and organizational readiness, scalability, sustainability, maintenance and updating of platform content, and integration into teacher professional development programs. In addition, theory-driven frameworks, such as the self-determination theory–based classification of teacher motivational behaviors proposed by Ahmadi et al [30], could be used to better understand how the platform supports autonomy, competence, and relatedness in inclusive PE practice. Mapping the platform's strategies and digital features onto these motivational behaviors may strengthen the theoretical basis and replicability of future evaluations. This approach could move research beyond usability outcomes toward examining behavioral and instructional mechanisms that influence teachers' inclusive practices and the sustained implementation of inclusive PE.

Limitations

This study has several limitations. Although the sample size was appropriate for usability testing, the findings should be interpreted as preliminary and may not be generalizable to broader populations. The inclusion of both PE teachers and parents introduced diverse user perspectives and levels of familiarity with inclusive PE concepts, which may have influenced task performance and interpretation differently. In addition, this study focused on usability, acceptability, and perceived usefulness rather than evaluating the effectiveness of the platform in improving inclusive PE knowledge or practice. Recruitment through NCHPAD's social media channels may have introduced self-selection bias, favoring individuals already engaged with adapted physical activity resources. The study also did not track long-term classroom implementation or student outcomes, and usability testing was conducted via Zoom rather than in real-world PE settings, which may limit how well the findings reflect actual use.

Conclusions

This study demonstrates that a web-based platform for delivering school-based PE inclusion solutions is both usable and acceptable to PE teachers and parents, as evidenced by high satisfaction scores and successful task completion across user groups. The integration of quantitative and qualitative user-testing data provided insights into the platform's strengths, such as its professional value and resource accessibility, as well as areas for improvement, including navigation, terminology, and support for nonexpert users.

These findings reflect users' perceptions of the platform during initial usability testing and should not be interpreted as evidence

XSL•FO
RenderX

that platform use improves teachers' knowledge, confidence, or inclusive teaching behaviors, or that it leads to improved student participation or educational outcomes. Future research is needed to examine whether sustained use of the platform produces these downstream benefits.

Acknowledgments

The authors would like to acknowledge Michelle Grenier for her contribution withto the physical education solution development. The authors would also like to acknowledge Tejaswini Chilke and Rohit Doddapani for developing the system.

As part of our commitment to transparency and ethical publishing practices, the authors disclose that generative AI were used during the preparation of this manuscript in a limited and clearly defined manner. Specifically, Claude was used to support language improvement and stylistic refinement of the manuscript text, without altering the scientific content, data interpretation, or conclusions. In addition, Claude was used to generate the procedural diagram for our mixed method. All scientific analyses, results, interpretations, and conclusions presented in this manuscript were conceived, verified, and approved entirely by the authors. The authors take full responsibility for the integrity, accuracy, and originality of the work and confirm that the use of AI tools did not replace critical scholarly judgment, data analysis, or authorship responsibilities.

Abstract

Background: Alexithymia is a cognitive-emotional condition characterized by difficulties in identifying and expressing emotions. It lacks recognition among Chinese college students due to cultural norms that emphasize emotional restraint. Traditional interventions often rely on verbal expression, which poses challenges for students with alexithymia. Coloring-based digital art therapy provides a nonverbal, low-cognitive-load alternative that facilitates emotional expression through visual and interactive methods.

Objective: This study aimed to explore expert opinions on developing a coloring-based digital art therapy intervention for alexithymia among Chinese college students, develop an intervention framework, and create a digital game prototype tailored to this population.

Methods: This study was conducted in 2 phases. First, semistructured expert interviews were conducted with 10 experts to gather insights and create the intervention framework for coloring-based digital art therapy. In the second phase, a co-design process with the same experts refined the framework into a game prototype, with their feedback on design recommendations and game elements guiding the iterative development of *Coloring the Emoji*.

Results: Experts identified four core design themes: (1) visual over verbal expression, (2) creating a natural and everyday experience, (3) supporting implicit expression, and (4) ensuring psychological safety and data protection. These principles were incorporated into *Coloring the Emoji*, which guides students through color selection, emoji-based pattern selection, and free drawing to promote emotional expression. Key features of the game include the use of familiar emojis, customizable options for emotional expression, and robust privacy protections. The game is freely accessible and is well-suited for Chinese college students dealing with academic pressures and financial constraints.

Conclusions: This study presents a novel intervention framework for coloring-based digital art therapy tailored to Chinese college students with alexithymia. The game *Coloring the Emoji* provides a nonverbal, intuitive platform for emotional regulation and self-reflection, addressing the cultural and emotional challenges specific to this population. Future research should focus on user testing and explore its applicability to other cultural and age groups.

Introduction

Background

Alexithymia is a cognitive-emotional condition [1] that affects about 10% of the general population and more than 20% of college students [2]. It results from disrupted brain circuitry in emotional processing and is characterized by deficits such as difficulty distinguishing between emotions and bodily sensations, a lack of emotional vocabulary, and reduced symbolic imagination [3]. Our previous survey of Chinese college students (n=332) revealed that 12.05% of students exhibited significant alexithymia (20-item Toronto Alexithymia Scale ≥70), with an overall average score of 59.90 (SD 8.15), which is close to the clinical threshold, suggesting a significant prevalence of alexithymia in this population.

Existing interventions primarily rely on psychotherapy approaches such as cognitive behavioral therapy (CBT) and mindfulness-based stress reduction, which aim to alleviate

XSL•FO
RenderX

symptoms by enhancing emotional awareness and expression [4]. These interventions typically require college students to verbally describe their emotions and engage in self-reflective emotional processing, which can be particularly challenging for college students with alexithymia due to their limited ability to identify emotions and express them verbally [3]. In China, where emotional restraint is culturally valued [5], reluctance to express emotions is often seen as normal social behavior rather than a clinical symptom [5], resulting in a lack of recognition of alexithymia and insufficient focus on tailored therapeutic approaches. Chinese college students face additional emotional challenges due to cultural expectations that prioritize emotional control and social conformity, making emotional expression more difficult [6]. Furthermore, practical barriers such as heavy academic workloads, geographic limitations, and financial constraints further hinder access to therapy, complicating the identification and treatment of alexithymia in this population [7,8].

Art Therapy and Its Limitations

Art therapy offers a structured and theoretically grounded approach to addressing alexithymia [9]. By involving nonverbal creative media, such as color, imagery, and movement, art therapy facilitates emotional identification and expression in a psychologically safe and cognitively manageable way [1]. This process can enhance emotional awareness, reduce avoidance, and externalize implicit emotions [10], thereby supporting long-term self-understanding and emotional regulation. By facilitating the externalization of suppressed emotions and overcoming verbal barriers, art therapy alleviates symptoms of alexithymia [11], reduces anxiety and depression [12], and enhances overall well-being [13].

However, several significant limitations continue to constrain their broader applicability. First, attitudinal barriers, such as shame and embarrassment, may hinder full engagement [14], especially among Chinese college students, for whom emotional restraint is culturally valued, and open emotional expression is often seen as a weakness [6]. Second, a lack of initiative, often driven by emotional avoidance and suppression, impedes their ability to regulate and express emotions effectively [15]. Chinese students are often taught to suppress emotions in favor of academic and social expectations, making emotional engagement more challenging. Third, time constraints, spatial limitations, and financial barriers reduce the feasibility and accessibility of interventions [16]. Chinese college students face heavy academic workloads, which limit their time for therapy. Additionally, geographic barriers and limited financial resources make it difficult for students to consistently participate in traditional therapy.

To address these challenges, digital art therapy has emerged as a promising intervention that leverages technology to enhance emotional expression and psychological healing [17]. Compared to traditional methods, it offers greater accessibility, continuity of care, adaptability for college students, and expanded modes of self-expression.

Coloring-Based Digital Art Therapy

Digital art therapy encompasses various approaches that combine creative expression with therapeutic intent. Among these, virtual reality–based art therapy offers an immersive, gravity-free environment that encourages full-body engagement and provides users with a sense of control. However, it requires costly equipment and may cause sensory discomfort, limiting its practical applicability, particularly for college students with limited finances [18]. Augmented reality–enhanced therapy, which overlays digital images onto real-world settings, is beneficial for trauma exposure and social interaction but poses challenges related to technical requirements and privacy concerns, which can hinder its widespread use [19].

Digital drawing platforms, such as Procreate or artificial intelligence–assisted tools, provide a low-pressure environment for precise, reversible emotional expression. However, they lack therapeutic framing and professional guidance, which can limit their effectiveness in addressing emotional regulation needs [20]. Therapeutic mobile apps offer a more structured approach, typically integrating mood tracking, daily prompts, and simple creative tasks. These apps are particularly accessible and well-suited for daily use, especially for college students dealing with emotional regulation challenges. However, they generally lack therapist involvement and offer limited depth of engagement, which may reduce their therapeutic effects [21]. Remote art therapy, delivered through live or asynchronous interaction, provides professional guidance and contextual sensitivity but may be hindered by technical disruptions and reduced nonverbal cues [22].

In this context, coloring-based digital art therapy builds on the accessibility and user-friendliness of digital platforms while offering unique advantages [23]. Unlike general digital drawing platforms, it integrates therapeutic guidance into its design by focusing on nonverbal emotional expression through color selection, pattern selection, and simple painting tasks [24]. This approach not only reduces cognitive load but also provides structured emotional support via predesigned templates, emotion tracking, reflective journals, and optional asynchronous therapist feedback [23]. By blending creative expression with therapeutic intent, coloring-based digital art therapy provides a safe, nonjudgmental space for users, making it particularly suitable for Chinese college students with alexithymia [25]. It helps them cope with the challenges posed by cultural emotional restraint and enables emotional exploration in a supportive environment [26].

Serious Games in Digital Art Therapy

Serious games are widely used in therapeutic contexts, designed to achieve specific goals such as emotional regulation, behavior change, or psychological healing, while also engaging users with interactive and enjoyable gameplay [27]. These games are different from traditional entertainment games, as they balance 2 key elements: achieving therapeutic outcomes and maintaining user engagement through fun and immersive experiences [28]. This combination makes serious games effective in offering users an interactive platform for emotional expression and self-reflection, which is especially beneficial for individuals with alexithymia, who may find verbal expression challenging

XSL•FO
RenderX

[29]. By incorporating structured tasks and feedback, serious games enable users to process and express emotions in a nonthreatening, low-pressure environment [27].

Among various serious games, coloring-based games stand out because of their simplicity and accessibility. These games create a low-cognitive-load environment for nonverbal emotional expression, allowing users to engage in activities such as color selection, pattern selection, and painting [24]. These tasks are specifically designed to help users externalize their emotions without the need for verbal expression, making them particularly useful for individuals with alexithymia [30]. In the case of Chinese college students, these games are especially beneficial as they provide a safe, nonjudgmental space for emotional exploration, which is crucial in a culture where emotional restraint is valued and emotional expression may be suppressed [31]. The game's structure, which involves tasks such as selecting colors, choosing patterns, and free drawing, offers a broad scope for users to express emotions creatively [32,33]. Additionally, the game settings—including visual style, real-time feedback, customizable options, and privacy measures—ensure that the intervention is engaging, accessible, and culturally sensitive [34]. These elements create a therapeutic yet enjoyable experience that respects cultural norms and encourages students to express themselves in a way that feels both safe and meaningful [35]. By integrating creative expression with therapeutic support, coloring games offer a comprehensive, user-friendly intervention that promotes emotional regulation, self-reflection, and personal growth [36].

Objectives

This study examines the use of coloring-based digital art therapy as an intervention for Chinese college students with alexithymia, focusing on how low-cognitive-load digital coloring tasks can support emotional identification and expression. The research began with expert interviews from fields including art therapy, human-centered design, digital health, and software development. These interviews provided valuable insights, which were used to create an intervention framework specifically tailored to the emotional and expressive needs of Chinese college students with alexithymia. Following the development of the framework, we engaged in a co-design phase with the same experts to refine and adapt the framework into a practical prototype. This iterative process ensured that the final game design, *Coloring the Emoji*, met both design recommendations from the previous framework and the specific needs of Chinese college students. The game, which incorporates color theory, pattern design principles, and human-computer interaction concepts, aims to facilitate nonverbal emotional exploration through intuitive color and pattern interactions. Future work will involve user testing to assess its therapeutic impact and further refine the system for broader application.

In summary, our contributions can be summarized as follows:

- An intervention framework for coloring-based digital art therapy was proposed to help Chinese college students with alexithymia better identify and describe their vague emotions, as well as effectively express and process them.
- Based on the proposed intervention framework, the authors collaborated with experts during a co-design phase to develop and refine *Coloring the Emoji*, a digital coloring game specifically designed to address the emotional needs of Chinese college students with alexithymia.

Methods

Overview

This study was conducted in 2 phases to construct the framework of coloring-based digital art therapy and to develop a coloring game for Chinese college students with alexithymia. In the first phase, semistructured expert interviews were conducted to gather professional insights and create an intervention framework for coloring-based digital art therapy. This qualitative approach helped identify key design principles and therapeutic mechanisms for the coloring game. In the second phase, we collaborated with the same experts in a co-design process to refine the framework and transform it into a game prototype. Through a series of collaborative discussions, the experts provided feedback on design recommendations and key game elements, allowing for the iterative development of *Coloring the Emoji*.

Recruitment

Purposive sampling was conducted until thematic saturation was achieved. Participants were selected through the authors' professional networks, targeting both professional experts and graduate students with relevant expertise in art therapy, digital health, human-centered design, or mobile app development. Professional experts were recruited for their extensive experience, with a minimum of 5 years in the field, as their expertise offers deeper insights and a broader understanding of the subject matter. Graduate students were chosen based on having over 5 years of professional experience in their respective fields and having participated in multiple practical projects relevant to the research topic. These graduate students were selected for their ability to provide insights closely reflecting real-world user experiences, given their engagement in daily life environments. To ensure diversity, experts were recruited from various regions of China. In addition to experts from the researchers' base in Shanghai, representing the eastern region, experts were also sought from the northern and southwestern regions to capture the regional and cultural differences across the country.

As data collection progressed, the research team continuously analyzed the interviews to assess thematic redundancy and determine when saturation had been reached. Based on this criterion, a total of 10 participants (4 graduate students and 6 professional experts) were included in the study. The inclusion criteria were as follows: (1) a master's degree or higher; (2) a minimum of 5 years of experience in art therapy, digital health, human-centered design, or mobile app development; and (3) demonstrated enthusiasm and willingness to participate. Exclusion criteria included experts who reported limited familiarity with the relevant fields or who provided low-quality responses during the initial consultation.

Procedure

We arranged semistructured interviews with each expert between April 2024 and June 2024, coordinating the time and location

XSL•FO
RenderX

in advance via email, phone, or text message. Due to geographical constraints, 2 experts were interviewed remotely via Zoom (Zoom Communications, Inc), while the remaining 8 experts were interviewed face-to-face by 2 members of the research team in a private setting. A semistructured interview guide with open-ended questions was prepared to allow each expert to share their perspectives and recommendations regarding coloring-based digital art therapy. The interview guide (Multimedia Appendix 1) was developed with 17 questions and addressed the following themes: (1) experiences in art therapy, (2) attitude toward digital art therapy, (3) suggestions for coloring-based digital art therapy, and (4) willingness of the expert to facilitate and support the follow-up study. Each interview lasted between 28 and 90 minutes. All interviews were audio- and video-recorded and verbatim transcribed within 3 days of each interview.

After the interviews, from June 2024 to July 2024, we proceeded to the second phase, engaging the same experts in multiple co-design sessions. These sessions were held remotely via Zoom and the Figma platform to refine the intervention framework and translate it into a game prototype. Experts provided feedback on the categorization of design recommendations and key game elements, ensuring the final design aligned with previous insights and therapeutic goals.

Data Analysis

Data collected from the semistructured expert interviews were analyzed using NVivo 15 (Lumivero) and an inductive approach by 2 independent researchers who were part of the research team, identifying themes related to experts' views on using digital art therapy for emotion regulation and their opinions on designing color-based interventions for Chinese college students with alexithymia. Each researcher independently reviewed the transcripts, coded the insights, and organized these codes into themes. The researchers then discussed their findings to reach a consensus on the key themes, ensuring agreement on the categorization of the data.

Ethical Considerations

The study was conducted following ethical standards and was approved by the institutional review board of the main researchers' affiliated institution (approval: TJDXSR076). Before participation, experts were informed of the study's purpose, procedures, and potential risks. Verbal informed consent was obtained when scheduling the interview via phone or email. All participants took part in this research voluntarily without any financial compensation. All participants were assured of their confidentiality, and data were anonymized to prevent identification. Personal information was securely stored and anonymized throughout the study, ensuring compliance with data protection regulations.

Results

Expert Characteristics

A total of 10 participants were involved in the study, comprising 6 professional experts and 4 graduate students with relevant expertise. The gender distribution was balanced, with 5 males and 5 females. The graduate students, aged between 24 and 27 years, included 2 students aged 24 years and 2 students aged between 25 and 27 years. All were master's degree students who had studied in their respective fields for 5 to 8 years. Their areas of expertise included art therapy (n=1), digital health (n=1), human-centered design (n=1), and mobile app development (n=1), with the students in art therapy and digital health each having more than 1 year of work experience. The experts ranged in age from 28 to 44 years, with 2 experts aged under 34 years and 4 experts aged between 34 and 44 years. All 6 experts held doctoral degrees, including 4 associate professors and 2 lecturers. The experts' years of industry experience varied: 2 experts had nearly 10 years, 3 had nearly 20 years, and 1 had more than 20 years. Their areas of expertise included art therapy (n=1), digital health (n=2), human-centered design (n=2), and mobile app development (n=1). An overview of the expert characteristics is provided in Table 1.

Intervention Framework for Coloring-Based Digital Art Therapy

The thematic analysis of expert interviews provides valuable insights into the construct of coloring-based digital art therapy for addressing alexithymia among Chinese college students.

Theme 1: Visual Instead of Verbal

Subtheme: Draw the Emotions

Most experts (7/10) believed that art therapy plays a significant role in the treatment of emotional expression disorders. They pointed out that art therapy not only helps visualize abstract emotions but also eliminates language barriers through visual expression, providing college students with a low-pressure, nonthreatening way to externalize their emotions. A smaller group (3/10) mentioned more detailed points. They expressed that color makes the process more tangible and perceptible, promoting emotional regulation and self-awareness, and helping students more intuitively recognize and process their feelings. One expert mentioned that one of her college students used warm yellow to express maternal love and the warmth of ginger soup, "As I observed the boy's coloring, he colored the 'umbrella in the rain' warm yellow, saying, 'This is the steam from my mom's ginger soup'" [E1].

Another expert also pointed out similar cases involving a student who used an orange boat to symbolize secret affection, "In one of my cases, … the student painted gray waves for 3 days, then suddenly added an orange boat, saying, 'That's the color of the headband of the girl I secretly like'" [E7].

Subtheme: Express Through Symbolism

Some experts (4/10) suggested that symbolic emotional expression is not limited to color alone, but also includes shapes, sounds, and other sensory elements, which can help college students more deeply recognize and communicate their emotions. Integrating various sensory symbols, such as visual and auditory cues, can make emotional expression more concrete and diversified. By adapting to different college students' preferences, it breaks the limitations of traditional verbal expression. One expert stated, "When the student exhibited anger, the system responded with fast music and flames appeared around the character" [E6].

Subtheme: Describe Emotional Stories in the Third Person

Experts who have had long-term communication with college students (5/10) have found that by attributing emotions to virtual characters or a third party, college students can avoid directly confronting their own emotions, which makes it easier for them to express and understand their feelings. This method provides

XSL•FO
RenderX

an indirect way to externalize emotions, making emotional expression more natural and less stressful:

> *Asking "What does the person in the picture see?" works much better than asking "How do you feel?"* [E1]

> *Every time I asked about her feelings, the girl stubbornly said, "I feel nothing," but when her cloud avatar turned gray, the system said, "Little Cloud is raining," and she cried, "It's because I want to cry."* [E9]

Subtheme: Provide Interactive Options

Experts with hands-on therapeutic experience (3/10) noted that body language, especially tactile and auditory feedback, can make emotional expression more concrete and vivid. By activating the body's instinctive responses, college students can perceive and express emotions more intuitively. This method is beneficial for those who struggle with expressing emotions, as body language provides an effective alternative, such as adjusting brush size or the intensity of movements. This sensory experience makes emotional externalization more natural and enhances the emotional regulation process:

> *A little girl I once treated expressed, "When I'm happy, I use a small brush to paint carefully, but when I'm unhappy, I use a thick brush." So, it would be better to give them different choices.* [E1]

> *It would be beneficial to incorporate some interactive features, such as adding sound effects when the student clicks a button.* [E8]

Theme 2: Create a Natural and Everyday Experience

Subtheme: Refuse to Judge

Most experts (9/10) stressed the importance of avoiding the judgment of emotional expressions, as this could lead to students feeling evaluated or restricted in their emotional expression. When students are aware that their work will be graded or categorized according to predefined emotional labels, it introduces an element of judgment, which can hinder their ability to freely express their emotions:

> *Core rule: No grading! Do not label the patient's work. Grading and labeling will make students feel that they are being evaluated, which will affect their emotional expression.* [E1]

> *Students should have the freedom to give meaning to their own emotional expressions without having fixed labels imposed by the system or the outside world.* [E5]

Subtheme: Integrate Into Life Scenes

In addition, experts (7/10) believe that the design of digital art therapy should integrate emotional expression into daily life to make it closer to students' real experiences. By combining the stress and emotions of life with artistic expression, students can release their inner emotions in a familiar situation.

> *When students face exam anxiety, some test paper-style patterns can be added to the system to help students vent their emotions through artistic expression when facing pressure and reduce the burden of stress.*

> *[E7]*

Subtheme: Establish Event Connection

More than half of the experts (6/10) mentioned that through contextual connection, students can more naturally connect emotions with specific events, which helps them understand and express emotions more easily. The design of contextual connection can provide a guide to enable students to connect emotions with real-life events and situations, making it easier for them to identify and express emotions:

> *Seeing the sunset makes the child calm, and the system learns to associate sunsets with relaxation.* [E2]

> *After watching her favorite flowers, the system links happiness with similar content.* [E3]

Subtheme: Leverage Digital Technology

Experts (3/10) emphasized that the application of digital technology can further enhance the effectiveness of digital art therapy. By using modern digital tools, students can enjoy a more fluid, intuitive, and multisensory experience of emotional expression. One expert stated, "Quick responses and smooth experiences can reduce students' anxiety caused by technical issues and help them focus on emotional expression rather than technical distractions" (E10).

Theme 3: Support Implicit Expression

Subtheme: Anonymization

Experts (4/10) emphasized that anonymity is a key feature of digital art therapy, helping students feel safe and unjudged when expressing emotions. Anonymizing the process of emotional expression allows students to explore their feelings without fear of exposure or social judgment. This feature is especially beneficial for those who experience social anxiety or feel vulnerable when discussing their emotions openly. One expert stated, "Works should provide an anonymous upload option while retaining the students' right to refuse uploading" (E10).

Subtheme: Protect Personal Privacy

Experts with a technical background (3/10) pointed out that privacy protection is another crucial issue in digital arts therapy and highlighted several methods for protecting personal data and ensuring the confidentiality of students' emotional expressions. Protecting privacy is especially important when dealing with sensitive topics such as emotional distress, mental health issues, or trauma. Students need to be assured that their personal information and emotional content will not be exposed to others without their consent:

> *Implement strict controls on who can access user data and when, ensuring only authorized people or systems can access sensitive data.* [E3]

> *Using a WeChat mini-program and bypassing campus network restrictions ensures that students can continue their coloring even if the internet is down at night.* [E6]

XSL•FO
RenderX

Theme 4: Ensure Psychological Safety and Data Protection

Subtheme: Protect User Data

Experts (10/10) agreed that data protection is a fundamental component of any digital therapy platform. Ensuring that students' personal information and emotional data are securely handled and erased when no longer needed is essential for maintaining trust and preventing exploitation. One expert stated, "When deleting data, provide a destruction certificate to ensure complete disappearance" (E6).

Subtheme: Focus on Psychological Safety

In addition to data protection, experts (7/10) emphasized that the game's design should prioritize mental safety. Ensuring that students feel emotionally safe, supported, and free from stress during the emotional expression process is essential. The design should minimize factors that could lead to psychological harm or cause unnecessary anxiety.

> *Many college students I met expressed concerns that they could not draw, had no artistic talent, and were afraid that their paintings would not look good when they first encountered coloring art therapy. Psychological counselors and digital systems should always support and protect college students' fragile hearts, encourage college students to try, and avoid any content that would frustrate college students' psychology as much as possible.* [E1]

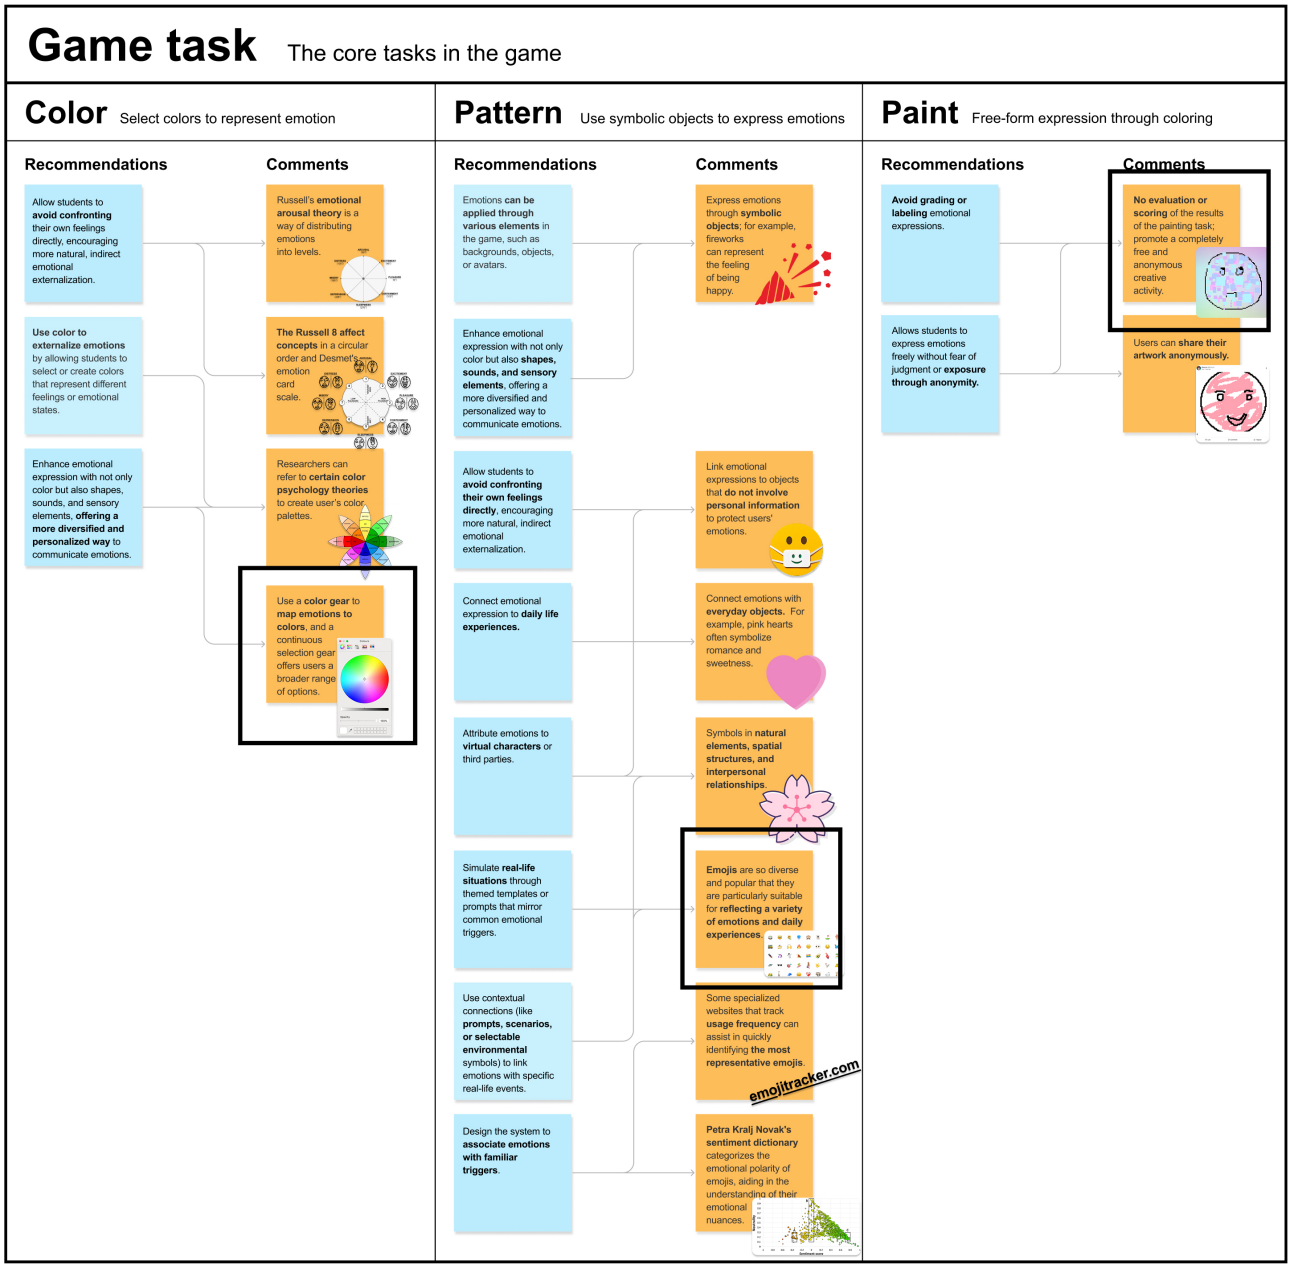
> *…Such as detecting repeated modifications triggers a pop-up: "Do you want to take a break?"* [E3]

Based on the qualitative analysis of expert interviews, the intervention framework for coloring-based digital art therapy is summarized in Table 2.

XSL•FO
RenderX

Table . Intervention framework for coloring-based digital art therapy.

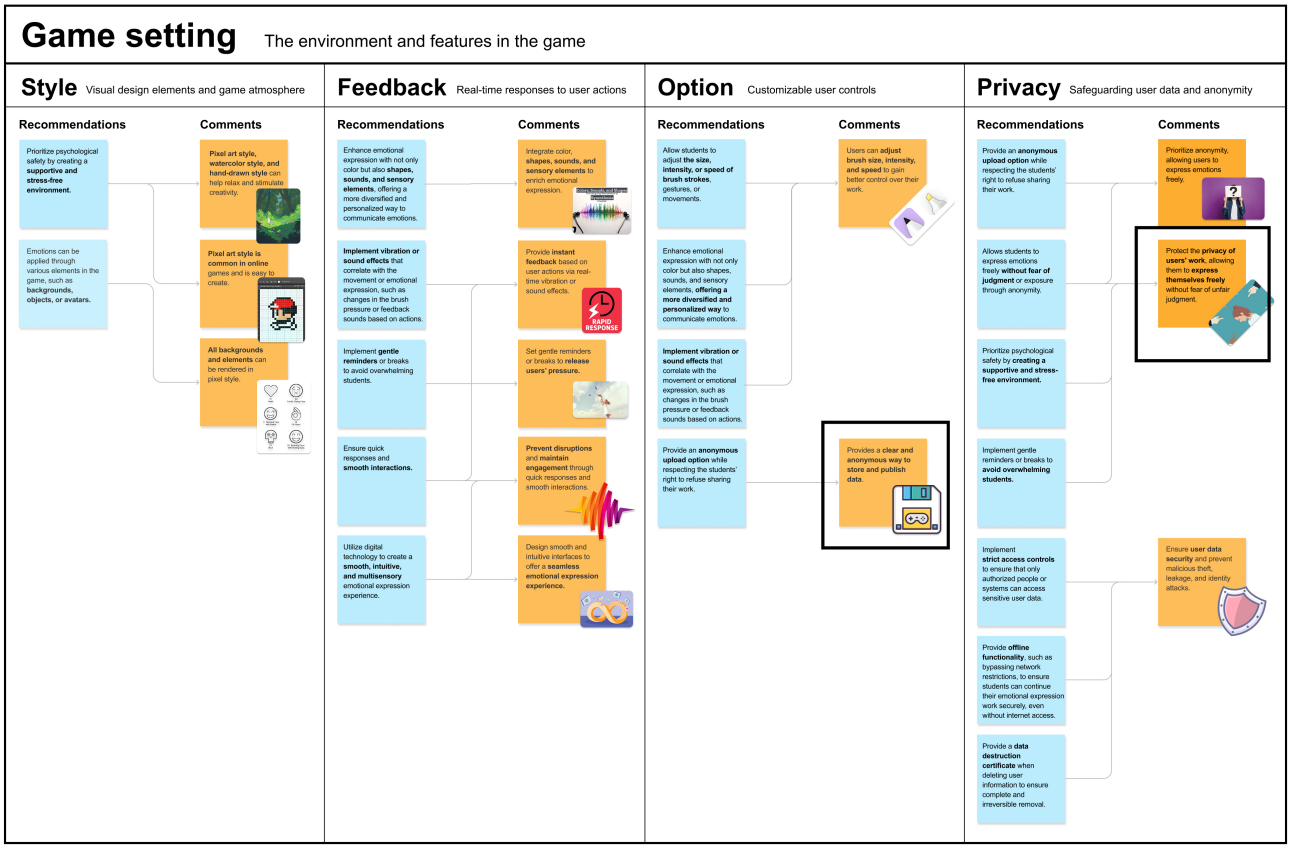
Themes and subthemes	Design recommendation
Visual instead of verbal	
Draw the emotions	• Use color to externalize emotions by allowing students to select or create colors that represent different feelings or emotional states. • This can be applied through various elements in the game, such as backgrounds, objects, or avatars.
Express through symbolism	• Enhance emotional expression with not only color but also shapes, sounds, and sensory elements, offering a more diversified and personalized way to communicate emotions.
Describe emotional stories in the third person	• Attribute emotions to virtual characters or third parties. • Allow students to avoid confronting their own feelings directly, encouraging more natural, indirect emotional externalization.
Provide interactive options	• Allow students to adjust the size, intensity, or speed of brush strokes, gestures, or movements. • Implement vibration or sound effects that correlate with the movement or emotional expression, such as changes in the brush pressure or feedback sounds based on actions.
Create a natural and everyday experience	
Refuse to judge	• Avoid grading or labeling emotional expressions.
Integrate into life scenes	• Connect emotional expression to daily life experiences. • Simulate real-life situations through themed templates or prompts that mirror common emotional triggers.
Establish event connection	• Use contextual connections (like prompts, scenarios, or selectable environmental symbols) to link emotions with specific real-life events. • Design the system to associate emotions with familiar triggers.
Leverage digital technology	• Use digital technology to create a smooth, intuitive, and multisensory emotional expression experience. • Ensure quick responses and smooth interactions.
Support implicit expression	
Anonymization	• Allows students to express emotions freely without fear of judgment or exposure through anonymity. • Provide an anonymous upload option while respecting the students' right to refuse sharing their work.
Protect personal privacy	• Implement strict access controls to ensure that only authorized people or systems can access sensitive user data. • Provide offline functionality, such as bypassing network restrictions, to ensure students can continue their emotional expression work securely, even without internet access.
Ensure psychological safety and data protection	
Protect user data	• Provide a data destruction certificate when deleting user information to ensure complete and irreversible removal.
Focus on psychological safety	• Prioritize psychological safety by creating a supportive and stress-free environment. • Implement gentle reminders or breaks to avoid overwhelming students.



Coloring Game: *Coloring the Emoji*

Based on the insights gathered from the co-design process, *Coloring the Emoji* was developed to address the emotional and cognitive challenges faced by Chinese college students with alexithymia. During co-design sessions, experts provided feedback on how to organize and apply the design recommendations, which led to the refinement of key game

XSL•FO
RenderX



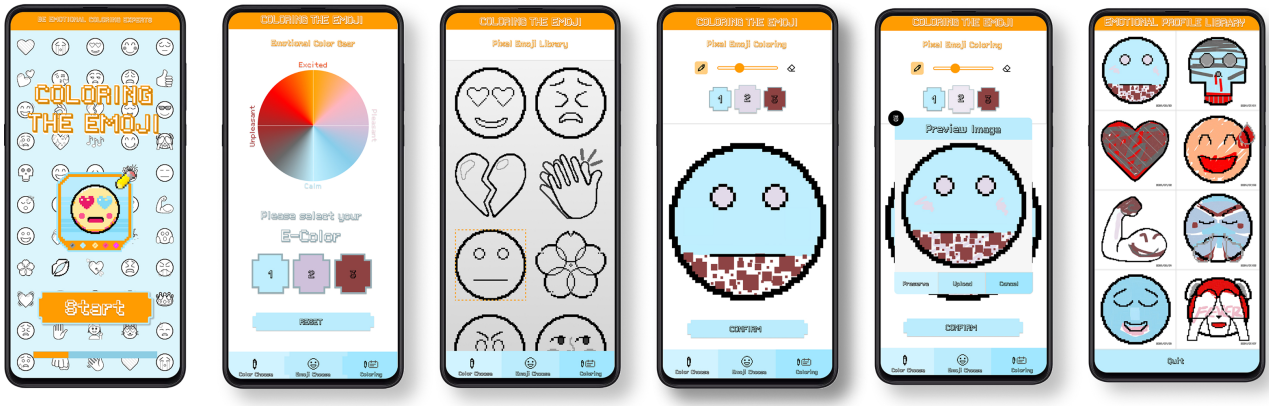
components, ensuring alignment with therapeutic goals (Figure 1 and Figure 2). The game was designed to facilitate intuitive, nonverbal emotional expression and recognition, incorporating expert insights into its core elements.

Figure 1. Game task.

XSL•FO
RenderX

Figure 2. Game setting.

The game task includes 3 key components: color, pattern, and paint [32,33]. For color, experts recommended using color to externalize emotions, allowing students to select colors that represent different feelings. Experts also suggested incorporating a continuous color selection gear to offer a broader range of options for more personalized emotional expression. This led to the creation of the *Emotional Color Gear*, which maps emotions to colors based on Russell's [37] emotional arousal theory and Desmet's [38] emotion card scale, simplifying emotions into 2 dimensions—pleasure and arousal—for easier emotional identification. In pattern, experts emphasized the use of symbolic objects and familiar symbols to help students externalize emotions indirectly. This led to the development of the *Emoji Scene Library*, which includes 53 emojis with strong emotional polarity and the highest use frequency among college students [39,40], allowing students to connect their emotions to familiar symbols and everyday experiences. The system was designed to associate emotions with common triggers, facilitating easier emotional identification [41]. For paint, experts highlighted the importance of creating a nonjudgmental space for emotional expression, with no grading or labeling of expressions, and features enabling students to share their artwork anonymously, promoting free, creative activities.



The game setting includes 4 key components: style, feedback, option, and privacy [34,35]. For style, experts recommended creating a supportive and low-pressure environment through visual elements that could help students relax and stimulate creativity. Based on this, we chose the pixel art style, which is common in online games, easy to create, and helps to create a relaxed atmosphere. In feedback, experts emphasized enhancing emotional expression not only with color but also with shapes, sounds, and sensory elements to provide instant feedback, while introducing gentle reminders and breaks to avoid overwhelming students and maintaining their engagement. For option, experts recommended allowing students to adjust brush size, intensity, and speed to better control their emotional expression, thereby enhancing engagement [42]. In privacy, experts stressed anonymity and data security, implementing strict access controls and offering the option to share artwork anonymously. Additionally, the game includes a data destruction certificate to ensure the irreversible deletion of personal data.

To ensure *Coloring the Emoji* meets the specific needs of Chinese college students with alexithymia, several design features were integrated based on expert feedback. These features address challenges such as emotional restraint, heavy academic workloads, and financial limitations. First, to accommodate emotional expression, the *Emotional Color Gear* offers a continuous selection option, allowing a broader range of color choices to represent emotions. Second, considering the popularity of emojis in Chinese digital communication, a diverse set of emojis was incorporated, reflecting a wide range of emotions and linking them to daily life experiences. Third, the game avoids grading or scoring emotional expressions, aligning with the cultural preference for privacy and reducing social pressure. Finally, robust privacy protection measures ensure students can express themselves freely without fear of judgment, with the option to share artwork anonymously. These design choices address the unique emotional challenges faced by Chinese college students, offering a culturally sensitive space for emotional exploration and self-expression.

XSL•FO
RenderX

Coloring the Emoji helps college students with alexithymia recognize and express their emotions through 3 core stages: color selection, pattern selection, and free drawing (Figure 3). In the color selection stage, students select colors to externalize and convey their feelings, thereby clearly identifying their emotions. In the pattern selection stage, students choose emojis that represent their emotions, allowing them to express their feelings indirectly and reduce emotional confrontation. Finally, the free drawing stage provides a safe, private space for unrestricted emotional expression, promoting emotional exploration and self-reflection without fear of judgment. These stages work together to offer students an intuitive, nonverbal way to engage with and understand their emotions (Multimedia Appendix 2).

Figure 3. The core interface of *Coloring the Emoji*.

Discussion

Principal Findings

This study aimed to develop a coloring-based digital art therapy intervention for treating alexithymia among Chinese college students. Through expert interviews, we gathered valuable insights that informed the creation of the intervention framework. The findings emphasized the effectiveness of using color, symbolism, and nonverbal emotional expression methods to address the challenges faced by college students with emotional processing difficulties. These insights align with existing theories highlighting the importance of visual over verbal expression in facilitating emotional regulation and expression for individuals with alexithymia [43]. Based on this framework, the *Coloring the Emoji* game was developed as a therapeutic intervention that uses coloring tasks to enhance emotional recognition and expression, offering a nonverbal, intuitive platform for self-reflection.

Intervention Framework

The intervention framework for coloring-based digital art therapy, developed through expert input, focuses on addressing the core features of alexithymia, specifically the difficulty in identifying and describing emotions. By integrating visual symbols such as colors and patterns, the framework provides a tangible method for Chinese college students to externalize their emotions, making it easier for them to communicate feelings they may struggle to verbalize [44,45]. Experts also emphasized the importance of creating a nonjudgmental and low-pressure environment for emotional expression. The design of the intervention explicitly avoids grading or labeling emotional outputs, ensuring that students can express themselves without the fear of judgment, which is particularly important for those with alexithymia who may already experience difficulties with emotional expression [46]. Furthermore, the integration of digital technology was deemed essential for creating a seamless, intuitive, and multisensory experience, allowing students to explore their emotions continuously and with reduced anxiety [47].

By combining expert insights, the intervention framework incorporates visual, symbolic, and contextual elements, making emotional exploration more relatable and personalized for students. The framework emphasizes incorporating body language and sensory feedback through adjustments to brush size and intensity, further enhancing the emotional expression process and providing a more immersive and realistic experience [42]. These principles were then directly applied in the development of *Coloring the Emoji*, creating a user-friendly, digital intervention that meets the therapeutic goals outlined in the framework.

Coloring Game

In the design of *Coloring the Emoji*, several key features were incorporated based on expert feedback to specifically address the emotional needs of Chinese college students with alexithymia. The color selection phase draws upon emotional psychology models, simplifying complex emotions into 2 dimensions—pleasure and arousal—and mapping these to specific colors [48]. This approach helps users quickly identify and select colors that best represent their emotional state, facilitating easier emotional expression. The pattern selection phase further supports emotional identification by offering a library of emojis, which were carefully selected for their strong emotional polarity [49]. Emojis are widely used in Chinese digital communication, providing students with a familiar and culturally relevant means to connect emotions with symbolic representations, thus making the emotional expression process more relatable.

The free drawing phase allows for uninhibited emotional expression, reinforcing the importance of a nonjudgmental space for self-reflection. The inclusion of interactive options, such as brush resizing and adjusting movement intensity, enhances user

XSL•FO
RenderX

engagement and allows students to express their emotions more freely [50]. These features also align with expert recommendations for integrating sensory feedback into the therapeutic process, providing a more interactive and immersive emotional exploration experience. Additionally, the game's structure supports nonverbal emotional expression, which is particularly beneficial for Chinese students, who may face cultural challenges in verbalizing their emotions.

The game also incorporates robust privacy protection measures to ensure the confidentiality of students' emotional data [51]. The option to share their artwork anonymously supports a safe, private space for emotional expression, reducing the social pressure that might otherwise inhibit participation. These privacy features, combined with the therapeutic design elements, ensure that students can engage with the game in a way that feels secure and supportive, while respecting their cultural values and emotional boundaries [52].

Limitations and Future Directions

While *Coloring the Emoji* shows promise in supporting emotional expression and regulation for Chinese college students with alexithymia, several limitations remain that need to be addressed in future research. This study focused specifically on Chinese college students, whose emotional challenges are influenced by cultural factors such as emotional restraint and social conformity. While the game design addresses these cultural nuances, its applicability to other populations remains uncertain. Future studies should explore how the game can be adapted to meet the needs of different cultural and age groups, as well as individuals with varying emotional processing difficulties. This would involve adjusting the game to accommodate diverse emotional challenges in different contexts, ensuring that the intervention remains relevant and effective across various demographics.

The current prototype requires rigorous user testing to assess its therapeutic impact and identify areas for improvement. Although expert feedback has been crucial in shaping the design, real-world testing is essential to evaluate how well the game supports emotional regulation and expression in practical settings [53,54]. Additionally, continuous collection of user data and qualitative feedback will provide insights into the game's effectiveness and adaptability to users' specific emotional needs.

Although the *Coloring the Emoji* game is beneficial for individuals with alexithymia, it may not fully replace other therapeutic methods, such as CBT or traditional art therapy [55,56]. Future research could investigate the potential integration of this coloring-based intervention with established therapeutic methods, creating a more comprehensive treatment plan. Combining digital art therapy with conventional therapies could offer a more holistic and adaptable model for treating emotional processing difficulties [57].

Conclusions

This study proposes a coloring-based digital art therapy framework developed to address alexithymia among Chinese college students. Based on this framework, we created *Coloring the Emoji*, a platform that provides an intuitive, nonverbal, and low cognitive-load method for emotional identification and expression. By integrating color, symbolism, and sensory feedback, the game offers a nonjudgmental space for anonymous self-expression, which directly addresses the cultural norms of emotional restraint and societal barriers faced by this population. The inclusion of emojis, which are widely popular in Chinese digital communication, further assists students in connecting emotions with familiar symbols. Additionally, the platform is free of charge and easily accessible, making it suitable for students facing academic pressures and financial constraints.

While the intervention shows promise, further research is needed to assess its real-world effectiveness and adaptability across diverse cultural and age groups. Future studies could explore the integration of *Coloring the Emoji* with other therapeutic approaches, such as CBT, to enhance its therapeutic impact. Further research should also examine its long-term effects, particularly in addressing co-occurring emotional issues, such as anxiety and stress.

Acknowledgments

The authors thank all the experts who participated in the interviews and co-design process for their valuable insights and contributions to this study.

Funding

The authors declared no financial support was received for this work.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

All authors contributed to the conceptualization and methodological design of the study, as well as the co-design process. SL and HD conducted the interviews, performed data analysis, wrote the first draft of the manuscript, and contributed to subsequent revisions. JC and QW provided guidance throughout the study and reviewed and edited the manuscript. All authors contributed to the final draft of the manuscript.

Abstract

Background: Diabetes mellitus management requires considerable patient self-efficacy, knowledge, and support for social determinants of health. These needs become particularly acute during pregnancy. Mobile health (mHealth) tools are a promising approach to enhance patient engagement with the health care system, education, and health promotion and may be particularly helpful during the period of rapid skills acquisition, which is a hallmark of experiencing diabetes during pregnancy. Therefore, we developed SweetMama, a web-based mHealth app designed to support and provide information to low-income pregnant individuals with gestational diabetes mellitus (GDM) or type 2 diabetes mellitus (T2DM).

Objective: This study aimed to understand the user experiences of low-income pregnant people who were randomized to use SweetMama during a feasibility trial.

Methods: This mixed methods secondary analysis of data from a feasibility randomized controlled trial (RCT) included participants randomized to SweetMama, an interactive, web-based mHealth app with multiple motivational and educational features that help reduce barriers to care, offer health education, and aim to improve diabetes self-care for low-income pregnant people. In the parent trial, English-speaking pregnant individuals with GDM or T2DM were randomized to use SweetMama during pregnancy or usual care. SweetMama users experienced an individualized curriculum from enrollment through 6 weeks postpartum. Upon exit, users completed 2 qualitative interviews (during the delivery hospitalization and at the postpartum visit) and surveys assessing standardized usability metrics. The surveys included the System Usability Scale (SUS), the Usefulness, Satisfaction, Ease of Use (USE) scale, and the mHealth App Usability Questionnaire (MAUQ) to assess usability. Qualitative data were analyzed using constant comparative techniques.

Results: Of 30 SweetMama users, 60% (n=18) had GDM, 83.3% (n=25) had publicly funded prenatal care, and the majority identified as non-Hispanic Black (n=17, 56.7%) or Hispanic (n=11, 36.7%). Scores on the SUS (median 85.0/100, IQR 70.0 - 88.8; ≥71% indicates acceptable or higher usability), USE (overall median 84.5/100, IQR 81.0 - 91.4), and MAUQ (median 84.1/100, IQR 79.0 - 91.3) indicated favorable usability assessments, particularly for the “ease of learning” domain. Qualitative interviews supported these findings: participants described the app as easy to navigate, well organized, and helpful for staying on track, citing features such as clear visual design, timely text reminders, and actionable tips. Users valued motivational elements and content specificity, while recommending increased customization and enhanced esthetics.

Conclusions: In this user experience evaluation of a web-based mHealth app for low-income pregnant individuals with diabetes, participants found the tool to be user-friendly, visually appealing, informative, and motivating. Constructive feedback for application improvement for use in a future larger trial of clinical effectiveness was collected.

Introduction

In the wake of a growing obesity epidemic, pregnant people are more likely to develop gestational diabetes mellitus (GDM) or enter pregnancy with type 2 diabetes mellitus (T2DM) [1-8]. Both GDM and T2DM increase the risk of maternal and fetal complications, such as preeclampsia, cesarean birth, and macrosomia, among others [3,6-10]. The rise in diabetes prevalence before and during pregnancy disproportionately affects low-income pregnant people of color, highlighting the need for interventions to incorporate social determinants of health in their development to reduce the risk of adverse outcomes [2,8-18].

Although diabetes treatment can lower the risk of complications [19-21], many logistical and social barriers prevent adequate diabetes self-management [22-27]. To optimize health outcomes, pregnant individuals with diabetes must be skilled in communication, organization, health literacy, and numeracy [22,25,28]. Strong social support systems are also beneficial [25,26,29-31]. Socially vulnerable individuals may not have sufficient access to educational resources for diabetes and are at greater risk of having suboptimal social support, leading to inadequate glucose control and poor health outcomes [25,26,28-31]. Thus, there is a need for interventions that educate patients, promote the skills needed for self-management, and address socioeconomic and racial disparities for pregnant individuals with diabetes [27,29].

Mobile health (mHealth) technology has the potential to address health disparities and promote health education through tailored and literacy-appropriate content [27]. With the widespread use of smartphones, mHealth can reach many individuals and reduce burdens such as transportation to and from health care providers [32]. In addition to being accessible, mHealth interventions are relatively low-cost and capable of providing support outside of clinical encounters [32,33]. mHealth tools for diabetes in nonpregnant populations have been effective at promoting self-management [34,35]. However, for both pregnant and nonpregnant populations, there is a lack of technology centered on increasing health literacy and self-efficacy skill development for diabetes management [36]. Furthermore, the tools that do exist are rarely designed to be user-centered (eg, they tend to rely on text message- or telemedicine-based communication rather than user-friendly applications) and are infrequently targeted toward individuals at greater social disadvantage [37].

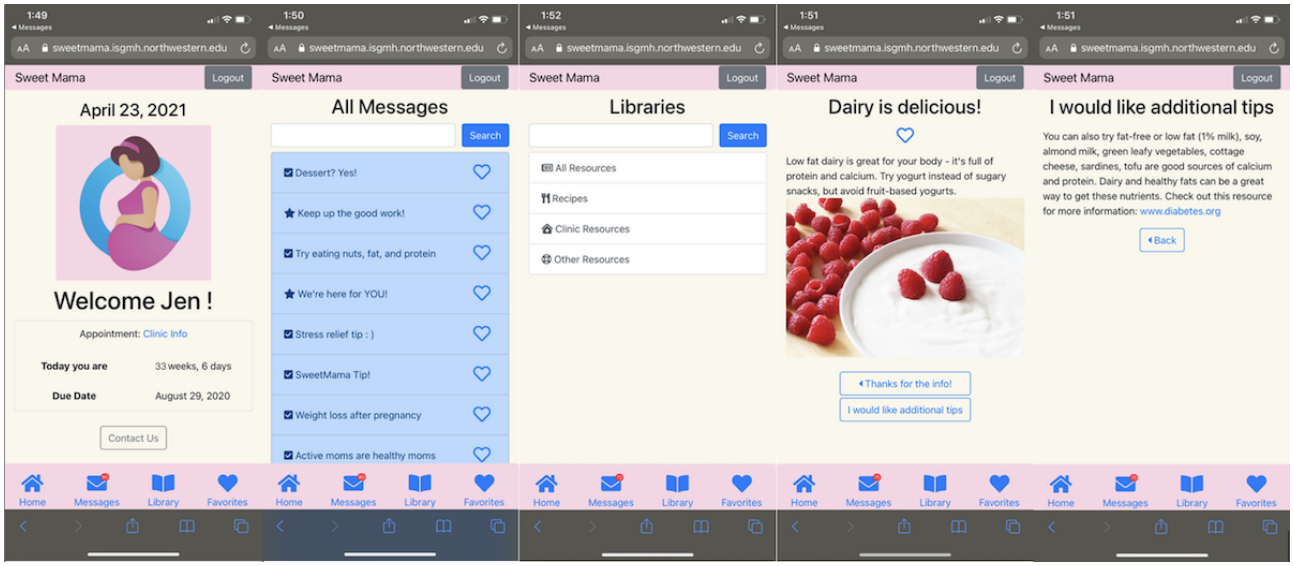
To address the lack of mHealth tools aimed at supporting diabetes self-management among low-income, racially marginalized pregnant people, we created a multiphase project called SweetMama (NCT03240874). User feedback from an earlier phase of this project, which tested a text message–based intervention to promote diabetes self-management, expressed the desire for a more interactive, expansive mHealth tool [38]. In response, we developed the SweetMama app, a motivational and educational tool aimed at addressing diabetes self-management needs disproportionately experienced by English-speaking, socially vulnerable pregnant individuals [39]. Early feedback on this tool was explored in focus groups that included low-income, racially marginalized, English-speaking pregnant people. This feedback ensured that the app was literacy-appropriate and tailored toward the needs of this population (eg, by including preferred recipes and local resources). In the next phase of the study, a randomized controlled trial (RCT) was conducted to evaluate the feasibility of SweetMama use. The purpose of this planned secondary analysis from data gathered in the feasibility RCT is to evaluate the user experience of SweetMama participants, in order to consider how user experiences inform the optimization of mHealth interventions for this unique population.

Methods

Study Overview

This is a mixed methods analysis of data collected from the SweetMama feasibility RCT, which aimed to understand the user experience with this web-based mHealth app, including usability and satisfaction. Per users' requests from an earlier phase of the project, we created a web-based mHealth app, which expanded upon our previous text message–based intervention and was an accessible, interactive option for our patient population. The home screen of SweetMama provides the app's logo as well as personalized information, including the participant's name, gestational age, upcoming appointments, and a support portal (Figures 1 and 2). SweetMama delivered literacy-appropriate weekly motivational tips and individualized goal reminders, housed in a message center for easier access (Figure 2). Goal achievement was designed to include an element of gamification, whereby users could earn trophy icons for stating they had achieved their personalized goals. A library feature offered trusted educational materials, clinic-based resources, and recipes, with the option for users to "favorite" items for later use (Figure 2). If participants were interested in receiving further information from a certain message, they could click "I would like additional tips" to receive an in-depth description related to the message (Figure 2). During the postpartum period, the SweetMama curriculum focused on reminding participants about postpartum visit attendance, while also providing resources on diet maintenance during breastfeeding, mood changes, and more. This curriculum aimed to instill self-efficacy skills in patients and ensure that they were staying on track with the goals they set during pregnancy.

Data included in this analysis were generated from qualitative interviews addressing participants' opinions and feedback on SweetMama, which was designed to provide insight into the app's usability, as well as surveys assessing standardized usability metrics. The aim of the overarching SweetMama study was to test the feasibility and acceptability of this socially tailored, educational mHealth curriculum to encourage maternal self-efficacy for diabetes management among English-speaking



XSL•FO
RenderX

pregnant individuals. This mixed methods secondary analysis analyzed user experiences and satisfaction with SweetMama, both of which were predesignated secondary outcomes of this study assessed only in the participants randomized to use SweetMama.

Figure 1. SweetMama logo.

Figure 2. SweetMama screenshots of application features.

Recruitment

In the parent trial, research team members met with SweetMama participants at 3 separate visits: the enrollment visit (<30 wk of gestation), delivery visit, and postpartum visit. Consent was obtained at the enrollment visit. Individuals were recruited from the study site, Northwestern Medicine, at the initiation of prenatal diabetes care. Participants met the following inclusion criteria: age 18 and older, GDM or T2DM, English-speaking, confirmed intrauterine pregnancy prior to 30 weeks' gestational age, low income (defined as use of public insurance for prenatal care or household income <200% of the poverty line for family size), and access to a smartphone. This analysis focuses only on data from those who were randomized to use SweetMama. Users engaged with SweetMama throughout their pregnancy.

Quantitative Data Collection and Analysis

Users completed 3 validated, standardized assessments of usability at the time of their delivery hospitalization or within the first week after delivery. These included the System Usability Scale (SUS), the Usefulness, Satisfaction, Ease of Use (USE) scale, and the mHealth App Usability Questionnaire (MAUQ). The SUS, USE, and MAUQ were scored using standard scoring strategies for each scale, with scores normalized

XSL•FO
RenderX

to a 0 to 100 scale for each questionnaire. The SUS survey is a 10-item questionnaire using a 5-point Likert scale that provides a measure of overall user satisfaction [40,41]. A system is "acceptable" if scores are above 70, "marginal" if scores are between 51 and 70, and "not acceptable" if scores are 50 and below [41]. The USE survey (a 30-item questionnaire), which similarly assesses the usability of a system through a 7-point Likert scale, has components that address 4 domains: usefulness, ease of use, ease of learning, and satisfaction [40,42]. The MAUQ (21 items, 7-point Likert scale) assesses ease of use and satisfaction, system information arrangement, and usefulness in its version specifically for interactive mHealth tools and patients [43]. These tests are also reliable indicators of usability, acceptance, and satisfaction for evaluating mHealth resources (Cronbach α=0.91 [SUS], 0.98 [USE], 0.90 [MAUQ]) [41-43]. All scores were converted to a standard scale of 0 to 100. Descriptive summary statistics (median and IQR) were calculated. Quantitative analyses were performed using Stata v15 (StataCorp).

Qualitative Data Collection and Analysis

Two interviews were conducted to gather qualitative data about participants' experiences. The first interview occurred during the participants' delivery hospitalization or within the first week after delivery. Research personnel used an interview guide developed by the research team to ask questions and obtain feedback on areas of improvement for SweetMama through addressing three domains: (1) user experience, (2) app functionality (including features, curriculum, and preferences), and (3) user diabetes management. All interviews were conducted by a trained full-time research team member who was not involved in participants' clinical care, and who had no prior clinical relationship with participants. Participants were informed that their responses would not affect their medical care or study incentives, and they were encouraged to provide both positive and negative feedback to improve SweetMama. The second interview took place at the postpartum visit, approximately 6‐8 weeks postpartum. This qualitative interview focused on SweetMama's postpartum curriculum, with questions tailored toward feasibility, improvement, and user engagement with the app. Interviews lasted approximately 20 to 40 minutes. They were audio-recorded and transcribed using a professional service. Qualitative data were analyzed using the constant comparative method with a team-based approach [44,45]. A subset of 5 transcripts was reviewed by trained independent coders, who identified recurring concepts, referred to as subthemes, related to users' experiences with SweetMama. These subthemes were used to develop a preliminary codebook, which was discussed and refined by the full research team to ensure clarity and consistency. Two independent coders trained using Dedoose (SocioCultural Research Consultants, LLC), a qualitative coding software, then used the revised codebook to iteratively code the transcripts. The codebook continued to be updated during regular team meetings, and those changes were applied. Any discrepancies between coders were resolved on a code-by-code basis. Delivery and postpartum interviews were analyzed as a single corpus because the interview guides were designed to capture complementary aspects of a continuous user experience over time. Thematic saturation was determined through an iterative, team-based process.

Mixed Methods Integration

We used a mixed methods design in which qualitative interviews and quantitative usability surveys were collected during the same study visits and analyzed independently. Following separate analyses, results were brought together during interpretation using a narrative, side-by-side approach to examine areas of convergence and divergence. Quantitative usability scores were used to contextualize qualitative themes, and areas of alignment or mismatch were discussed during team meetings. These integrated insights informed overall conclusions on the user experience of SweetMama.

Ethical Considerations

All participants provided written informed consent prior to enrollment. Participants received up to US $100 via gift cards for their participation in the parent trial (US $25 for the enrollment visit, US $50 for the delivery visit, and US $25 for the postpartum visit). Participants who completed an interview received an additional US $10. This study was approved by the Northwestern University Institutional Review Board (IRB STU00205609).

Results

Overview

From January 2020 to October 2020, 30 participants were randomized to use SweetMama and were included in this analysis. Of these 30 participants, 18 had GDM and 12 had T2DM. The majority identified as non-Hispanic Black (n=17, 56.7%) or Hispanic (n=11, 36.7%). The majority (n=21, 70%) had completed at least some college education. All participants met the study criteria for low-income status, and 83.3% (n=25) had publicly funded prenatal care (Table 1).

Table . Participant demographics of SweetMama.

Characteristic	SweetMama users (N=30)
Age (y), mean (SD)	31.4 (4.7)
Self-reported race and ethnicity, n (%)	
Non-Hispanic white	1 (3.3)
Hispanic	11 (36.7)
Non-Hispanic Black	17 (56.7)
American Indian/Alaska Native	1 (3.3)
Medicaid, n (%)	25 (83.3)
Education, n (%)	
Some high school or less	3 (10)
High school graduate	6 (20)
Some college or technical school	9 (30)
College or technical school graduate	12 (40)
Relationship status, n (%)	
Married	14 (46.7)
Single or other relationship status	16 (53.3)
Nulliparous, n (%)	6 (20)
Current work status, n (%)	
Work full-time	11 (36.7)
Work part-time	8 (26.7)
Unemployed, student, or other employment status	11 (36.7)
Body mass index at first prenatal visit, kg/m^2 (n=29), mean (SD)	42.94 (12.4)
Diabetes diagnosis during pregnancy, n (%)	
Gestational diabetes mellitus	18 (60)
Type 2 diabetes mellitus	12 (40)
Gestational age at enrollment >20 weeks, n (%)	14 (46.7)

Quantitative Usability Metrics

At the delivery visit, 28 participants completed the surveys, and 2 participants were lost to follow-up. SUS, USE, and MAUQ scores demonstrated positive experiences with the SweetMama tool (Table 2). The median score on the SUS survey was 85.0/100 (IQR 77.0 - 88.8), and 71.4% (n=20) of participants found SweetMama to be acceptable. This generally positive feedback was corroborated by similarly high USE scores (median score 84.5/100, IQR 81.0 - 91.4), with the 4 domains of the USE scale (usefulness, ease of use, ease of learning, and satisfaction) scoring 82.1 (IQR 71.4 - 85.7), 88.3 (IQR 84.4 - 94.8), 91.1 (IQR 85.7 - 100.0), and 82.7 (IQR 73.5 - 93.9), respectively. Finally, the median MAUQ score was 84.1/100 (IQR 79.0 - 91.3). All quantitative metrics suggest favorable usability assessments.

Table . System Usability Scale (SUS), Usefulness, Satisfaction, Ease of Use (USE) scale, and mHealth App Usability Questionnaire (MAUQ) quantitative metrics (N=28).

Scale and score type	Values
SUS	
Overall score, median (IQR)	85.0 (70.0 - 88.8)
Acceptability, n (%)	
Acceptable (>70)	20 (71.4)
Marginal (51-70)	7 (25)
Not acceptable (<51)	1 (3.6)
USE scale, median (IQR)	
Overall score	84.5 (81.0 - 91.4)
Usefulness score	82.1 (71.4 - 85.7)
Ease of use score	88.3 (84.4 - 94.8)
Ease of learning score	91.1 (85.7 - 100.0)
Satisfaction score	82.7 (73.5 - 93.9)
MAUQ, median (IQR)	
Overall score	84.1 (79.0 - 91.3)

Qualitative User Experience Data

Qualitative Themes

At the delivery visit, 28 participants completed interviews, while 2 participants were lost to follow-up. At the postpartum visit, an additional 3 participants were lost to follow-up, resulting in 25 completed postpartum interviews. Most participant feedback centered on technical aspects of the application that enhanced the user experience. Analysis revealed four major themes; participants cited aspects of the (1) usability, (2) visual features, (3) content, and (4) frequency of communication in their feedback. Themes and subthemes, as well as participant-identified areas for improvement, are described later and in Table 3.

XSL•FO
RenderX

Table . Qualitative interview quotes on SweetMama user experience.

Theme and subtheme	Exemplary quotation
Usability	
Ease of use	"The app, it was easy, self-explanatory. You really didn't need anybody to explain it to you. But it was helpful in the sense that you know where to go and what you were doing, if that makes sense."
Organization	"Everything was set up in folders. I remember that. Motivation, goals. It was well organized. Easy to go back into and see what I wanted to remember or to read again."
Visual features	
Logo	"Well, I love the picture of the pregnant mommy. But mainly it, it comes directly to my, to my messages, so I was able to see when I had one from you guys. And they come, it came right up, so it was like, you know if, even if I didn't open it up right away, I could just click on the link and then still get it sent back to me. You know…that was cool."
Gamification	"I mean it had recipes and notes and little trophy award things if you were doing stuff correctly. It's like you had your own personal champion cheering you on. So yeah [I liked it]."
Content	
Tips and messages	"I think the tip messages were slightly more specific and I appreciated that. It gave me something more specific of a goal or an idea to think of just like when it's like did you sign up for WIC or this is a way to like relieve stress specifically or this is a specific way to increase your protein and your snacking and things like that. I felt like it was very tangible."
Goals	"It's still giving me information and still staying on top of what I need to be doing. So if I need to set a goal and you guys do remind me to stay on that goal…"
Recipes	"I really did like that because I know things that I thought were okay to eat, I would go on there and I would look at it and it was high in sugars so it was kind of new to me and I was like okay, I didn't know that."
Appointment reminders	"There were appointments that I would completely forget about and your text messages actually helped."
Frequency of communication	
Appropriate frequency	"[Message frequency] was just right to me…to keep you active…So you know how you get an app or something and you don't even use it you know. So like keep you active."

Usability

Themes emerged relating to two specific aspects of the app's usability: (1) ease of use and (2) app organization. SweetMama was widely appreciated for its *ease of use* by the cohort. When asked about their experience with the app, participants found SweetMama to be self-explanatory and easy to navigate. SweetMama also helped promote feelings of self-efficacy, as participants felt in control of their app experience. One participant commented: "You really didn't need anybody to explain it to you."

The *organization* of the app also helped participants with the comprehension of resources. It was easy for users to find the specific information they were seeking and to return to information they had saved or "favorited" for later review. One participant reported: "The goals are where the goals are… it's easy to get the stuff you need, information you need. You know it's easy."

Visual Features

SweetMama users favored the visual features of the app. These attributes helped promote user engagement, as they created a sense of recognition and reward when accessing and using the application. Two specific areas of positive feedback regarding visual recognition were the logo or icon and gamification aspects.

Regarding the *logo*, participants appreciated the SweetMama logo of the pregnant mother. Participants felt like they were able to relate to the picture: "It shows me that it, you know that it's about expecting mothers."

The use of a representative logo created a sentiment of belonging and support. Participants also reported that the logo was recognizable and aided in identifying information from the application.

Participants also enjoyed the addition of awards to the app. *Gamification* heightened participants' sense of accomplishment

XSL•FO
RenderX

and motivation to continue striving to achieve their goals: "It's like you had your own personal champion cheering you on."

Content

Another highlight of the SweetMama app was its content. Analysis revealed that the feedback centered around four key areas: (1) tips and messages, (2) goals, (3) recipes, and (4) appointment reminders.

First, *tips and messages* served as a guiding force, coaching participants on what they were "supposed to do." Participants liked how holistic the tips and messages were, targeting "every aspect of diabetes," and were even excited to see new content from SweetMama: "I was curious about what was the tip or what was the goal this time, you know? I was always looking forward to reading the messages."

In addition, participants noted that the specificity of the messages and the tangible nature of the tips made lifestyle goals more realistic to accomplish. Participants liked the references to specific foods to incorporate into their diets or support programs to find locally or online.

Goals set in the app also helped participants stay on track with diabetes management. Multiple participants reported that the goals motivated them to "work a little bit harder." Several participants reported how the goal-setting function and the reminders about those goals specifically helped with being proactive and motivating action: "They were inspirational, they made me want to use the app more… They made me want to set goals and complete them and then go back into the app and show that I actually did something."

Many participants reported diet as their largest struggle. Thus, they found *recipes* on SweetMama especially useful to help them navigate their new diets. Participants appreciated that SweetMama gave them guidance on diet, which helped dispel any uncertainties: "things that I thought were okay to eat, I would go on [SweetMama] and I would look at it and it was high in sugars...and I was like okay, I didn't know that." Recipes addressed issue areas such as portion sizes and the blood sugar levels of foods. Participants also appreciated the variety in recipe options, which covered meals and snacks.

Finally, the SweetMama text messaging system for *appointment reminders* was effective in helping participants remember their appointments. One participant shared: "There were appointments that I would completely forget about and your text messages actually helped."

Frequency of Communication

Participants were specifically queried about the frequency of communication and reminders within the SweetMama curriculum. Most participants found that the communication was of an appropriate intensity (3 times per wk, with additional reminders for upcoming appointments). The frequency promoted user engagement, retained user activity, and did not detract from their purpose.

Areas for Improvement

In addition to strengths, participants identified several areas for improvement. Interview guides included explicit prompts asking users to describe frustrations, dislikes, and suggested changes to encourage candid negative feedback. Suggested improvements clustered into 3 primary themes.

First, participants desired greater personalization, including the ability to tailor goals, reminders, and educational content to their specific diabetes type, treatment plan, and daily routines.

Second, users noted that the app's visual design and esthetics felt "rudimentary" and recommended enhanced graphics, more engaging layouts, and opportunities for customization (eg, personalized icons or themes) to improve user engagement.

Third, participants expressed interest in expanded content breadth, such as additional practical resources and more individualized messaging throughout pregnancy and postpartum. These findings highlight opportunities to refine SweetMama's usability in future iterations.

Discussion

Principal Findings

This study used both qualitative and quantitative methods to examine the user experience of a novel web-based mHealth app designed to augment health literacy and patient motivation and reduce logistical and social barriers for marginalized English-speaking pregnant individuals with diabetes. To our knowledge, this is among the first mixed methods evaluations of a pregnancy-focused, web-based mHealth app specifically designed to be literacy-conscious, responsive to practical barriers (eg, time constraints and food access), and intended to support individuals experiencing socioeconomic challenges. SweetMama users demonstrated high usability, including high satisfaction scores, based on quantitative assessments completed during postpartum hospitalization. These favorable usability metrics were corroborated by qualitative data; in interviews, participants cited usability, visual features, content, and frequency of communication as beneficial. Participants perceived appointment reminders and goal-tracking features as helpful for navigating competing responsibilities and time-management challenges common in settings of socioeconomic stress or low social support. Specific, actionable tips, including guidance on WIC enrollment (Women, Infant, Children—a federally funded nutrition program implemented by the Chicago Department of Public Health), affordable nutrition strategies, and recipes, were described as useful by participants facing food insecurity and limited nutrition literacy. Participants also valued the app's timely messages, motivational elements, and gamification, which contributed to perceived encouragement and support. Together, these findings illustrate how SweetMama's design features function as practical interventions for social barriers to diabetes self-management in an English-speaking, low-income pregnant population. In terms of areas of improvement, participants expressed a desire for increased personalization and esthetic appeal of the application, such as tailoring the tool's goals to patients' specific diabetes needs and allowing users to personalize the icon.

Comparison to Previous Work

These findings are consistent with the literature on mHealth interventions for patients with GDM. While various mHealth

XSL•FO
RenderX

options for GDM have been developed, only a few have evaluated the user experience of their participants. Nicholson et al [46] developed a web-based intervention, GooDMomS, which was designed to change the behavior of and educate users with GDM through informative web lessons, an online self-monitoring diary (for glucose, exercise, and diet tracking), recipes, a peer-support message board, and weekly text messages. Similar to our findings, guidance on diet was an important component for these participants. One new feature that users in GooDMomS desired was a list of suggested entrées from restaurants, rather than solely providing recipe options [46]. Personalization was also underscored in GDM literature as an important feature of an mHealth app. Duan et al [32] found that participants desired customizable features for diet and exercise goals so that they would be able to receive information about foods and workouts that were amenable to them. This individualization can help to engage patients and make them feel as though the tool is addressing their specific needs [32]. Our findings expand on existing literature by providing a mixed methods approach among a low-income, racially and ethnically diverse population of urban, American pregnant people.

These themes were also reflected in the broader type 1 diabetes mellitus (T1DM) and T2DM literature, in which several mHealth interventions have been evaluated for nonpregnant populations. In an mHealth app called Diabetes Journey, Schmidt et al [47] implemented a learner-centered curriculum for adolescents with T1DM. Consistent with our findings, the researchers found that the following factors promoted usability: interactive components, consistency in content and interaction design, variety, and interface esthetics. Furthermore, in a qualitative evidence synthesis of T2DM mHealth tools, O'Neill et al [48] found that people living with T2DM felt motivated to use mHealth tools for self-management. Similar to our findings, they favored applications that are visually appealing and incorporate features to communicate with a provider [48].

Existing literature also noted features that can be considered or expanded upon in future iterations of SweetMama. Participants in the study by Duan et al [32] emphasized that amidst the increased stress during pregnancy, being able to quickly reach out to a health care professional to ask questions would help relieve uncertainty and reduce the burden of traveling to the clinic. SweetMama did not include direct, personalized patient-to-provider communication options as patients had access to the institution's electronic medical record patient portal for such communication. Since participants were advised to use that portal for clinician communication, interviews did not directly query about this concept, but future work may benefit from incorporating a connection to the portal within an mHealth educational tool. Additionally, while participants did not explicitly mention peer support as a desired feature of SweetMama, this could serve as another aid in diabetes self-management, as users could interact with other people with similar experiences and goals [49-51]. Peer support can foster a sense of community and emotional support among pregnant individuals, which can be especially helpful for SweetMama's target audience who may lack adequate psychosocial support. Future work may aim to identify ways to connect users through a virtual SweetMama community of active users.

Strengths and Limitations

This study's strengths lie both in its population and its mixed methods approach. SweetMama was tailored specifically toward socially vulnerable people with fewer socioeconomic resources. Historically, the health concerns of socially vulnerable populations have been neglected; this study adds to the existing literature by obtaining feedback from a more diverse population regarding an emerging web-based mHealth app focused on building self-efficacy, motivation, and health literacy. These perspectives are key in building equitable mHealth interventions and can inform the development of future iterations of the tool. An additional strength is the study's use of both standardized surveys and interviews; the SUS assessed the overall usability of SweetMama, USE assessed user satisfaction and ease of learning, and MAUQ was specifically tailored to mHealth tools. When coupled with qualitative interviews and rigorous methodological analysis, we were able to glean a holistic understanding of the SweetMama user experience.

However, this study has several limitations. First, participants were recruited from a single urban academic institution and represent a relatively narrow demographic scope, which limits the generalizability of findings to pregnant people receiving care in other geographic, clinical, or socioeconomic settings. The small sample size and single recruitment location, both of which were appropriate for this phase of work, may not capture the full range of experiences among individuals with GDM or other high-risk pregnancies. For this phase of work, our sample size aligned with established norms for usability testing and mixed methods evaluations, allowed us to achieve thematic saturation in qualitative interviews, and was sufficient to detect patterns in quantitative usability scores, which showed limited variation across participants. Nonetheless, the sample lacked representation from Asian and other underrepresented groups. Additionally, all participants had to be English-speaking, despite diabetes being prevalent in Hispanic and immigrant populations, due to budgetary limitations during the intervention development process [1,2]. Future work must include a larger sample size with increased racial and ethnic representation to more fully develop and test an intervention tailored to different cultures. Another necessary next step is translating the app into different languages to suit a more linguistically diverse patient population, as well as studying the effect of SweetMama use on clinical outcomes.

The visual appeal of the app was also limited due to budgetary constraints; therefore, future work toward greater customization and enhanced graphics could enhance the appearance of SweetMama. Next, while we did not formally integrate datasets (eg, by comparing qualitative responses with quantitative scores), the qualitative and quantitative findings were used to complement one another and provide a more holistic understanding of user experiences. Due to limited variation in user scores (ie, scores were generally high), further subgroup analysis was not feasible. In addition, because participants had regular contact with the research team and received incentives for study completion, social desirability bias may have influenced both usability ratings and qualitative feedback. Finally, the current study was designed to evaluate perceived usability, satisfaction, and early user experiences with

XSL•FO
RenderX

SweetMama; sustained user engagement and clinical effectiveness were beyond its scope and should be assessed in future studies.

Future Directions

Based on our findings, several key design implications for maternal mHealth tools emerge: (1) prioritize ease of learning and low-burden access to support engagement among users with competing demands; (2) incorporate structured, organized content with actionable guidance (eg, recipes, nutrition tips, and resource navigation) to address health literacy and social needs; (3) include reminders and goal-tracking features to facilitate self-management and appointment adherence; and (4) leverage motivational framing, timely messaging, and light gamification to enhance user engagement and perceived social support. With these in mind, there are several clinical implications that can be gleaned from this work. mHealth apps like SweetMama can be highly appealing to users if they incorporate visual and knowledge-building features, while remaining focused on basic usability concepts such as ease of use and ease of learning. Applications designed with patient-centered features may support initial uptake and user satisfaction. These factors are ultimately important for sustained user engagement and improved self-management, particularly for those with greater social needs. Although SweetMama is not yet available outside of the research context, the lessons learned from this assessment can inform the development and sustainability of other interactive mHealth tools to support pregnant patients with diabetes. Our findings suggest that future maternal mHealth interventions may benefit from emphasizing low-burden interaction, actionable content, supportive reminders, and motivational features that help users integrate self-management tasks into their daily routines. For example, features such as appointment reminders, gamification, and a diverse array of recipe options, educational tips, and messaging are recommended by participants for inclusion in future designs. Additionally, new iterations of SweetMama can be created in different languages to support wider audiences and reduce health literacy and language barriers for non–English-speaking individuals. Future work may further consider whether and to what extent the experiences of users with different types of diabetes (eg, diet-treated vs medication-treated; pregestational vs gestational) may warrant alterations of interventions such as SweetMama. Further personalization can include opportunities to tailor the application based on stage of pregnancy or postpartum status, dietary preferences and restrictions, reminder frequency, and desired support resources.

In conclusion, mHealth tools are a promising avenue for GDM self-management, education, and addressing disparities. SweetMama users found this web-based mHealth app to be engaging and motivational, with its strengths lying in usability, visual features, and content. Areas for improvement included increased customization of the app's features, such as the logo and personal diabetes needs. These findings support user satisfaction and the perceived usefulness of the tool, but further research is needed to evaluate sustained engagement with the app, behavior change, and clinical outcomes. Future directions for this work also include testing SweetMama in a larger sample size, in multiple languages, and across multiple institutions. In addition, implementing new features, such as peer support and connection to patient portals, may enhance the user experience.

Acknowledgments

We would like to thank research coordinator Jenise Jackson, MPH, and research assistant Karolina Leziak, MD, for their work on the study. We would also like to thank the Eunice Kennedy Shriver National Institute of Child Health and Human Development (R21 HD094271) for their support.

Generative AI tools were not used in the conceptualization, data curation or analysis, visualization, or original drafting of the manuscript. However, Generative AI tools were used solely for grammatical and stylistic improvements while revising the manuscript text. Abstract

Background: Shared goal-setting is a common feature of quality guidelines to improve care quality for children with medical complexity, but few studies have examined the efficacy of interventions designed to improve goal-setting.

Objective: This study aims to evaluate a novel internet-based tool to promote shared goal-setting (GoalKeeper) in the care of children with medical complexity.

Methods: We conducted a randomized stepped-wedge trial (intervention vs usual care) between April 1, 2019 and March 21, 2021, at primary and subspecialty care clinics at an academic medical center, including 11 medical providers (medical doctor, doctor of osteopathic medicine, or nurse practitioner). Adult parents of children with medical complexity were eligible if they were English-speaking, with home internet access, and with children with medical complexity aged younger than 12 years. Participants were clustered by provider, with providers crossing over from control to intervention at different stages. The assignment of timing for crossover was random. Control group participants received usual care without any additional interventions. Intervention group participants received a novel web-based tool called GoalKeeper for initial use during the clinic visit and subsequent continued use after the clinic visit. GoalKeeper was co-designed by parents, providers, and computer scientists to include 2 modules, meant to be used by both the parent and medical provider for each child: (1) goal elicitation, used synchronously during a clinic visit; (2) tracking, used asynchronously between visits by parents and providers of children with medical complexity. The primary outcome was quality of goal-setting assessed by the Patient Assessment of Care for Chronic Illness Care goal-setting domain at baseline (t1) and 1 month (t2). We conducted a repeated-measures mixed-effects ANOVA to evaluate between- and within-group differences over time for fixed effects (timing of intervention, intervention×time) and random effect (provider cluster).

Results: We enrolled 67 parent-child dyads (control: n=32 control; intervention: n=35). Parents had a mean age of 37.4 (SD 8.2) years, children with medical complexity with mean age 5.6 (SD 0.5) years, and 29 (44%) parents identified as Hispanic. Of the 35 intervention parents, 34 successfully used GoalKeeper during the clinical encounter with their provider. During the follow-up period, quality of goal-setting was sustained at t2 for the intervention group but declined for the control group (δ=0.03 vs −0.43; F_{49}=3.52, P=.06). Similar patterns were observed for care quality (δ=0.01 vs −0.48; F_{49}=4.28, P=.04).

Conclusions: Our study demonstrates that family-centered goal-setting may help combat the gradual decline in care quality otherwise experienced by children with medical complexity in between clinic visits. Successful use of the tool with providers in clinic suggests that digital tools are feasible interventions to change family-provider communication around family goals.

Introduction

Children with medical complexity and their families face many challenges. Defined by high service needs, high resource use, and functional disability, children with medical complexity represent less than 5% of all children but a disproportionately high share of pediatric care use, coordinated across multiple health care systems, providers, and agencies [1-4]. This complex ecosystem of care hinders caregivers' and providers' abilities to have a shared understanding of care priorities to effectively address health needs as a team. Moreover, the fluctuating nature of health issues faced by children with medical complexity results in constant changes to the care team, and helping new team members be up-to-date is highly challenging. Thus, parents of children with medical complexity are less likely to report high care quality and shared decision-making during ambulatory care encounters than parents of children with noncomplex chronic conditions [5-7].

To improve care quality and shared decision-making for children with medical complexity, several national pediatric organizations have suggested the importance of a family-centered care framework centered around shared goal-setting to create individualized care plans [8,9]. While prior studies have used multidisciplinary teams for individualized care plan creation, few models exist for effective and scalable tools that facilitate shared goal-setting when prolonged visits with highly resourced teams are unavailable [10,11]. Studies of noncomplex chronic conditions in pediatrics (eg, asthma or type 1 diabetes) suggest that technology-based tools may provide efficacious ways to establish and track goals during and between ambulatory care visits [12-14]. These tools result in improved satisfaction, reduced urgent care visits, and improved outcomes. However, technology-based solutions for the care of children with medical complexity must overcome unique challenges such as team hierarchies, loosely coupled teams (eg, most providers care for children with medical complexity in diffuse teams rather than tightly coordinated team-based clinics), and asynchronous time scales among providers [15]. Prior work suggests that shared care plans for children with medical complexity require common goals to be set synchronously by the provider and caregiver, then tracked asynchronously by both but has not previously been tested [15]. It is unknown whether technology-based tools can be effective in improving the care of children with medical complexity.

In this study, we evaluate the effectiveness of a technology-based tool for eliciting and tracking shared goals in the ambulatory care of children with medical complexity. Working in a multimodal development team comprised of health care providers, behavioral scientists, computer scientists, and parents of children with medical complexity, we developed a novel, health-information technology platform, called GoalKeeper, to improve goal-concordant conversations in real-world, outpatient care settings. We hypothesized that parents of children with medical complexity exposed to GoalKeeper would report higher care quality and higher quality goal-setting when compared to parents who received usual care.

Methods

Study Design

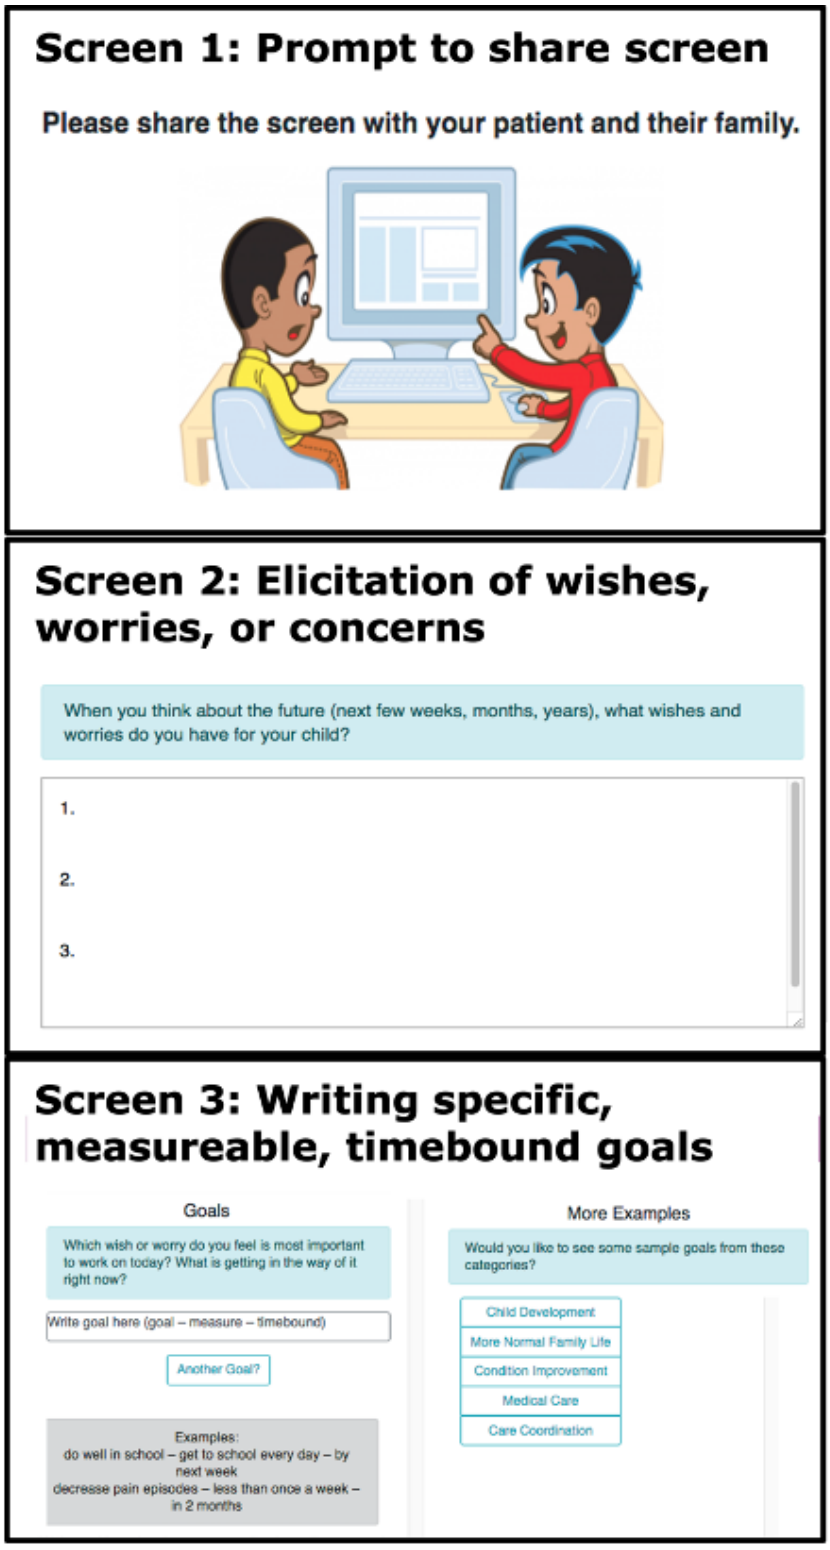
We conducted a prospective, stepped-wedge, randomized controlled trial of intervention efficacy. The study was conducted at primary and subspecialty ambulatory clinics associated with a children's hospital at an academic medical center. In the stepped-wedge design, each provider first spent at least 3 weeks in the control condition, when research staff recruited parent-child dyads from their clinic to be in the control group, followed by crossover into the intervention group for 3 weeks. Providers crossed over at different intervals spaced 3 weeks apart (Figure S1 in Multimedia Appendix 1). The order that providers crossed over was randomized in R Statistical Software (v.3.5.3 R Core Team 2019) via RStudio (v.1.1.463 Posit team 2019) by author JL, with allocation and enrollment conducted by research assistants [16]. Each parent-child dyad served in either the control or intervention group, with the control group receiving usual care. We chose a stepped-wedge design because it offers the most feasible and effective approach to randomization of the parent-child dyads without introducing bias in the control group by changing provider behavior through exposure to the intervention [17]. Ethically, stepped-wedge designs are better suited for studies in which true equipoise has not been established for the interventions being tested [18]. Prior interviews with providers of children with medical complexity found that most providers were familiar with the practice of goal-setting and endorsed some level of goal-setting in their current practice, but structured approaches to goal-setting were not part of routine practice in these clinics [15]. For this study, we adhered to the CONSORT guidelines for reporting randomized clinical trials (see Checklist 1).

Study Population

We recruited medical providers (medical doctor, doctor of osteopathic medicine, nurse practitioner, and physician assistant) from 2 ambulatory clinics that see a high proportion of children with medical complexity—pediatric neurology and complex primary care clinics (CPCC) at the main location of a single academic health center. The health center is part of a standalone tertiary children's health system in northern California. All providers that were not trainees at these clinics were eligible for recruitment. We recruited a convenience sample of primary caregivers (eg, parents) of the patients seen by enrolled providers in person at the time of their clinic visit. We capped enrollment per provider cluster at 10 parents. Parents were eligible if they were aged 18 years or older, English-speaking, and with a child with medical complexity aged younger than 12 years. We excluded parents without home internet access or with known neurocognitive or psychiatric issues that precluded the ability to offer informed consent. We excluded older children, who may have the capacity to participate in decision-making, since the intervention was not designed for interaction with children [19]. We defined medical complexity as meeting each of 2 criteria in the 12 months prior to study enrollment: (1) ambulatory visits with at least 2 different subspecialties affiliated with the medical center and (2) medical fragility due to technology dependence (gastrostomy tube, nasogastric tube, ventriculoperitoneal shunt, or tracheostomy) or clinic visits at

XSL•FO
RenderX

CPCC. Enrollment occurred between April 1, 2019 and December 21, 2020, with follow-up through March 21, 2021. Due to institutional restrictions prompted by the COVID-19 pandemic prohibiting in-person research activities that were necessary for study activities at enrollment, recruitment was paused between March 13, 2020 and July 20, 2020.



Intervention

We designed a technology-based family-centered goal-setting tool (GoalKeeper) using iterative feedback from parents and providers of children with medical complexity and informed by the challenges of technology-based tools elucidated in our prior work [15]. In the first phase of the design process, we interviewed parents and providers to develop a taxonomy of goals and effective approaches to discussing goals in an outpatient clinic visit, based on prior frameworks for goal-concordant, chronic-illness care [20-22]. In the second phase, we conducted iterative user testing with parents and providers initially via paper-based prototypes and subsequently a technology-based version. We chose to host the intervention on the internet and to function outside of the electronic health record (EHR) to allow for rapid iteration of the intervention design and ease of access to the intervention from any device (eg, computer, tablet, or smartphone). We designed GoalKeeper using responsive web technology that optimizes its use for any device. This functionality enables parents and providers to quickly input data and access GoalKeeper in any setting with internet independent of the type of device used.

GoalKeeper consists of 2 separate modules: (1) Goal Elicitation and (2) Tracking. The key module and the focus of this study is the goal elicitation module, which was designed to be used in real time in the exam room, facilitating a conversation between the parent and the medical provider during a routine, nonurgent care visit, consists of 3 components, as shown in Figure 1. The first component provides prompts to elicit the parent's "wishes/worries/concerns" about their child's health. The second component helps the parent and provider derive from these "wishes/worries/concerns" at least 1 goal that is specific, measurable, and time-bound to ensure that the goals are actionable and attainable. Specific actions were not entered into the module to reduce documentation burden based on feedback during design interviews and pretesting. The third component provides sample goals as inspiration based on a taxonomy of common children with medical complexity goals developed in the design process (Assis-Hassid S et al, unpublished data, 2021). These 3 components are synthesized on the final screen, with a "copy" button to facilitate easy transfer (pasting) of the text into the EHR. The tracking module was designed to be set up by a provider immediately after the clinical encounter. The purpose of the tracking module was to address parents' desires for symptoms tracking in the tool but was not the focus of the GoalKeeper design process given the prevalence of symptom tracking technology already in existence. The tracking module provides customizable templates that providers can assign to parents to track their progress toward the elicited goal(s). To allow for asynchronous work outside of clinic visits, parents and providers had distinct interfaces. Providers could create goals, create and assign tracking templates, and view data while parents could view set goals and view and input data into tracking templates. We placed goal elicitation in the provider interface, based on user feedback, to help flatten the parent-provider hierarchy in the clinic visit. GoalKeeper requires the medical provider to elicit and type the parent's stated goals during the clinic visit. Prior prototypes that required parents to type their goals resulted in increased parental stress and decreased medical provider engagement. In contrast to usual practice, medical providers welcomed the during-encounter goal elicitation feature as an opportunity to engage more meaningfully with parents. We optimized the tracking module for use on smartphones or tablets based on parent feedback. During the trial, further development was frozen to ensure all participants were exposed to the same version of the intervention.

XSL•FO
RenderX

Figure 1. GoalKeeper goal elicitation module.

The intervention implementation process was developed and evaluated using the Consolidated Framework for Implementation Research (CFIR) [23]. Prior to the start of the trial, we conducted stakeholder focus groups using the CFIR companion interview guide to inform implementation of GoalKeeper that resulted in the selection of 3 implementation strategies: educational materials, individual technical assistance, and automated reminders [24]. Educational materials included paper and electronic copies of an instructional manual on GoalKeeper, with parent and provider versions. Parents received a 5-minute in-person overview of GoalKeeper while providers received a 30-minute orientation, including a 5-minute educational video [25]. The study team was available for in-person and remote technical assistance but did not attend clinic visits with participants. Parents received automated weekly email reminders to track their progress on goals. Details on the implementation process and evaluation can be found in a companion study [26].

XSL•FO
RenderX

Participants in the intervention group were given GoalKeeper to use during their initial clinic visit immediately after enrolling in the study. They created a unique login and password and were emailed the webpage link to access GoalKeeper on their own device. Study team members also accessed the GoalKeeper webpage on the clinic room computer immediately prior to the start of the participant's clinic visit. Participants in the control group received usual clinical care with their provider.

Measures and Outcomes

Our randomized controlled trial is a hybrid type I effectiveness-implementation trial with a primary focus on assessing the effectiveness of the intervention but included collection of preliminary data on barriers and facilitators to implementation, reported in a separate manuscript [26,27]. Measures of primary and secondary outcomes were collected electronically immediately after the initial clinical encounter for both parents and providers following study enrollment (T1) and at 1-month post-encounter (T2). Additional implementation outcome survey measures and exit interviews were collected at 3 months post-encounter (T3) for parents and, for providers, at the end of the study period for their last enrolled parent (Figure S2 in Multimedia Appendix 1). All measures were collected via secure electronic survey tools and stored electronically via the Stanford REDCap (Research Electronic Data Capture).

The primary outcome was the difference in parent-reported quality of goal-setting between the control and intervention groups from T1 to T2, as measured by adapted questions from the goal-setting domain of the Patients Assessment of Chronic Illness Care (PACIC), a 20-item (5-point Likert scale: no/never to yes/always) validated survey measure of chronic illness care quality based on the Chronic Care Model [28]. A mean composite score is calculated for each domain and the entire survey based on relevant items. The goal-setting domain contains 5 items that cover healthy behaviors, treatment plans, and community integration. We adapted this measure for children with medical complexity because of its wide use in assessing chronic illness care quality and the lack of alternate, validated, pediatric-specific measures. Secondary outcomes measure included the PACIC subdomains for problem-solving, care coordination, and composite outcome of care quality based on all measured PACIC subdomains.

Additional secondary outcome measures included quality of shared decision-making, quality of parent-provider communication, and parenting stress. We assessed quality of shared decision-making (T1 and T2) using the National Survey for Children with Special Health Care Needs 2009 - 2010 shared decision-making domain, which creates a binary composite variable for high versus low quality shared decision-making from 4 survey questions at T1 and T2 [29]. We assessed the quality of parent-provider communication using the Communication Assessment Tool (T1), a validated 15-item (5-point Likert scale: 1-poor to 5-excellent) survey measure with mean composite outcome [30]. We assessed parenting stress using the Parenting Distress domain of the Parenting Stress Index (T1), which captures parent stress levels related to partner conflicts, social support, and life restrictions due to child rearing [31]. Scores are presented as a sum of all answers (range 12 - 60) with higher scores indicating higher stress.

Intervention Fidelity

We assessed intervention fidelity and quality in 2 ways: (1) capture of information directly from the GoalKeeper platform and (2) participant interviews at T3. Within the app, we primarily assessed number of goals set per intervention group participant but also assessed frequency of app use, and counts of data entered into each field. Through semistructured interviews, we assessed barriers and facilitators to implementation using questions from the CFIR companion interview guide (Multimedia Appendix 2), detailed in a separate manuscript [26,32].

Sample Size

We aimed to identify a moderate change in the PACIC domain of goal-setting from T1 to T2. Prior studies of the PACIC have shown in the domain of goal-setting a mean of 2.43 out of 5 (SD 1.1) [33]. We anticipated at least a δ of 0.5 (medium effect size) which has been achieved in prior studies comparing different health care practices in Switzerland [33]. With a projected attrition rate of 33%, our targeted recruitment was 60 parents (control: n=30; intervention n=30) to reach a minimum sample size of 40 parents who completed the study (control: n=20; intervention: n=20), which provides 80% power using a 2-sided comparison of α .05 to detect a δ of 0.5.

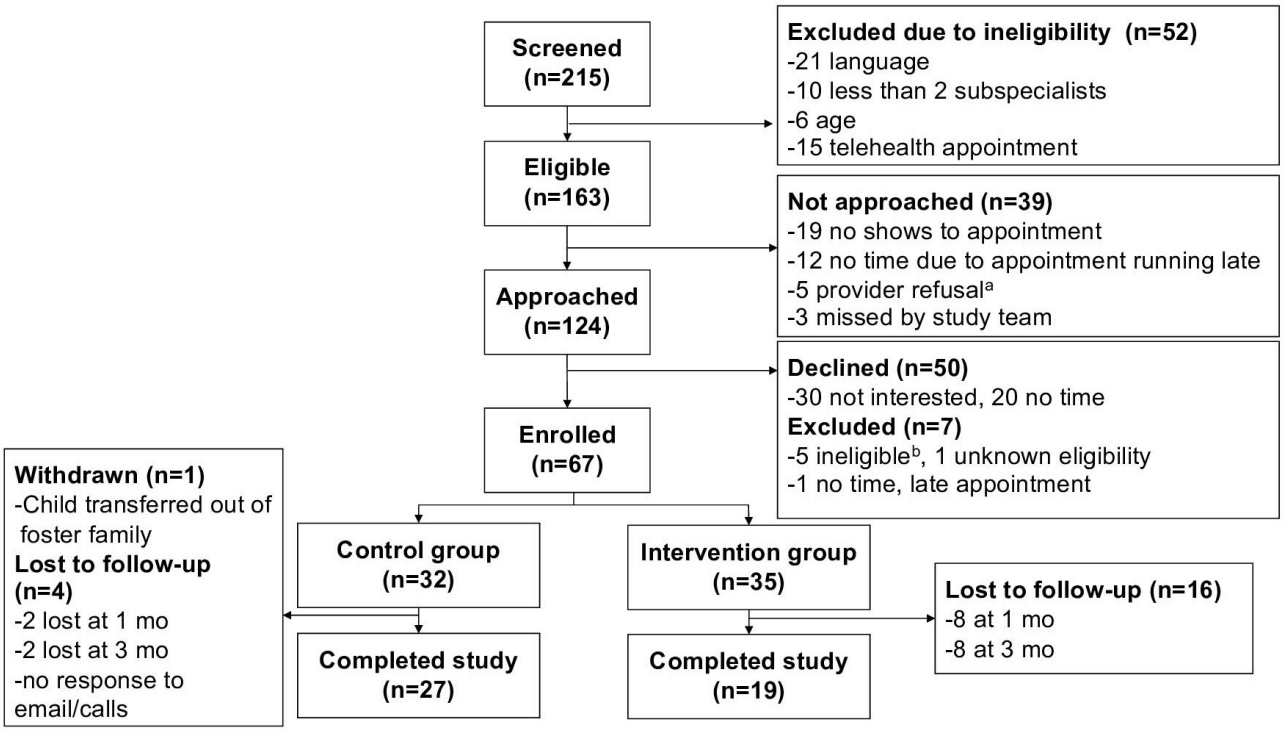
Statistical Analysis

For primary and secondary outcome measures, we used intention-to-treat analysis with repeated measures ANOVA to evaluate for between-group and within-group differences in the PACIC domain of goal-setting for intervention group versus control group while adjusting for fixed effects—timing of measurement (1: immediately after the visit and 2: 1 month after the visit) and intervention-by-time interaction—as well as random effects: provider cluster. We used a similar approach for our secondary outcomes. We conducted post hoc analyses of outcome variables with adjustment for population characteristics with statistically significant differences between subgroups. For baseline characteristics and feasibility outcome measures, we conducted descriptive analyses using Fisher exact test for binary and categorical variables and Wilcoxon sign-rank test for continuous variables. We used a statistical significance level of $P<.05$.

Ethical Considerations

This study was approved by the Stanford Single Institutional Review Board (Protocol 32161, approved 12/22/2016) and registered on clinicaltrials.gov (NCT03620071). All participants gave documented informed consent prior to enrolling in the study. All potential participants had the option to opt out of the study if they were not interested. Provider participants were approached at routine division meetings when the study team presented the study, reviewed the consent form, and gave ample time for questions. Providers could provide consent during or after the team meetings. Potential parent participants were approached in-person in the waiting room for consent and enrollment prior to their clinic visit with a participating provider. We did not use remote recruitment due to concerns of

XSL•FO
RenderX



intervention fidelity as GoalKeeper was designed to be used jointly with parents and providers during a clinic visit. Study team members presented the study, reviewed the consent form, and gave ample time for questions. Consent was obtained prior to the start of the clinic visit. Each participant was assigned a randomly generated 4-digit unique identifier. The key linking the unique identifier to participant name and contact information was stored in a separate database. Parent participants received gift card remuneration after surveys at t1 and t2 (US $10 each) and interviews at t3 (US $30). Providers received a US $5 gift card remuneration per completed survey and after interview completion totaling US $50 for the entire study period.

Results

Study Population

We enrolled 67 parent-child dyads out of 124 eligible parents approached across 2 outpatient clinics and 11 medical providers. Of parent-child dyads, 32 were enrolled in the control group and 35 were enrolled in the intervention group. During the study period, 10 parent-child dyads (control: n=2; intervention: n=8) were lost to follow-up at T2, and 1 control group parent who was fostering a child with medical complexity was withdrawn due to the child being transferred out of their custody. We also had 2 providers lost to follow-up due to leaving the institution (CONSORT [Consolidated Standards of Reporting Trials] diagram in Figure 2).

Figure 2. CONSORT (Consolidated Standards of Reporting Trials) flowchart. [a]Provider rationale for refusal: parent ineligible due to underlying neurocognitive or behavioral health issue, under isolation protocol for suspected COVID-19, 1 emergent health care concern, visit changed to telehealth, patient late and had to see their non-primary provider instead. [b]Participants ineligible at visit due to: no internet or email (1), language (1), legal (1), accompanied by non-guardian/non-primary caregiver (2).

Among parent participants, the mean age was 37.4 (SD 8.2) years, 50 (76%) were female participants, 32/66 (48%) identified as Caucasian, and 25 (38%) as Hispanic. Most were highly educated, with 51 (77%) having completed at least some college. Patients had a mean age of 5.6 (SD 0.5) years and 24 (36%) were female participants. All saw multiple subspecialties (median 3 [IQR 2‐4]). Most had technology dependence (34/66, 52%) and neurodevelopmental delay (36/66, 55%). Only the ventriculoperitoneal shunt was statistically significantly different between the control (0) and intervention (4) groups. The providers were mostly medical doctors (9/11, 82%), female participants (7/11, 64%), and neurologists (6/11, 54%). Parent, child, and provider characteristics are detailed in Table 1, Table S3 in Multimedia Appendix 1, and Table S4 in Multimedia Appendix 1, respectively.

[a]Statistical significance level is $P \leq .05$.

[b]Participants could select all categories that apply.

For our primary outcome measure, quality of goal-setting, scores were lower for the intervention group at t1 when compared to the control group, 2.41 (SD 1.07) versus 2.57 (SD 1.06). At 1-month follow-up (t2), the reverse was true with scores of 2.36 (SD 1.12) for the intervention group versus 2.15 (SD 1.23) for the control group. Quality of goal-setting between t1 and t2 remained stable for the intervention group but decreased for the control group (δ=0.03 vs −0.43, F_{49}=3.52, P=.06). Similar patterns exist for other PACIC outcome measures of problem-solving, care coordination, and overall care quality (composite). For other secondary outcome measures, parenting distress at t1 was higher in the intervention group when compared to the control group (mean [SD] 27.9 [11.6] vs 22.2 [7.6]; P=.02). There were no significant group differences in parent report of quality of shared decision-making or quality of doctor-patient communication (Table 2 and Figure 3). For post hoc analyses of ventriculoperitoneal shunt, the sample size of 4 was too small for valid statistical analysis.

Intervention Fidelity

Among the intervention group, 34 of 35 parents successfully used GoalKeeper with their provider to set goals during the clinic visit. For 1 parent, the provider decided during the visit that it was not an appropriate time to use GoalKeeper, but to preserve an intention-to-treat approach, that parent remained in the intervention group to complete the survey measures. Parents and providers set a median of 2.5 (IQR 1.5-3) goals per initial clinic visit, and providers assigned a median of 3 (IQR 3-4) tracking templates to each parent. Each provider saw a median of 2.5 (IQR 2-5) parent participants . After the initial clinic visit,

XSL•FO
RenderX

parents input information into GoalKeeper a median of 0 (IQR 0-3) times and providers viewed tracked data a median of 0.5 (IQR 0-1) times throughout the study period. A total of 19 parents (CPCC: n=8; neurology: n=11) did not enter any data into the tracking templates, while 13 parents (CPCC: n=4; neurology: n=9) entered data 1 - 10 times, and 3 parents, all from CPCC, entered data over 10 times. In total, 87 goals were set with the most common domains being development (parents: n=10; unique goals: n=16), child nutrition (parents: n=13; unique goals: n=13), and seizure control (parents: n=10; unique goals: n=10). There were no statistically significant differences in participant and patient characteristics between those who used the tracking module more extensively than those who did not. Of the 19 parents who completed the exit survey, 13 (68%) parents would recommend GoalKeeper to other parents. A total of 6 (67%) providers would recommend GoalKeeper to other providers (Table S3 in Multimedia Appendix 1).

In exit interviews, participants identified facilitators to GoalKeeper use to be the shared nature of the goal-setting activity, the tool being accessible by the internet, and the ability to set long-term goals as facilitators to tool use. Per parent participants, the main barrier for sustained tool use after the initial goal-setting clinic visit was lack of integration in the EHR and patient portal. Additional details about the interview results and the tool's feasibility and acceptability are reported in a companion manuscript [26].

Discussion

Principal Results

Our study demonstrated that the GoalKeeper intervention, a novel goal-setting platform for outpatient care of complex chronic illness, resulted in a better maintenance of overall chronic illness care quality, with no statistically significant impact on goal-setting, problem-solving, or coordination. Intervention fidelity results indicate that the sustained effect of GoalKeeper on care quality was likely the result of participant engagement with the intervention's goal elicitation module, in contrast to its tracking module, which had very low participant engagement. Furthermore, we found that the intervention is both feasible and acceptable in the context of busy outpatient care, in both primary and subspecialty care settings. Together, these results suggest that technology supports for goal-setting may be an effective way to maintain high-quality care in between clinic visits for children with medical complexity, but GoalKeeper itself needs further refinement to improve user experience. However, given the nonstatistically significant findings in individual PACIC domains, the exact mechanism for this remains unclear.

The sustained quality of care for those in the intervention group is notable compared to the decline in quality of care for the control group, even though the initial quality of care scores (PACIC composite and domain) were lower for the intervention group than the controls. One potential explanation for these initial lower scores may be that the parents in the intervention group were more stressed as indicated by the parenting distress scores. Additionally, the COVID-19 pandemic may have contributed to greater parent stress in the intervention group, since the control group was enrolled earlier in the trial, although this was not a theme found in the exit interviews. Since we collected baseline data after the encounter, another explanation may be a learning curve that participants experienced due to changing the dynamic of a clinic visit through the use of a new tool (GoalKeeper), which may cause the visit to seem of poorer quality due to the challenge of learning a new approach to care [34]. A final possible explanation is simple random variation, which justifies our choice of a randomized controlled trial design to examine intervention effects. Based on our observed participant and patient characteristics, our randomization approach appears strong and thus makes it unlikely that care quality scores were lower due to higher medical complexity or disparities in care delivery.

Comparison With Prior Work

Nonetheless, given the nonstatistically significant findings in individual PACIC domains, further research is necessary to extend and enhance the effectiveness of such platforms on care quality. Our results build on prior studies suggesting tools to improve care for children with medical complexity need to elicit and track family-centered goals [9,35]. Family engagement remains an urgent research priority for children with medical complexity, yet their providers report barriers including insufficient communication skills and supports [36,37]. Providers in our study acknowledged that they, too, struggled with the communication around goals with parents of children with medical complexity but endorsed that GoalKeeper facilitated better communication about parents' goals. Multidisciplinary care coordination programs that included family-centered goal-setting found that family-centered goals helped programs emphasize family priorities [11]. However, many approaches to family-centered goal-setting have used resource-intensive approaches, which face barriers to implementation including the scalability and replicability of programs across multiple centers. Our intervention may enable these programs to extend their reach by acting as an adjunct intervention in clinical care whereby family-centered goal-setting can be achieved without additional extended team support. Future work on tracking and adapting the goals longitudinally could further sustain engagement and lead to evaluations of how long-term care is affected by family-centered goals.

While our study demonstrates high initial adoption of GoalKeeper based on goal elicitation module use, future studies should investigate the mechanisms of effect and tools to sustain engagement, such as the effects of a more sophisticated tracking module. Other digital health interventions have initial high levels of adoption that decrease dramatically over time [38]. Prior studies have demonstrated that self-monitoring interventions may result in sustained engagement even if the initial motivation for using the app was different [39]. In our study, the design of the tracking module was not the focus of intervention development. Since other existing tools to improve care for children with medical complexity focus on symptom tracking, we wanted to avoid duplicative efforts [40,41]. Future directions should explore whether integration of the Goal Elicitation module with existing symptom trackers will improve sustained use of GoalKeeper. Sustained use of digital health

XSL•FO
RenderX

interventions after the initial adoption period has also been associated with user perceptions of usefulness, ease of use, fulfillment of user expectations, and satisfaction with the app [42]. Future evaluations should test whether these mechanisms can sustain use of our intervention in larger populations and in populations that prefer other languages.

Study findings also suggest additional design and implementation considerations for health-information technology platforms that aim to improve care for chronic conditions. Goal elicitation structures, similar to those developed for GoalKeeper, should be embedded across discrete elements of the EHR—especially the encounter note, the after-visit summary, and the patient portal. Additionally, goal-elicitation training should be integrated with provider-training modules, including simulated patient encounters, to enhance provider practice. While standalone tools could improve accessibility in community-based care, this study's findings suggest high feasibility and acceptability for integrating adaptive, chronic-illness management technology into existing workflows.

Limitations

Study findings should be interpreted in the context of a few limitations. This study was conducted in a single children's health system, which may not be reflective of the practice at other institutions caring for children with medical complexity. However, the CPCC was part of a multicenter collaboration to develop care coordination programs for children with medical complexity, so some program similarities may exist across these collaborating sites. More participants in the intervention group were lost to follow-up, which may have introduced selection bias, with those with poorer experiences with the intervention or with higher medical needs choosing not to continue to participate in the study. However, there were no statistically significant differences in parent and child characteristics between those lost to follow-up and those who completed the study. Notably, participants had to have home internet access, and while the divide between internet access is narrowing, this could have excluded populations with lower household income [43]. The majority of our study participants also had at least some college education, which is reflective of the local population. Overall, our study period was quite short. Thus, the long-term intervention use, particularly on repeat clinic visits, was not observed. The effects of long-term intervention use should be assessed with future studies.

Conclusions

Technologies that support real-time, shared goal-setting between a patient and their medical provider may serve as an adjunct to high-quality care of complex chronic illness. Informed by in-depth qualitative research and understanding of children with medical complexity-specific care needs and goals, health-technology tools like GoalKeeper are likely to be feasible and acceptable when integrated into both primary care and subspecialty care outpatient settings. Furthermore, in the context of learning health systems and emerging, generative artificial intelligence solutions, such platforms are likely to become easier to implement, scale, and study across care systems. As a result, goal-concordant care technologies, like Goalkeeper, co-designed with patients and caregivers in the context of a rigorous behavioral science framework, hold promise to improve care outcomes across a wide range of chronic and comorbid conditions.

Acknowledgments

The authors thank the patients, parents, and providers of children with medical complexity for their participation in study activities. The authors did not use generative AI for any part of this study or manuscript.

Funding

This work was supported by the National Institutes of Health, National Cancer Institute grant number R01CA204585. Abstract

Background: Digital health tools are increasingly prevalent in postoperative care management, yet limited research exists on digital health literacy and tool adoption among safety-net hospital populations. Understanding these factors is crucial for developing effective digital health solutions for historically underserved communities.

Objective: This study aimed to evaluate digital health literacy, assess technology adoption readiness, and examine the relationship between patient-reported capabilities and demographic factors in a postoperative care context at a safety-net hospital.

Methods: We conducted a mixed methods study with 71 postoperative patients and 29 health care providers at a safety-net hospital. Participants completed a modified eHealth Literacy Scale (eHEALS) assessment and a demographic questionnaire, followed by usability testing of PocketDoc, a digital health prototype. The modified 7-item eHEALS demonstrated adequate internal consistency (Cronbach α=0.77). Qualitative data from think-aloud protocols during usability testing were collected for future analysis. This study focused on quantitative assessments of digital health literacy (using the modified eHEALS on a 5-point Likert scale) and technology adoption readiness (via usability metrics on a 10-point Likert scale) analyzed using nonparametric statistical tests. Correlations between demographic factors and digital health literacy were examined using Spearman rank-order correlation.

Results: Despite common assumptions about technology barriers in safety-net populations, 69% (49/71) of patients reported high confidence (score of ≥3 on a 5-point scale) in finding health resources online, and 61% (43/71) expressed confidence in using the internet for health-related questions. However, only 49% (35/71) felt confident in using digital resources for health decision-making. Digital health literacy scores did not correlate with age or educational level, although 79% (56/71) of patients reported ≥10 years of digital device experience. Both patients and health care providers rated PocketDoc highly for ease of use (median 10, IQR 8-10) and task intuitiveness (median 10, IQR 8-10). Patients' confidence in finding and using health resources online positively correlated with interface satisfaction (ρ=0.262-0.304 and ρ=0.010-0.027, respectively).

Conclusions: Our exploratory findings from 100 participants suggest that digital health tools may be more feasible in safety-net settings than previously considered, although the sample size and single-site design limit generalizability. However, the gap between patients' ability to find health resources (49/71, 69% confident) and their confidence in using these resources for health decision-making (35/71, 49% confident) highlights the need for targeted support in translating digital capabilities to health management skills.

Introduction

Postoperative care increasingly relies on digital health tools to support patient recovery, manage symptoms, and facilitate physician-patient communication [1,2]. As health care systems transition toward digital solutions, understanding patients' ability to effectively engage with these tools becomes crucial, particularly in safety-net hospital settings, where digital health literacy barriers may impact care delivery and outcomes [3]. Digital health literacy, defined as "the ability to seek, find, understand, and appraise health information from electronic sources and apply the knowledge gained to addressing or solving a health problem" [4], plays a vital role in the successful implementation of digital health tools [2,5].

There is evidence suggesting that digital tools are effective in improving disease outcomes and health literacy [6-9]. Mobile health apps in the postoperative period have been correlated with earlier discharge, reduction of in-person follow-ups [10,11], promotion of rehabilitation [12], earlier detection of surgical complications [13], and improved communication between patients and health care professionals [14,15]. Beyond these clinical benefits, postoperative monitoring apps have shown potential to empower patients, providing autonomy over their own health and potentially improving satisfaction and recovery motivation [16-18].

However, it remains unclear what factors make these digital tools superior to human health navigators or resources available through simple internet searches [19], particularly in postoperative settings [20]. Despite the proliferation of digital health tools in postoperative care [21], limited research exists on digital health literacy and technology adoption readiness among safety-net hospital populations [22,23]. While studies demonstrate the efficacy of mobile apps in improving postoperative outcomes [24], these benefits presume a baseline level of digital health literacy that may not be universal across all patient populations, particularly in historically underserved communities [25].

In safety-net hospital settings, health literacy is shaped by factors such as educational level, language, and socioeconomic status, with lower health literacy levels linked to poorer health outcomes, reduced treatment adherence, and greater reliance on emergency care. Digital literacy, while related, is a distinct construct that poses additional barriers—particularly for older adults, non–English speakers, and individuals from lower socioeconomic backgrounds, who often face limited internet access and lack the digital skills necessary for navigating health care tools and systems. These separate constructs highlight a need for tailored tools to improve both forms of literacy [26].

The assumption that patients in safety-net hospitals face substantial barriers to digital health tool adoption has shaped both the development and implementation of digital interventions [23]. However, this assumption may not fully reflect current realities as smartphone ownership and digital technology use have become increasingly prevalent across socioeconomic groups [27,28]. As digital health tools continue to expand in postoperative care, understanding the actual digital health literacy levels and technology adoption readiness of safety-net hospital patients is essential for designing effective and equitable solutions [29].

In this study, we distinguished between 2 related but distinct constructs. *Digital health literacy* refers to patients' perceived ability to seek, evaluate, and apply online health information, whereas *technology adoption readiness* reflects patients' ability and confidence to engage with a specific digital health tool. Differentiating these constructs is critical as baseline literacy does not necessarily translate into successful interaction with or adoption of digital interventions.

In this paper, we present PocketDoc, a digital health application designed to support postoperative patient care, and use its evaluation to examine digital health literacy and technology adoption readiness in a safety-net hospital setting. We pursued 2 interrelated objectives. The primary aim was to assess digital health literacy levels among postoperative patients and health care providers. The secondary aim was to evaluate the usability of PocketDoc to determine whether a user-centered digital tool could be accessible to populations traditionally considered vulnerable to the digital divide.

These objectives are intentionally linked. Baseline digital health literacy provides essential context for interpreting usability findings, whereas usability outcomes inform whether patients are likely to adopt and meaningfully engage with digital health resources. By examining both constructs through a mixed methods approach—combining a modified eHealth Literacy Scale (eHEALS) assessment [30] with usability testing of a digital health prototype—we aimed to challenge prevailing assumptions about digital health literacy barriers and identify opportunities for more effective postoperative digital health tool implementation.

Methods

Study Design and Setting

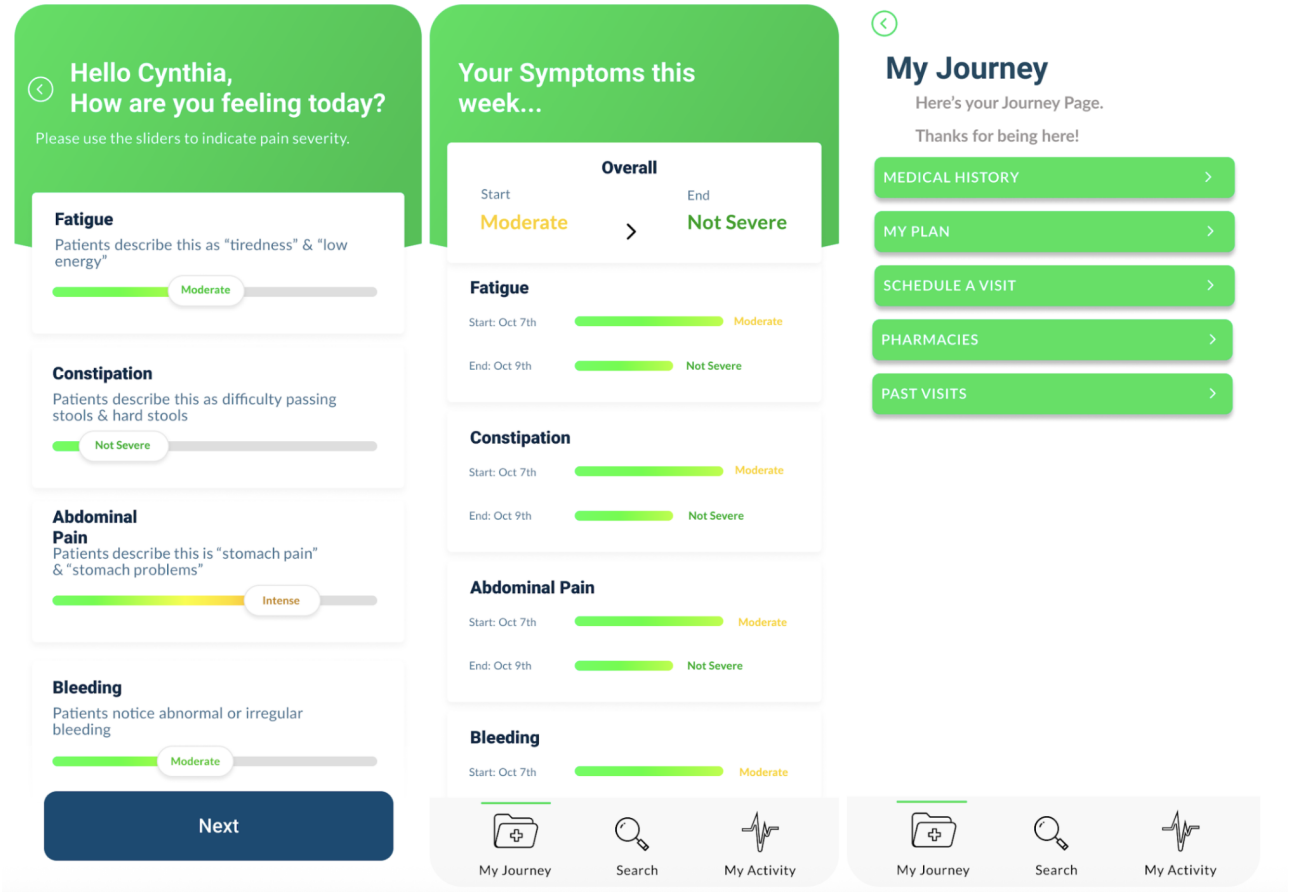
This research was conducted at a large safety-net hospital in a Southern US state. We used a mixed methods approach combining quantitative assessments of digital health literacy with a qualitative usability testing of a digital health prototype.

Study Population and Recruitment

Participants included 71 postoperative patients and 29 health care providers. Study inclusion criteria required participants to be adults (aged ≥18 years) who had had surgery within the previous year, were caretakers of someone who had had surgery in the previous year, or provided clinical care in the postsurgical period. Participants were not excluded based on health status, gender, race, or socioeconomic status, although patients with cognitive deficits or functional impairments preventing the use of digital devices were not recruited.

Digital Health Literacy Assessment

Participants completed a modified version of the eHEALS, a validated instrument for measuring individuals' combined knowledge, comfort, and perceived skills regarding finding, evaluating, and applying online health information [30]. The modified eHEALS included 7 of the original 8 items using its standard 5-point Likert scale (1="not at all confident";



XSL•FO
RenderX

5="completely confident"). One question from the original eHEALS instrument, "I know how to use the health information I find on the internet to help me," was inadvertently omitted during survey implementation. The modified 7-item scale demonstrated adequate internal consistency among the 71 patient participants (Cronbach α=0.77). We proceeded with analysis of the collected data while acknowledging this limitation in our interpretation of the results. This assessment captured perceived digital health literacy and did not evaluate task-based interaction with a specific technology.

PocketDoc Development and Testing

PocketDoc (Figure 1) is a comprehensive digital health tool designed to support patients during the postoperative period, particularly in historically underserved populations. Key functionality includes symptom tracking, medication management with reminders, secure messaging for communication with health care providers, and educational resources tailored to specific procedures. The platform also includes appointment scheduling, follow-up management, and real-time tools for assessing symptom burden, all aimed at enhancing recovery and improving patient outcomes. These features were designed to accommodate varying levels of digital literacy, with particular attention to intuitive navigation and clear information presentation. The interface incorporated evidence-based design principles for health care applications [31], including consistent layout patterns, clear call to action elements, and simplified medical terminology. The development process included multiple rounds of iterative design and input from design professionals, business consultants, and historically underserved patients through multiple rounds of feedback.

Figure 1. Select screenshots of the introduction page and "My Journey" tab of PocketDoc.

For the usability testing and posttask surveys, responses were collected using a 10-point Likert scale (1="strongly disagree"; 10="strongly agree") to obtain granular insights into participants' experiences with the digital health prototype. Usability testing and posttask surveys were used to assess technology adoption readiness and perceived usability rather than digital health literacy.

Data Collection Procedures

Data collection occurred in 2 phases: the first phase included the demographic questionnaire, modified eHEALS assessment, and technology experience survey, and the second phase was the usability test, including standardized introductions to tasks, think-aloud protocols during task completion, and a posttask survey [32]. Sessions were conducted either in person or virtually via videoconference to accommodate participant availability, with each session lasting approximately 20 minutes.

Data Analysis

Survey results were analyzed using the Kruskal-Wallis *H* test to examine differences in digital health literacy and tool adoption across geographic categories. Post hoc Dunn-Bonferroni tests were conducted to examine rural-suburban and rural-urban comparisons in terms of digital health literacy. The Spearman rank-order correlation was used for associations between patient-reported capabilities and use of health resources, as well

XSL•FO
RenderX

as relationships between technology experience and tool adoption. Descriptive statistics were calculated for demographic and survey data. Exploratory linear regression analyses were conducted to examine whether technology experience (≥10 years vs <10 years) and overall digital health literacy were associated with patient confidence in their ability to use PocketDoc.

Ethical Considerations

This research was approved by Emory University's institutional review board in collaboration with a safety-net hospital in a southern US state (STUDY00004346). Written informed consent was obtained from all participants before taking part in the study. The informed consent process included a detailed explanation of study procedures, potential risks and benefits, the voluntary nature of participating, and the right to withdraw at any time. Participants were provided the opportunity to ask questions before providing consent. Participants received a US $20 gift card as compensation for their time. All data were deidentified before analysis.

Results

Participant Demographics

All 71 patients completed the modified eHEALS presurvey and subsequent assessments. Patient demographics are presented in Table 1. We found that there was diverse representation across age groups, with approximately half (n=33, 47%) between the ages of 18 and 34 years. Most participants came from urban (n=23, 32%) and suburban (n=43, 61%) environments, with limited rural representation (n=3, 4%). Most participants (n=41, 58%) had undergone surgery within the previous month, whereas 27% (n=19) had had surgery within the previous 6 months, and 14% (n=10) had had surgery within the previous year. Chronic conditions were reported by 58% (n=41) of the participants, indicating a population with ongoing health care needs. The patient sample was predominantly composed of Black individuals, reflecting the racial composition of the safety-net hospital population served.

Table . Demographic and clinical characteristics of postoperative patient participants (N=71).

Characteristic and category	Participants, n (%)
Survey completion	
eHEALS[a] presurvey	71 (100)
PocketDoc postsurvey	71 (100)
Time when surgery was conducted	
Within the previous month	41 (57.7)
Within the previous 6 months	19 (26.8)
Within the previous year	10 (14.1)
Chronic conditions	
Yes	41 (57.7)
No	27 (38)
Number of chronic conditions (n=41)	
1	23 (56.1)
2	12 (29.3)
3	6 (14.6)
Age group (y)	
18-24	14 (19.7)
25-34	19 (26.8)
35-44	9 (12.7)
45-54	7 (9.9)
55-64	12 (16.9)
65-74	7 (9.9)
75-84	3 (4.2)

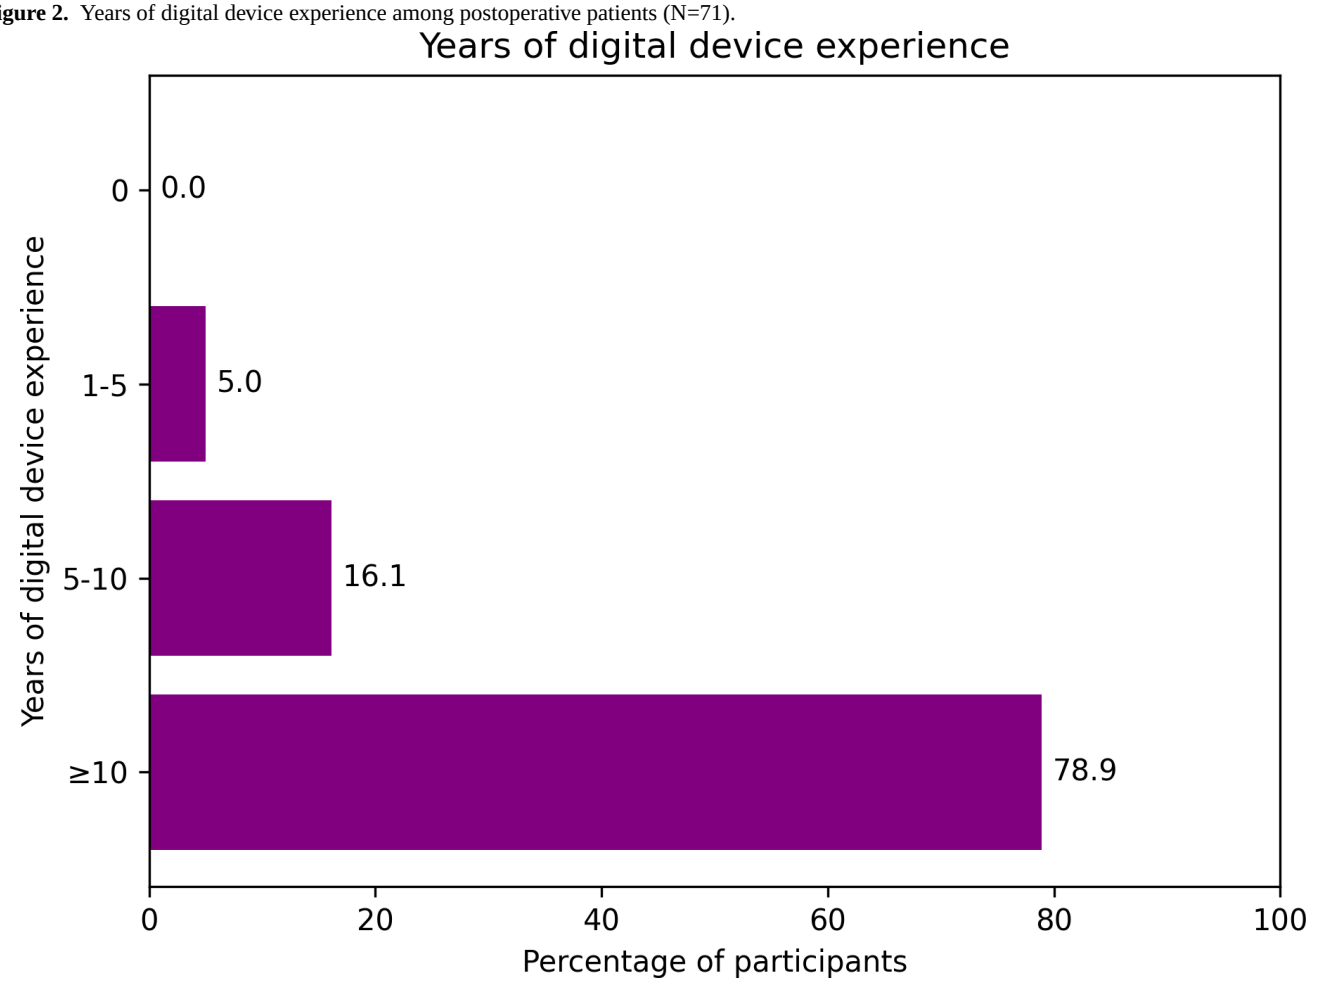
[a]eHEALS: eHealth Literacy Scale.

XSL•FO
RenderX

Digital Health Literacy Levels

Analysis of the modified eHEALS survey (Table 2 and Multimedia Appendix 1) revealed that 69% (49/71) of patients reported high confidence (score of ≥3 on a 5-point scale) in finding health resources online (median 3, IQR 2-3). Furthermore, 61% (n=43) of participants expressed confidence in using the internet for health-related questions (median 3, IQR 2-3), and 63% (n=45) reported feeling capable of evaluating health resources (median 3, IQR 2-3). However, a notable drop occurred when examining confidence in health decision-making, with only 49% (n=35) feeling confident in using digital resources for making health decisions (median 2, IQR 2-3). Statistical analysis revealed that patients' confidence in finding health resources was positively correlated with interface satisfaction (ρ=0.262, 95% CI 0.03 - 0.47; *P*=.03). Similarly, patients' confidence in using these resources showed a significant positive correlation with interface satisfaction (ρ=0.304, 95% CI 0.07 - 0.52; *P*=.01).

Table . Item-level digital health literacy scores measured using the modified 7-item eHealth Literacy Scale (eHEALS).



eHEALS item	Score (1-5), median (IQR)
Evaluating resources	3 (2-3)
Knowing how to find resources	3 (2-3)
Using resources	3 (2-3)
Knowing about the existence of resources	3 (2-3.5)
Identifying the quality of resources	3 (2-3.5)
Knowing where to find resources	3 (2-4)
Making decisions with resources	2 (2-3)

Technology Experience and Demographic Correlations

Analysis of technology experience (Figure 2) revealed that 79% (56/71) of the participants reported 10 or more years of digital device experience, indicating substantial familiarity with technology within the study population. Statistical analysis demonstrated no significant correlation between digital literacy and age or educational level. However, geographic location emerged as a notable factor in digital literacy levels. The Kruskal-Wallis *H* test revealed significant differences in perceptions based on living environment (effect size=0.112; *P*=.05). Urban and suburban patients reported similarly high mean confidence scores (urban: mean 9/10, SD 1.33; suburban: mean 9/10, SD 1.19), whereas rural patients reported significantly lower scores (mean 7/10, SD 0.0). Post hoc Dunn-Bonferroni tests showed differences between rural-suburban (*P*=.081) and rural-urban comparisons (*P*=.080), which did not meet the significance threshold.

XSL•FO
RenderX

Figure 2. Years of digital device experience among postoperative patients (N=71).

Tool Adoption and Use Patterns

In the usability assessment of the digital health prototype (Tables 3 and 4), participants demonstrated high levels of engagement and capability. Usability ratings across participants were high for ease of use (median 10, IQR 8-10), with task intuitiveness scoring highly at an average of 8.82 of 10 (median 10, IQR 8-10). Analysis revealed a significant correlation between prior technology exposure and perceived helpfulness of a digital health tool such as PocketDoc (ρ=0.230, 95% CI 0.01 - 0.43; *P*=.04). Participants with ≥10 years of digital device experience showed particularly strong performance in information-finding tasks (median 9, IQR 7-10).

Table . Usability and technology adoption readiness of the PocketDoc prototype among postoperative patients (N=71).

Usability metric	Survey item	Score (1-10), median (IQR)
Ease of use	"I think PocketDoc was easy to use."	10 (8-10)
Task scenario intuitiveness	"I think the Task Scenarios were intuitive to complete with PocketDoc."	10 (8-10)
Interface satisfaction	"I like the interface of PocketDoc."	9 (8-10)
Information findability	"I think my health information was presented to me in a way that was easy to find."	9 (7-10)
Information organization	"I think my health information was presented to me in a way that was well organized."	8 (7-10)
Compassionate wording	"I think my health information was presented to me in a way that was worded compassionately."	10 (9-10)
Information summary	"I think my health information was presented to me in a way that was useful for summary."	9 (7-10)
Health journey support	"I think PocketDoc would help me record my health journey after surgery."	9 (7-10)
Patient confidence	"I am confident in my ability to use PocketDoc (as demonstrated)."	10 (9-10)

XSL•FO
RenderX

Table . Internal consistency of the modified 7-item eHealth Literacy Scale (eHEALS; Cronbach α=0.77).

Item	eHEALS item wording
1	"I know what health resources are available on the Internet."
2	"I know where to find helpful health resources on the Internet."
3	"I know how to find helpful health resources on the Internet."
4	"I know how to use the Internet to answer my questions about health."
6	"I have the skills I need to evaluate the health resources I find on the Internet."
7	"I can tell high-quality health resources from low-quality health resources on the Internet."
8	"I feel confident in using information from the Internet to make health decisions."

Interestingly, participants' ability to distinguish high-quality health resources showed a significant negative correlation with ease of finding information (ρ=−0.251, 95% CI −0.46 to −0.02; *P*=.04), whereas the correlation with information organization perception was marginally significant (ρ=−0.215, 95% CI −0.42 to 0.01; *P*=.07).

In an exploratory regression analysis examining predictors of confidence in ability to use PocketDoc, the overall model was statistically significant (R^2=0.15; *P*=.004). Higher digital health literacy was independently associated with lower usability confidence (β=−0.31, 95% CI −0.50 to −0.12; *P*=.002), whereas technology experience (≥10 years vs <10 years) was not independently associated after accounting for literacy (β=0.36, 95% CI −0.19 to 0.91; *P*=.20).

Discussion

Principal Findings

Digital health literacy and technology adoption in safety-net hospital populations present a more nuanced picture than traditionally assumed. Prior research has suggested that patients in safety-net settings face barriers to digital health tool adoption due to limited access, lower digital literacy, and poor health literacy [26]. Our findings challenge the universality of these assumptions while highlighting specific areas in which targeted support may still be necessary for effective postoperative digital health implementation.

Importantly, digital health literacy and technology adoption readiness represent related but distinct constructs. The eHEALS captures patients' perceived ability to seek, evaluate, and apply online health information broadly, whereas usability findings reflect patients' interaction with a specific digital health tool within a defined clinical context. Distinguishing these constructs is critical for interpreting how baseline capabilities translate into real-world technology use.

In this study, relatively high levels of self-reported digital competency were observed, with 69% (49/71) of participants reporting high confidence in finding health resources online. This suggests that basic digital literacy barriers may be less universal among safety-net hospital patients than previously assumed [26]. These findings align with broader trends of increasing smartphone ownership and digital technology use across socioeconomic groups [27]. The high prevalence of substantial technology experience (n=56, 79% reporting ≥10 years of device use) further supports this shift.

Assessing digital health literacy alongside prototype usability provided important contextual insights. The relatively high baseline confidence in finding online health information helps frame the strong usability ratings observed for PocketDoc, including high scores for ease of use and task intuitiveness (median 10, IQR 8-10 in both cases). Together, these findings suggest that user-centered design approaches may facilitate accessibility across varying levels of digital health literacy.

A more granular pattern emerged when examining specific domains of digital health literacy. While many participants felt confident evaluating health resources (45/71, 63%) and using the internet for health-related questions (43/71, 61%), fewer reported confidence in using digital information for health decision-making (35/71, 49%). This pattern is consistent with prior work demonstrating that digital health literacy comprises multiple competencies, with decision-making often representing the greatest challenge [4,25,33,34].

The gap between general digital competency and confidence in health decision-making mirrors findings from recent studies highlighting the complexity of translating basic digital skills into applied health management [35,36]. This challenge may be particularly salient in postoperative care, where patients must interpret complex instructions and make time-sensitive decisions that carry immediate health implications [37].

Geographic differences in digital health literacy could not be robustly assessed due to the small rural sample size (n=3). Although rural participants demonstrated lower mean confidence scores than urban and suburban participants, these observations are exploratory and not suitable for inferential conclusions. Nonetheless, the observed pattern aligns with broader literature on rural-urban digital health disparities and underscores the need for future studies with adequately powered rural samples [35,38].

An additional insight emerged from the relationship between digital health literacy and usability perceptions. The negative association between critical evaluation skills and satisfaction with information organization (ρ=−0.251; *P*=.04) reflects a paradox observed in prior digital health research [39-41]. More

XSL•FO
RenderX

digitally literate users may hold higher expectations for information presentation and usability rather than experiencing reduced capability.

This interpretation is further supported by exploratory regression analyses, which suggested that higher digital health literacy was associated with lower confidence in usability. Together, these findings highlight a key design challenge: digital health tools must accommodate users with varying levels of sophistication and expectations. Adaptive interfaces that provide both simplified overviews and optional advanced features may be particularly well suited for postoperative care contexts.

While this study also collected rich qualitative data through interviews and extended usability observations, this manuscript focuses on quantitative analyses and usability themes. A forthcoming manuscript will explore qualitative findings in greater depth to further contextualize patient experiences and perspectives. This approach was chosen to maintain focus on the study's primary quantitative and usability outcomes.

Limitations

Several limitations should be considered when interpreting these findings. Our use of a modified eHEALS, which inadvertently omitted question 5 ("I know how to use the health information I find on the internet to help me"), may have affected the comprehensiveness of our digital health literacy assessment. This modification constitutes use of a nonvalidated tool, and while the modified version demonstrated internal consistency (Cronbach α=0.77), this omission limits direct comparability with other eHEALS-based studies and potentially overestimates overall literacy levels.

Our sample included limited representation from rural areas (n=3), which precludes any meaningful conclusions about geographic disparities. Any observed differences between rural and both urban and suburban participants are reported as exploratory findings only and require replication in adequately powered samples. Relatedly, post hoc power for the geographic group comparison was low; thus, this study is underpowered to detect true rural–urban and suburban differences. This limitation is relevant given the differences we observed between both urban and suburban and rural participants.

This study's reliance on self-reported measures of digital health literacy may not fully capture actual capabilities. While self-reported measures are widely used in digital health literacy research [42], they may be subject to social desirability bias and over- or underestimation of abilities. Our study may be subject to Berkson bias and self-selection bias as individuals with extremely low digital literacy or limited interest in digital tools may have been less likely to participate, and individuals with greater comfort with or interest in digital technologies may have been more likely to enroll.

Correlation analyses were exploratory and not adjusted for multiple testing, raising the possibility of type I error; therefore, the findings should be interpreted as hypothesis generating. Exploratory regression analyses were intentionally constrained to a small number of predictors due to sample size and ceiling effects in usability ratings and should not be interpreted as supporting causal inference.

Conclusions

This study advances our understanding of the evolving landscape of digital readiness among postoperative patients in safety-net settings. While participants reported substantial experience with digital devices, the data highlight a persistent challenge: translating general digital familiarity into confidence in managing personal health decisions. This gap suggests that, even when access and basic skills are present, patients may still struggle to apply digital tools meaningfully in complex clinical contexts such as postoperative care. Moreover, preliminary geographic trends point to location-based factors rather than traditional demographic variables as potential influences on confidence and engagement with digital health tools. These insights underscore the importance of designing tools that go beyond increasing access or general literacy, instead emphasizing support for decision-making and personalization based on patients' lived environments. Addressing these nuanced barriers may be key to optimizing digital health strategies and ensuring equitable postoperative support across diverse care settings.

Abstract

Background: Digital mental health tools, such as SMS text messaging and online resources, are increasingly used to support well-being. However, user satisfaction across these formats remains insufficiently explored.

Objective: The study assessed participants' engagement, perceived impact, and overall satisfaction with the Text4Support program and the e-mental health resources.

Methods: This randomized controlled study was conducted in Nova Scotia, Canada. Participants were assigned to either the Text4Support group, which received daily supportive text messages, or the control group, which received a single text message with a link to the Nova Scotia Mental Health and Addiction Program e-mental health resources. Responses to various aspects of the interventions were evaluated using a 5-point Likert scale, while overall satisfaction was measured on a scale from 0 to 10. The chi-square test and Fisher exact test were employed for data analysis.

Results: A total of 69 participants in the control group and 130 in the Text4Support group completed the satisfaction survey. The overall mean (SD) satisfaction score in the control group was 5.1 (2.3), and the overall mean (SD) satisfaction score for the Text4Support group was 7.1 (2.2). Compared to the control group, participants in the Text4Support group reported greater engagement and positive program impact. While 53.8% (70/130) of Text4Support recipients always read the messages, only 39.1% (27/69) of the control group rarely accessed the eHealth resources. When compared to the control group, participants allocated to the Text4Support group were reported to sometimes take positive action upon reading the messages (42.3% vs 33.3%). A significantly higher proportion of Text4Support users strongly agreed or agreed that the messages were supportive (81.4% vs 41.5%), positive (88.4% vs 49.2%), and helpful in coping with stress (44.2% vs 11.9%), loneliness (40.3% vs 13.4%), and improving mental well-being (51.2% vs 17.9%). In contrast, the majority of responses from the control group were largely neutral.

Conclusions: Results showed that Text4Support group participants were significantly more satisfied with the program than those receiving standard eHealth resources. This highlights that daily supportive SMS text messaging is an effective, low-cost adjunct to care delivery and mental health improvement. These findings suggest that aggregate, brief, and low-cost text-based interventions have great potential for increasing health access and engagement, particularly among traditionally disadvantaged populations with limited access to traditional services.

Introduction

Psychiatric care has increasingly incorporated digital mental health interventions, which offer accessible and scalable support beyond traditional therapy and medication. Patient feedback through user satisfaction measures is vital in assessing the effectiveness of digital mental health interventions [1]. Patient experiences are gaining recognition as a key factor in enhancing health care quality alongside clinical effectiveness and safety [2,3]. These patient care experiences are included in public reporting and health performance programs [3]. Supportive SMS text messaging programs and eHealth services have become popular and convenient tools for managing mental health [4,5]. The structure and approaches of these interventions may vary in terms of user engagement and perceived effectiveness, but all aim to enhance well-being [6]. Nevertheless, satisfaction levels often vary, highlighting an area that requires more attention to optimize the effectiveness of such interventions for individuals with mental illness.

Supportive SMS text messaging programs like Text4Hope, Text4Mood, Text4PTSI, and Wellbeing offer automated text messages that provide preprogrammed positive reinforcement to users [7-9]. These coping message text programs require minimal input from users while guiding users through daily coping skills and emotional support [7-11]. Literature has shown that these programs increase feelings of connectedness and reduce mental health conditions [10]. Two randomized controlled trials (RCTs) conducted in Canada revealed that supportive text messages reduced depression and alcohol intake of subscribers [12,13].

Various studies have shown that eHealth resources such as online self-help services, psychoeducational tools, and virtual peer support groups provide an accessible way to seek help, as well as an independent role in receiving care [14,15]. These entail being able to partake in the content through specific timestamps, which ensures self-governance [16]. Nevertheless, there is little standardization regarding how users engage with eHealth interventions; it remains their prerogative to seek and employ the information furnished, and this influences overall satisfaction and perceived efficacy.

. This study aims to compare supportive SMS text messaging interventions with eHealth resources to better understand users' perceptions and feedback on the impact, engagement levels, and overall satisfaction. The study will evaluate engagement and user satisfaction with Text4Support in comparison to eHealth resources and assess the perceived relevance and impact of supportive SMS text messaging relative to these eHealth tools.

Given the importance of the perceived adequacy of digitally delivered tools as a core component of modern psychiatric intervention delivery systems to their success, it is essential to understand how users evaluate the adequacy of digitally delivered interventions. This study aims to compare supportive SMS text messaging interventions with eHealth resources to better understand users' perceptions and feedback on the impact, engagement levels, and overall satisfaction. The study will evaluate engagement and user satisfaction with Text4Support in comparison to eHealth resources and assess the perceived relevance and impact of supportive SMS text messaging relative to these eHealth tools.

The intervention, Text4Support, provides daily cognitive behavioral therapy (CBT)-informed supportive text messages for 6 months, tailored to users' primary mental health concerns and delivered as an adjunct to usual care. In contrast, the control group receives the usual care plus a single text message directing participants to freely available e-mental health tools offered through the Nova Scotia Mental Health and Addictions Program website.

Methods

Study Design

This RCT adopted a multicenter, two-arm design with a rater-blinded methodology. Participants were recruited and randomized into the Text4Support group and the control group.

Ethical Considerations

The study was approved by the Nova Scotia Health Research Ethics Board (REB File #1028174) and registered with ClinicalTrials.gov (NCT05411302). Each study participant provided informed consent, and the study was conducted according to the Declaration of Helsinki [17] and Good Clinical Practice (Canadian Guidelines) [18]. Participation was voluntary, with the option to withdraw at any time without impact on care. Participants' privacy and confidentiality were rigorously protected. All data were deidentified at the point of collection, stored, and secured. No compensation or incentives were provided to participants.

Data Collection/Intervention

The published study protocol detailed the data collection procedure [19]. In summary, data were collected via a self-administered survey powered by the Research Electronic Data Capture (REDCap) software program [20]. Participants' age, gender, income, education, housing status, relationship status, and clinical information were obtained. Data were collected between October 11, 2022 and July 31, 2024. After thoroughly informing participants about the study, we used an electronic consent form to obtain their consent.

Participants randomized to the control group received one text message with the Nova Scotia Mental Health and Addictions Program website link embedded in the message. This resource was freely accessible, and this service was provided as an add-on to participants' usual care. The website offers free, evidence-based e-mental health resources designed to address various psychiatric conditions with programs such as the early psychosis program, the eating disorder program, and recovery support [21]. Participants randomized to the Text4Support group received free daily, unilateral, CBT-based text messages tailored to their specific diagnosis as an add-on program to their usual care for 6 months. The supportive text messages were developed using evidence-based principles of CBT. Each message, limited to 160 characters, was designed to provide brief, accessible prompts that encourage adaptive coping, cognitive reframing, and emotional regulation. The content was collaboratively

XSL•FO
RenderX

created by CBT therapists, mental health professionals, and individuals with lived experience to ensure both clinical relevance and user-centered design. The underlying mechanism is grounded in the concept that regular exposure to concise, positively framed messages can reinforce helpful thinking patterns, enhance self-efficacy, and foster emotional resilience over time. Through consistent daily reinforcement, these messages aim to augment usual care by promoting psychological well-being and perceived connectedness. Participants completed the baseline surveys on enrollment via the online link. A text message with follow-up surveys, which includes the satisfaction survey, was sent to all participants at 6 weeks, 3 months, and 6 months.

Outcome Measures

The primary outcome measure was the participants' overall satisfaction with the Text4Support program or the Nova Scotia Health e-mental health online resources. Overall satisfaction was rated on an 11-point Likert scale, where zero indicated "very dissatisfied," 5 indicated "neutral," and 10 showed "very satisfied."

Secondary outcomes included the perceived impact and feedback on the Text4Support program and the Nova Scotia Health e-mental health online resources among the Text4Support and control groups. Study participants provided feedback on their satisfaction by responding to questions that assessed their engagement and use of each intervention and its perceived impact.

Engagement and use of each intervention were measured on a 5-point Likert scale (always, mostly, sometimes, rarely, and never). The perceived impact of each intervention on how participants coped with stress and loneliness, improved quality of life, overall physical and mental well-being, and the intervention's relevance, encouragement, and supportiveness were measured on a 5-point Likert scale, ranging from "strongly agree" to "strongly disagree" and including "neutral." For analysis purposes, responses were collapsed into 3 categories: strongly agree/agree, neutral, and strongly disagree/disagree.

The reliability and validity of this scale for testing satisfaction have not been examined; however, the survey was adopted in various studies to assess user satisfaction [8,10,22].

Data Analyses

Data were analyzed using SPSS for Windows (version 28; IBM Corporation) [23]. Participants' satisfaction data were presented as a continuous variable. We measured participants' overall satisfaction by rating the program from 0 to 10 (0=very dissatisfied, 5=neutral, and 10=very satisfied). The results were presented as means and SDs. Participants' engagement and use of each intervention (Text4Support/online resources) and the perceived impact of each intervention were summarized and presented as categorical variables and reported as frequency and percentages among the control group and Text4Support group. A chi-square and Fisher exact test were run to examine any differences in reporting user satisfaction, engagement, or perception of the Text4Support or online resources among the 2 groups, and a 2-tailed criterion (α<.05) was used to determine statistical differences. To handle missing data, we adopted imputation techniques, focusing on the last observation carried forward method.

Results

Figure 1 illustrates the flowchart of the participants. Eight hundred and ninety-eight patients were assessed for eligibility to enter the trial, of whom 781 eligible patients were randomized: 69 in the control group and 130 in the Text4Support group completed the satisfaction survey. The response rate in the control group was 18% (69/387), whereas the Text4Support group achieved a higher response rate of 33% (130/394).

Figure 1. Participant flowchart.

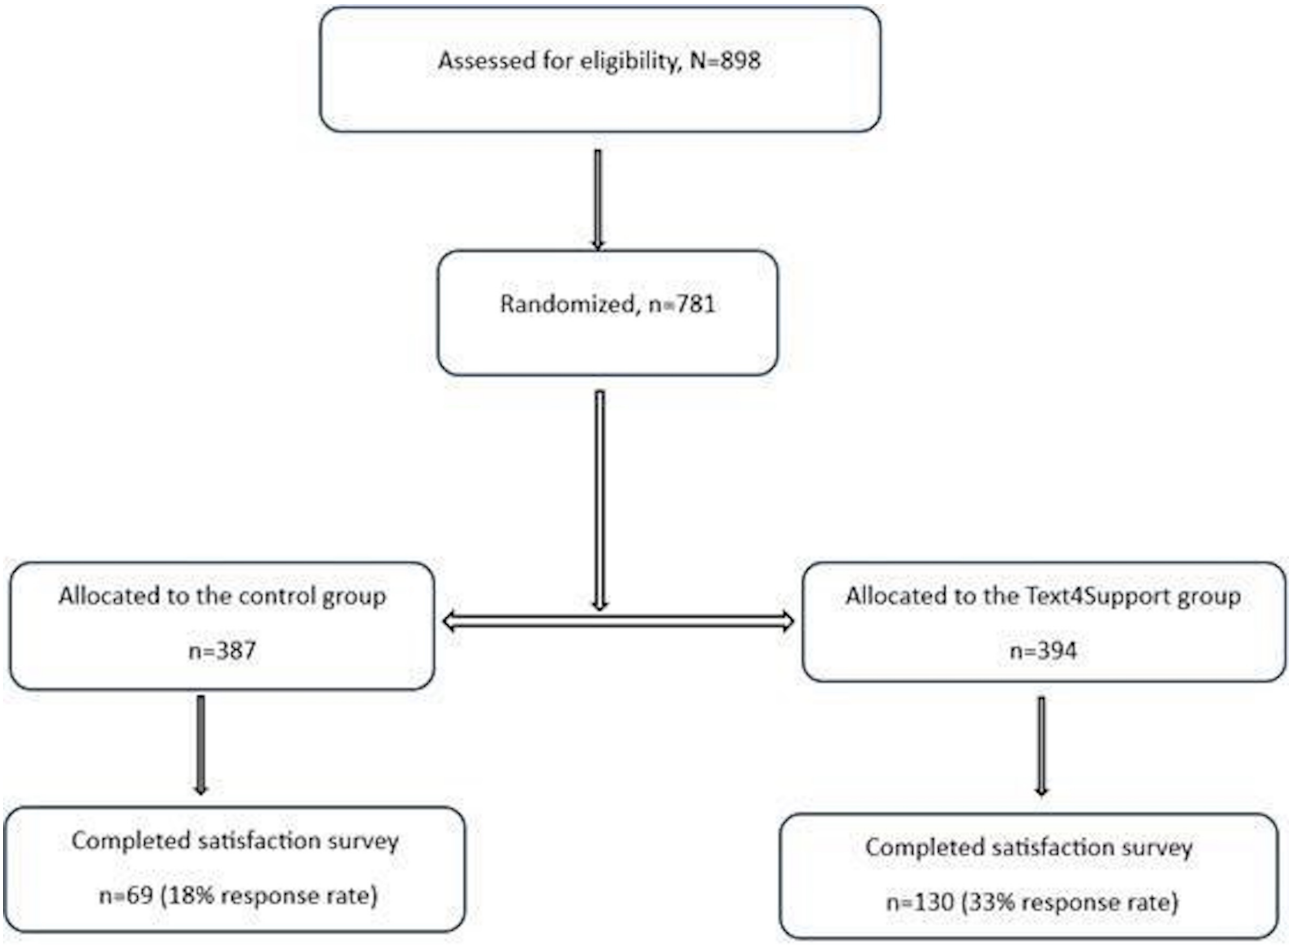

Table 1 shows the demographic characteristics of participants who completed the satisfaction survey. In total, across the 2 groups, the majority were between 26 and 60 years old (72.9%, 145/199), female (66.8%, 133/199), Caucasian (84.8%, 168/198), employed (52.3%, 103/197), and partnered/married (45.2%, 90/199) and had obtained a postsecondary education at a college or university (57.1%, 113/198). About 49% (97/199) of the study participants live in rented accommodation, 28.5% (55/193) have an income range of less than $29,590 (1 CAD≈US $0.77 at the time of the study), and 23.1% (27/117) have a primary diagnosis of depression. The chi-square analysis revealed no statistically significant differences in the demographic characteristics of participants in the Text4Support group and the control group, suggesting no differences in their demographic characteristics.

[a]Fisher exact values.

Most study participants were neutral when asked if the eHealth resources were on the topic (32/65, 49.2%), on point (32/65, 49.2%), supportive (30/65, 46.2%), helpful in coping with loneliness (38/67, 56.7%), and helpful in coping with stress or improving their physical and mental well-being (40/67, 59.7%). However, 49.2% (32/65) strongly agreed or agreed that the eHealth resources were positive. In terms of how eHealth improved quality of life, 64.2% (43/67) were neutral as well as for negativity of the online resources (36/67, 55.4%), not encouraging (33/65, 50.8%), not helpful (34/65, 52.3%), and not relevant (33/67, 50.8%). In contrast, the majority of participants in the Text4Support group strongly agreed or agreed that the messages were on the topic (105/129, 81.4%), were on point (104/129, 80.6%), supportive (105/129, 81.4%), positive (114/129, 88.8%), and helped them cope with loneliness (52/129, 40.3%), stress (57/129, 44.2%), or improve their overall mental well-being (66/129, 51.2%). In terms of how the messages improved quality of life, 42.6% (55/129) in the Text4Support group were neutral and strongly disagreed or disagreed with the messages being negative (112/129, 86.8%), not encouraging (101/129, 78.3%), not helpful (98/129, 76%), and not relevant (86/129, 66.7%). The results revealed statistically significant differences between groups, indicating that the observed effects were not due to chance and were not coincidental.

Discussion

Principal Findings

This study provides new insights into how patients perceive text message interventions, eHealth resources, and their engagement with the Text4Support program and the Nova Scotia Health online resources. Findings reveal that the overall mean (SD) satisfaction score in the control group was 5.1 (2.3), and the overall mean (SD) satisfaction score for the Text4Support group was 7.1 (2.2). Compared to the control group, participants in the Text4Support group reported greater engagement and positive program impact. While 53.8% (70/130) of Text4Support recipients always read the messages, only 8.7% (6/69) of the control group always read the eHealth resources. Participants allocated to the Text4Support group were reported to sometimes take action upon reading the messages (42.3% vs 33.3%). A significantly higher proportion of Text4Support users strongly agreed or agreed that the messages were supportive (81.4% vs 41.5%), positive (88.4% vs 49.2%), and helpful in coping with stress (44.2% vs 11.9%), loneliness (40.3% vs 13.4%), and improving mental well-being (51.2% vs 17.9%). In contrast, responses from the control group were largely neutral. The majority of respondents in the Text4Support group agreed or strongly agreed that the messages had a positive impact on them, which achieved statistical significance (P<.001) when compared with the e-mental health resource group; however, physical well-being was neutral across the 2 groups and not statistically significant (P=.1).

The response rates observed in this study provide important insights into participant engagement with digital mental health interventions. The Text4Support group demonstrated a notably higher response rate (33%) compared to the control group (18%). Although the response rates remain relatively low, raising concerns about potential attrition bias and the representativeness of the findings, the differences suggest that supportive SMS text messaging interventions may play a significant role in enhancing participant engagement and willingness to interact with mental health research and services. Improved response rates have important implications for the validity and generalizability of study findings. Higher response rates enhance the appropriateness and representativeness of the sample [24].

The findings indicate a high level of satisfaction among participants in the Text4Support group, with an average score of 7.1. Although our study participants expressed high satisfaction, other studies recorded higher satisfaction with the supportive text intervention [22,25-27]. For example, a study conducted among educators showed a mean satisfaction of about 8.5 among administrative educators [26]. Again, a cross-sectional study among 2032 participants recorded 8.55

XSL•FO
RenderX

overall mean satisfaction with the Text4Hope program [27]. Among the control group, an overall average satisfaction rate of 5.1 for online mental health resources suggests moderate user satisfaction. In terms of context and use, this measure aligns with the literature in that satisfaction with online mental health services is low to moderate [28]. As an example, one study making use of the Client Satisfaction Questionnaire-8 found that most patients reported low-to-moderate satisfaction with online psychiatric services [28].

The Text4Support program produced significant participant engagement, as 53% of participants consistently read text messages, while only 8.7% of control group members always read online resources. Outcomes from various studies have shown that interactive text-based interventions help maintain long-term therapeutic engagement, which delivers essential immediate mental health support [22,27,29,30]. A systematic review and meta-analysis found that SMS text messaging interventions for health promotion had widespread acceptance among participants and demonstrated high engagement rates throughout different health areas [29,30]. Although few participants always read the messages/eHealth resources and took action afterward, 73.8% and 83.8% of participants in the control and intervention groups, respectively, at least rarely read and took action in our study. However, the relatively low percentage of participants taking consistent action based on the messages suggests that passive consumption may not suffice for significant behavioral change. Integrating interactive components, such as bidirectional messaging, could enhance effectiveness. A scoping review of text message interventions in adolescent mental health services found that 65% of studies involved bidirectional messaging, indicating its potential to boost engagement and outcomes [31].

On the other hand, engagement with the provided eHealth resources was lower, with only a subset of participants actively utilizing them. Research indicates that eHealth interventions often struggle with uptake unless seamlessly integrated into daily routines [32]. Barriers to eHealth engagement usually stem from issues such as lack of time, perceived irrelevance, and digital literacy challenges [33]. Unlike text messages, which require minimal effort to consume, accessing eHealth resources demands additional steps that may deter some users. The brevity of text messages (limited to 160 characters) makes them easier to process, especially for individuals experiencing mental health challenges [34]. In contrast, studies on guided digital interventions suggest that providing step-by-step instructions or integrating behavioral prompts within text messages can enhance the utilization of eHealth resources [35]. One notable finding is that while 66.7% of the Text4Support group and 29.2% in the control group found the messages relevant, 9.3% and 20%, respectively, did not. The Text4Support group exhibited a notably higher percentage of perceived relevance, indicating that Text4Support was more effectively aligned with participants' mental health needs than the control condition. A significant percentage of participants, 9.3% in the Text4Support group and 20% in the control group, indicated that the messages/online resources were not pertinent to their needs. This disparity highlights the necessity of customizing digital interventions to individual users' specific needs, circumstances, and preferences. The control group's elevated percentage of irrelevance likely indicates the generic nature of nontargeted messages, while the Text4Support group's reduced percentage implies a degree of alignment with participants' needs, although there is still potential for enhancement.

Regarding perceived relevance and utility, the results show that most Text4Support participants (81.4%) found the messages relevant to the topic. In comparison, 46.2% strongly agreed or agreed with the online resource, underscoring the importance of tailored content. Personalization has been identified as a key factor in the success of text-based interventions. Literature has highlighted that those interventions allowing rapid, personalized exchanges, akin to natural conversation, were more effective in addressing individual needs [22,36].

The purpose of Text4Support was to provide emotional support through daily messages. The Text4Support group overwhelmingly found the messages supportive (81.4%) and positive (88.4%). These findings demonstrate that digital interventions with positive reinforcement significantly improve users' mental well-being [10,22,37,38]. Research indicates that such interventions can effectively develop therapeutic connections, meeting unmet needs for mental health care [10,27]. However, the debate persists on whether supportive messaging alone yields lasting psychological improvements. Studies suggest combining SMS text messaging with other treatment modalities, such as CBTs, may enhance effectiveness [39]. The supportive text messages delivered in this study were an addition to the patient's usual care, making it more effective.

The supportive text messages positively impacted mental well-being, with 51.2% of Text4Support participants reporting improvements, compared to 17.9% in the control group. Similarly, 40.3% of the intervention group reported reduced loneliness and 44.2% experienced lower stress levels. Other studies align with our findings; for example, a similar program, Wellness4Teacher, reported that 95.4% of its respondents reported that the messages were at least often positively impactful, while 93.3% reported that the messages were affirming [26]. These findings highlight the potential of digital interventions as supplementary tools for mental health support [40,41].

Our results show substantial differences in neutral responses across all groups in terms of improving the quality of life. The highest proportion of neutral participant responses was 64.2% in the control group and 42.6% in the Text4Support group, totaling 50% among the study sample. Participants who gave neutral responses were all neither for nor against the intervention having an effect on their quality of life. The slightly larger percentage of indifferent responses from the control group indicates either a lack of participation or ineffectiveness of regular care in significantly changing the participants' assessments of life quality. This is perhaps due to a more focused and structured approach, which is likely to impress participants more than those of general care. The findings align with previous research showing that participants' opinions about digital treatments vary [42,43]. For example, Proudfoot et al [43] found that while 68% of respondents indicated considerable improvements to their mental health following digital treatments,

XSL•FO
RenderX

about 25% reported neutral or unsure answers, underscoring that outcomes are determined contextually. A qualitative research study also documents instances of most respondents feeling neutral or holding dual views about digital mental health interventions [44].

Similarly, a meta-analysis of RCTs highlighted that, as a result of the differences in people's participation and expectations, neutral answers often emerge in studies involving smartphone-based mental health therapies [42].

Across groups, participants demonstrated similar disagreement percentages, with the coping of stress registering 28.4% in the eHealth resource group and 19.4% in the Text4Support group, resulting in an overall rate of 22.4%. Although digital interventions may have received more positive feedback, they were not effective for everyone, and some participants found them ineffective in stress coping [45].

However, both interventions had a weaker effect on physical well-being, with no significant differences between groups [46,47]. This finding is consistent with prior research, which has shown that text-based interventions can effectively improve mental health outcomes but have a limited influence on physical health behaviors [47,48]. Digital interventions targeting physical health require more structured behavior-change strategies, such as goal setting and reinforcement mechanisms, rather than passive messaging alone [49].

Implications for Policy, Practice, and Future Research

The findings of this study have several important implications for the design, implementation, and scaling of digital mental health interventions. First, the significantly higher satisfaction and engagement levels observed in the Text4Support group underscore the value of incorporating supportive, brief, and personalized messaging into routine mental health care. Policymakers and health care providers should consider integrating text-based interventions as a standard adjunct to traditional care, particularly for populations that may face barriers to in-person or web-based services.

Given the low engagement with static eHealth resources, health systems should prioritize low-barrier, mobile-first tools that align with users' daily routines. Moreover, to increase the effectiveness of such interventions, future policy should encourage the development of interactive, bidirectional messaging systems that foster active participation and allow for real-time support and personalization based on user feedback and needs. Tailoring content to individual needs, such as demographic or diagnostic profiles, can further enhance relevance and efficacy, as evidenced by the higher perceived relevance and positive impact of the Text4Support messages.

Although Text4Support currently relies on preprogrammed, therapist-developed messages, future iterations of supportive SMS text messaging interventions could leverage artificial intelligence, including generative artificial intelligence, to enhance message compilation, personalization, and responsiveness. Finally, given the limited impact on physical well-being, digital programs should integrate behavior change techniques (eg, goal setting, reminders, and progress tracking) when addressing physical health outcomes. Health authorities should support cross-sector collaboration between digital health developers, clinicians, and researchers to ensure interventions are both evidence-based and contextually responsive. These findings advocate for a patient-centered, adaptive approach to mental health support, where digital tools are not merely supplemental but are integral to comprehensive, accessible, and scalable care strategies.

Limitations

Our study has limitations that need to be considered when appraising the results. First, the generalizability of the results may be affected by the comparatively small sample size of participants who completed the follow-up satisfaction survey, particularly in the control group. The imbalance in group sizes (130 in the Text4Support group vs 69 in the control group) may have introduced bias or limited the statistical power to detect differences in some outcomes. The small sample size may be attributed to the online nature of the surveys; literature has reported that online distributed surveys are unlikely to keep participants in a study for follow-up assessment compared to paper-based surveys [50]. One notable limitation of this study is the relatively low survey completion rate. While this may impact the generalizability of the findings, it is consistent with patterns observed in other digital mental health and eHealth trials, which frequently report attrition rates exceeding 30% [51,52]. Again, participants' satisfaction, engagement, and perception were self-reported, which may result in recall bias since participants may overestimate their feedback. Lastly, the web-based questionnaire used to assess participant satisfaction and perception was not a validated instrument, which may reduce the reliability of the reported satisfaction rates. Nonetheless, this was one of the first RCTs examining user satisfaction among Text4Support users and Nova Scotia mental health and addiction online resources users in Nova Scotia.

Conclusions

This study's findings demonstrate the meaningful impact of personalized, supportive SMS text messaging in enhancing engagement, emotional well-being, and satisfaction among mental health service users. As mental health systems evolve to meet rising demands, digital interventions like Text4Support represent a promising, scalable solution that can complement existing care. To maximize their potential, policies must prioritize accessibility, personalization, and integration with broader care models, ensuring that digital tools meet people where they are, with the right message at the right time.

Funding

The study was funded by the Queen Elizabeth II Foundation and supported by the Global Psychological eHealth Foundation, the Department of Psychiatry at Nova Scotia Health, and Dalhousie University. The funders had no role in the study's design, execution,

data collection, analysis, interpretation, or writing. They were also not involved in reviewing, approving, or deciding to publish the results.

Data Availability

The data supporting this manuscript's conclusions will be made available upon reasonable request from the corresponding author.

Authors' Contributions

VIOA conceived, designed, and supervised the study. VIOA, RS, and GO-D conducted data analysis. The initial manuscript was drafted by GO-D. VIOA, RS, BA, SON, MKA, EE, and LW reviewed the initial draft. All the authors contributed to the study's design, revised the initial draft manuscript, and approved the final draft before submission. All authors have read and agreed to the published version of the manuscript.

Conflicts of Interest

VIOA is the founder and Principal Investigator of the ResilienceNHope messaging programs and volunteers as the Board Chair of the Global Psychological eHealth Foundation, a not-for-profit organization. BA volunteers as the President and Chief Executive Officer of the Global Psychological eHealth Foundation. RS volunteers as the Program Director of the Global Psychological eHealth Foundation. VIOA, BA, and RS receive no financial or other compensation from the Global Psychological eHealth Foundation and have no financial conflicts of interest about this article. GO-D, SON, MA, EE, and LW have no commercial or financial conflict of interest.

Abstract

Background: Overdose fatality review (OFR) is a public health process in which cases of fatal overdose are carefully reviewed to identify prevention strategies. Current OFR requires review of multiple unconnected data sources, which is a manually intensive process. The Substance Misuse Data Commons (SMDC) was created to link electronic health record data with data from local and state agencies into a single, cloud-based e-platform but does not currently have a data visualization tool.

Objective: We aimed to use human factors design principles to develop a comprehensive dashboard for the SMDC that could facilitate enhanced processes to support OFR.

Methods: We first surveyed OFR leaders in Wisconsin using the National Aeronautics and Space Administration-Task Load Index to understand the cognitive workload of 3 tasks: (1) analysis of population-level overdose trends, (2) selection and preparation of individual cases for review, and (3) abstraction of data from individual causes. We then conducted semistructured interviews to identify targets for workflow optimization. Next, we developed a prototype dashboard for evaluation using a synthetic dataset built with GPT-4. We subsequently performed iterative design sessions with heuristic evaluations and collected end-user feedback on the final prototype via a second round of semistructured interviews and targeted surveys, including the Unified Theory of Acceptance and Use of Technology and the Perceived Usefulness Questionnaire.

Results: The National Aeronautics and Space Administration-Task Load Index revealed a moderately high mental workload with the current workflow for all 3 tasks, with mean scores of 12.60 (SD 3.31), 11.90 (SD 3.57), and 12.43 (SD 5.41) for tasks 1, 2, and 3, respectively. Interviews pointed to causes including technological challenges and a reliance on manual processes. The prototype dashboard addressed these concerns by integrating multiple data sources to generate population-level visualizations and patient-level event timelines. End users reported the potential for improved efficiency and data accessibility compared to antecedent processes. The Unified Theory of Acceptance and Use of Technology results indicated the dashboard would likely be adopted if made available, with a mean of 4.07 out of 5.00 (SD 0.65). The Perceived Usefulness Questionnaire results suggested moderate usefulness for both the aggregate and individual-level data, with means of 3.61 (SD 0.82) and 3.64 (SD 0.85) out of 5.00, respectively.

Conclusions: OFR is a data-intensive process that traditionally demands substantial cognitive and manual effort, and there are multiple barriers to efficiently collecting data and presenting them for review. The dashboard offers a user-centered, informatics-based approach to streamline data aggregation and presentation, potentially enhancing the efficiency of case reviews. Implementing a dashboard that consolidates and visualizes disparate data sources has the potential to alleviate the manual workload in OFR. Ultimately, our aim is to deliver a finalized data dashboard with real-world SMDC data, giving OFR leaders additional tools to aid in their rigorous work shaping interventions to reduce overdose fatalities.

Introduction

Drug overdose death rates have been steadily rising over the past 2 decades, with the most significant annual spike occurring between 2019 and 2020, when rates surged by 31.0% in the United States [1]. To address this public health crisis, some local health departments around the country have assembled overdose fatality review (OFR) teams. OFR teams are multidisciplinary and multiagency teams with representatives from areas such as public health, safety, social services, medical examiners and coroners, emergency responders, substance use treatment providers, and other community stakeholders [2]. These teams discuss the local trends in overdose fatalities and review individual cases to identify and implement recommendations aimed at preventing overdose deaths [2]. OFR teams can help facilitate harm reduction strategies such as syringe services programs, naloxone education and training, outreach programs, and coordination of treatment services from health care settings [3]. However, many counties have yet to implement OFRs, and those that exist exhibit considerable heterogeneity in their data collection procedures, requiring substantial effort in data curation.

OFR teams in Wisconsin perform fatality reviews by integrating population- and individual-level data. These reviews involve an in-depth exploration of an individual's timeline before their death, focusing on potential opportunities for intervention. The data may come from different sources, including the medical examiners and coroners office, emergency medical services (EMS), the Department of Corrections, law enforcement, social media, and other local and state agencies. Often, obtaining these data requires collecting data on individual cases from each agency and linking across multiple sources.

The Substance Misuse Data Commons (SMDC) is a single, cloud-based data repository that links hospital electronic health record (EHR) data for patients with substance misuse to local and state agency data from EMS, the Department of Corrections, the Prescription Drug Monitoring Program, state and national death sources, statewide medical and pharmacy claims, and neighborhood-level socioeconomic data [4]. It was recently created by our team to address the issue of siloed datasets for substance misuse research, but it currently lacks an interface for data visualization [4]. Dashboards have been recognized as effective tools for visualizing public health data and facilitating disease surveillance, targeted analyses, and decision-making [5]. Additionally, a well-designed dashboard can reduce cognitive workload and improve efficiency by decreasing the amount of time spent gathering data [6]. In several states, such as Indiana and North Carolina, health departments have used dashboards of aggregate data to monitor overdose trends and uncover preventable risk factors [7,8]. While these dashboards are effective for tracking local and state-wide trends and setting case review priorities, they often lack the breadth of data and the level of detail needed by OFR teams. Currently, OFR teams in Wisconsin do not have access to the SMDC. Their data collection processes rely on manually requesting and compiling information from multiple partner agencies. The SMDC was established as a research infrastructure to enable secure multiagency data linkage, and this study represents the first effort to design a visualization interface that could make those linked data accessible and actionable for OFR teams in the future.

The objective of Phase 1 of this study was to assess the cognitive workload of OFR teams and their currently utilized data processes. The objective of Phase 2 of this study was to design a prototype data dashboard and then assess the usability and acceptability of the dashboard in a simulated study. This study introduces a novel, user-centered approach to understanding and improving the OFR process by combining cognitive workload assessment with prototype dashboard design. Unlike prior public health surveillance dashboards, our approach integrates multiagency data within a unified framework modeled on real OFR workflows and leverages synthetic data generation using large language models to enable privacy-preserving development and testing.

Methods

Phase 1: Analysis of Current Workflow

We conducted surveys and semistructured interviews with OFR leaders in Wisconsin to document the current workflow and associated cognitive workload for data collection and presentation. Participants were eligible if they took part in at least one of 3 tasks: (1) aggregating or analyzing population-level data, (2) selecting cases for case reviews, or (3) abstracting data for individual case reviews. Of the 29 counties with OFR teams, we recruited participants from 2 counties—one corresponding to the dataset currently included in our study, and the other in anticipation of future data collection for the SMDC. Recruitment occurred from organizational listservs in response to informational emails sent by local OFR leadership, followed by an invitation to the voluntary and confidential survey. Participants provided consent and were enrolled via a link to the survey in a secure, web-based Research Electronic Data Capture (REDCap; Vanderbilt University) database [9,10].

We used the National Aeronautics and Space Administration-Task Load Index (NASA-TLX) survey to assess the cognitive workload of the contemporary OFR process for each task listed above that the OFR leader participated in [11]. The NASA-TLX is a validated, multidimensional tool that assesses a task's subjective cognitive workload across 6 dimensions: mental demand, physical demand, temporal demand, performance, effort, and frustration [11]. The survey asks participants to rate each dimension on a scale between 1 and 20, with higher scores indicating greater perceived workload. For the performance dimension, lower scores correspond to higher perceived success [11]. Example items include "How mentally demanding was the task?" and "How hurried or rushed was the pace of the task?" Participants rated each applicable task they performed during the OFR process.

XSL•FO
RenderX

Domain-specific mean scores were calculated rather than a composite overall score, as the NASA-TLX dimensions are designed to capture distinct aspects of workload rather than a single latent construct. Therefore, the mean and SD for each dimension were calculated.

Survey participants were then invited to a 30-minute semistructured interview with a research team member (MP). This interview approach combined a predefined structure with flexibility for follow-up questions based on participants' responses [12]. The interview guide focused on participants' responsibilities, workflows, mental workload, key data sources, and challenges. Survey findings were shared, and participants were asked to provide insight on the results. Wisconsin OFR training and technical assistance providers and a senior qualitative research expert (JDG) reviewed the guide to ensure its relevance and rigor. Interviews were conducted between October 2023 and January 2024 with participants providing verbal informed consent through secure, virtual conference software. The audio recording was transcribed and reviewed by the interviewer.

Interviews were stored and analyzed using MAXQDA 2024 (VERBI Software). The constant comparative method was used to analyze the transcripts, and inductive coding was applied to organize the information into emergent categories [13]. The codebook was repeatedly revisited and revised during the process [13]. When no new categories emerged from the analysis of additional interviews, code saturation was determined to be met. Using the final codebook, all interviews were coded by 1 researcher. Around 3 interviews were coded by a second researcher to assess intercoder reliability (ICR), exceeding the typical 10% - 25% double-coded interviews required to establish ICR [14]. The 2 researchers then compared coded segments, and disagreements were adjudicated.

Phase 2: Data Dashboard Design and Evaluation

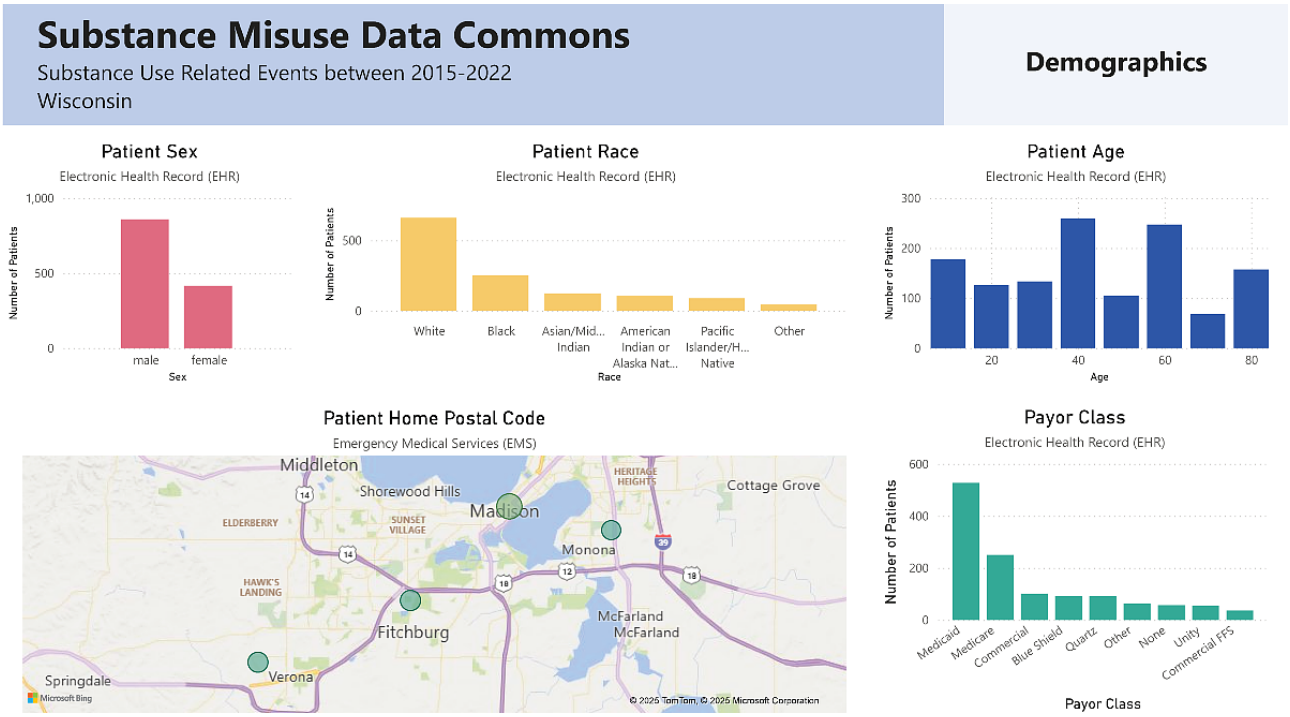
To mitigate data privacy concerns during dashboard development, a synthetic dataset was patterned on SDMC data [15]. The synthetic data were generated using the GPT-4 application programming interface (OpenAI) [16], with chain-of-thought instructions to create each variable from the data dictionary, similar to other best practices in prompt engineering [17]. The prompt incorporated aggregate cohort demographic descriptive statistics to preserve variable distributions within the SMDC dataset. Initial prompts were tested with 20 rows of patient data to evaluate the quality of the output before a dataset of 300 patients was created. This dataset was then scaled up to 1273 patients using YData Fabric (YData AI), a synthetic data generation software that employs generative adversarial networks to produce large volumes of data accurately replicating the statistical characteristics of the original data—in this case, the smaller synthetic dataset [18].

An initial prototype of the dashboard was developed using Microsoft Power Business Intelligence (Microsoft 2024) [19]. The dashboard was designed to emulate the workflow and highlight the priority data sources identified in Phase 1. The dashboard consisted of 3 functional components: (1) visualizations of population-level data to identify demographics and trends (Figure 1); (2) line-level data, such as individual patient timelines, to facilitate case-based reviews (Figure 2); and (3) prediction tools, including census tract-level EMS patient incident predictions, deidentified hospital note topics, and a 30-day risk score for hospital readmission or death.

We conducted 2 iterative design sessions with emergency medicine physicians, including 2 EMS medical directors, a prehospital informatician, and a clinical human factors design expert. This team provided expertise in data visualization principles and linking hospital systems with prehospital emergency services, while allowing us to reserve OFR leaders for participation in the main study. The Heuristic Evaluation Checklist for Dashboard Visualizations was used to identify and address major usability issues [20]. These sessions refined the dashboard's content, organization, and visual elements, culminating in a final prototype. After finalizing the prototype, a demonstration video was shared with participants to showcase its content, organization, and key features.

XSL•FO
RenderX

Figure 1. Substance misuse data dashboard: population-level visualizations.



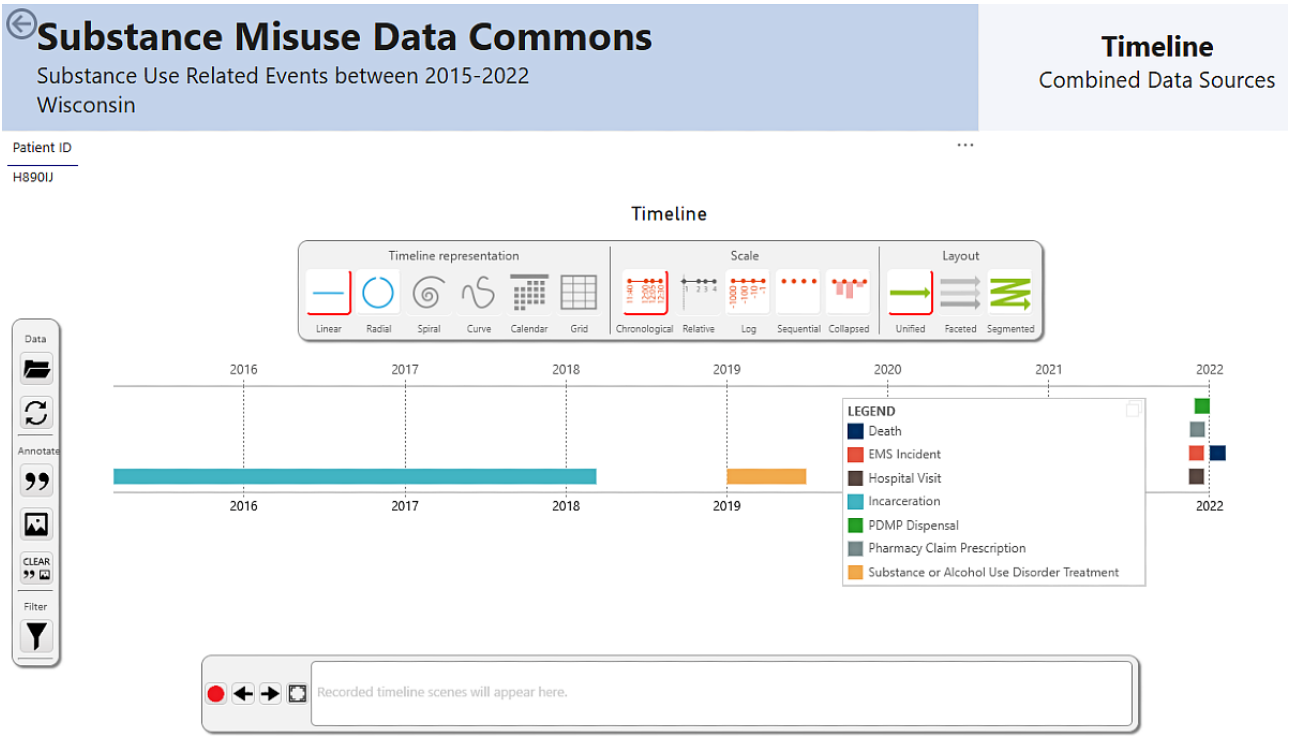


Figure 2. Substance misuse data dashboard: patient timeline visualizations.

Phase 2: Dashboard Design and Evaluation

End-user perceptions of the final prototype were assessed with semistructured interviews and surveys, using the same strategy and procedures to recruit OFR leaders as Phase 1. A total of 2 validated survey tools were used to evaluate end-user probability of adoption (Unified Theory of Acceptance and Use of Technology [UTAUT]) [21] and perception of usefulness (Perceived Usefulness Questionnaire) [22]. The interview guide explored participants' perceptions of the dashboard, conditions for use, advantages, and suggested changes. One researcher coded all 7 interviews using the final codebook, and a second researcher independently coded 3 interviews to establish ICR. Disagreements were adjudicated. The mean and SD of all survey responses were calculated.

The full set of NASA-TLX, UTAUT, and Perceived Usefulness Questionnaire questions; our interview guides and codebooks; our synthetic dataset and prompts; and our demonstration video are all viewable in our GitLab repository [23].

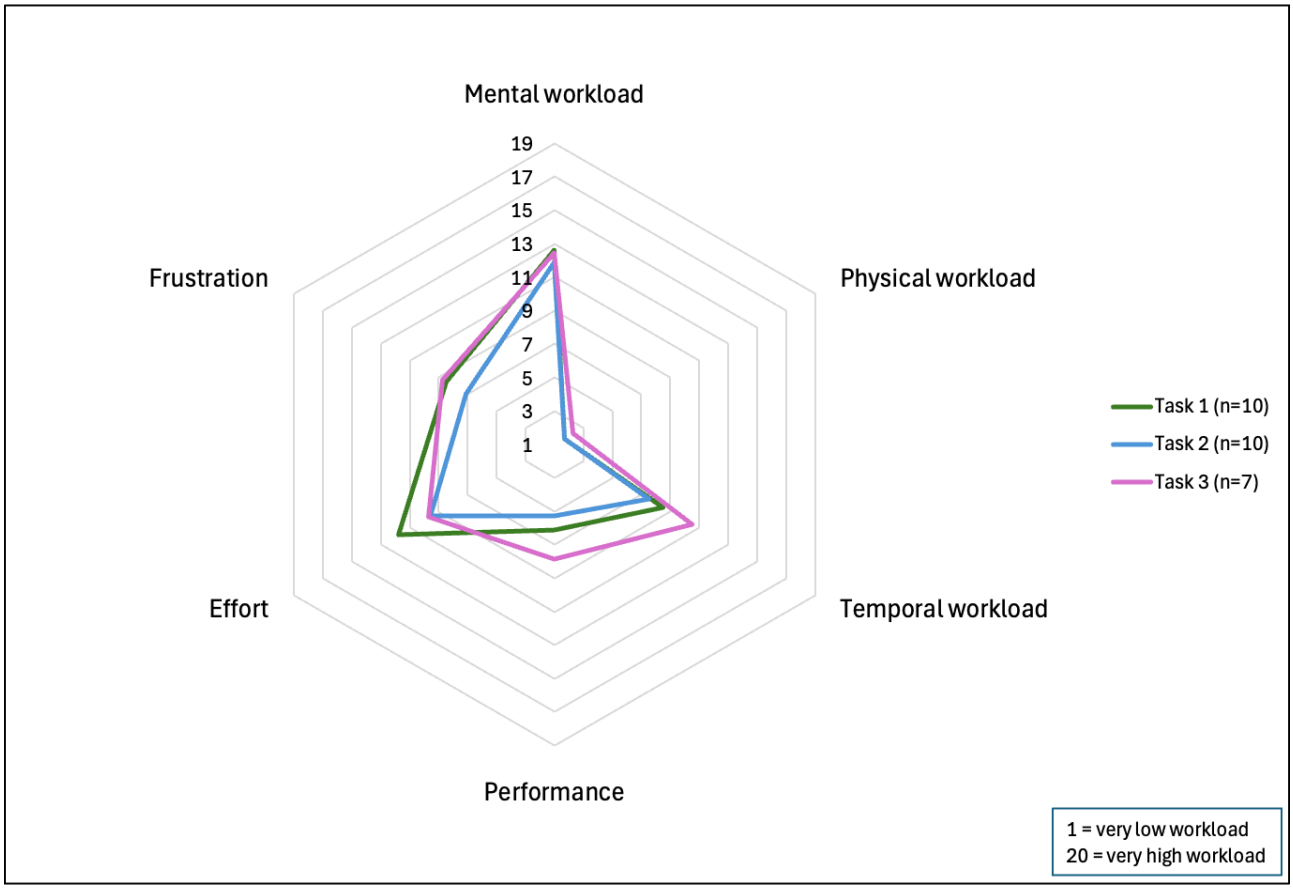
Ethical Considerations

The study followed the COREQ (Consolidated Criteria for Reporting Qualitative Research) reporting guidelines [24] (Checklist 1). This research was reviewed and approved by the Institutional Review Board at the University of Wisconsin, Madison (Institutional Review Board number 2023‐1091). Informed consent verbiage was included in our recruitment emails, and verbal consent was obtained during interviews. Participant email addresses were collected in the survey in order to invite the individual to participate in an interview. Survey and interview results were deidentified. No compensation was provided to participants.

Results

Phase 1: Analysis of Current Workflow

Surveys



A total of 11 OFR leaders, representing both county- and state-level agencies, participated in the survey. Table 1 provides the characteristics of the participants. The survey assessed the cognitive workload of 3 distinct tasks: (1) aggregating or analyzing population-level data, (2) selecting cases for case reviews, or (3) abstracting data for individual case reviews. Tasks had unequal sample sizes due to variations in task participation among participants. High mental workload was reported across all tasks (Figure 3). The time required for each task varied among participants. Per case review period of 1-3 months depending on the team, aggregating population-level data took an average of 5.5 hours (SD 3.09), selecting cases for case review averaged 7.95 hours (SD 5.67), and abstracting data for individual case reviews required an average of 10.50 hours (SD 8.86).

Table . Phases 1 and 2 survey demographics for overdose fatality review leaders in Wisconsin, 2023‐2024.

Demographic variables	Phase 1 participants (n=11)	Phase 2 participants (n=6)
Age (y), n (%)		
20‐29	5 (45.4)	2 (33.3)
30‐39	3 (27.3)	0 (0)
40‐49	2 (18.2)	3 (50)
50‐59	1 (9.1)	1 (16.7)
Sex, n (%)		
Female	10 (90.9)	6 (100)
Race, n (%)

Interviews

Key Data Sources

In total, 10 of the 11 participants completed qualitative follow-up interviews. Participants were asked to describe their data collection process, case selection methods, challenges, desires for a future state, and key data sources. Key OFR data sources highlighted by participants are presented in Table 2. Some of these sources were used for individual or population-level data only, but many were used for both. How these sources were used varied among participants. Summaries and selected quotes are highlighted below, while the full interview results and quotes are detailed in Multimedia Appendix 1.

Wisconsin Statewide Health Information Network 5. Overdose Detection Mapping Application Program 6. Consolidated Court Automation Programs 7. Internet 8. News 9. Social media

[a]OFR: overdose fatality review.

[b]ME: medical examiner.

[c]EMS: emergency medical services.

[d]DOC: Department of Corrections.

Process

Participants described a typical workflow while preparing for an OFR meeting. Population-level data are analyzed to identify recent community trends. Next, representative cases are selected for review, and permission is obtained from local law enforcement to review the cases. OFR leaders then coordinate the collection of available and pertinent information on the decedents across multiple sources, which may include their own sources, agency partners, and next-of-kin interviews with the decedent's family or friends. After compiling the data, they prepare a presentation for the case review meeting, often including a timeline of the decedent's interactions with various agencies. During the sessions, OFR members, agency partners, and community representatives review the data and collaboratively brainstorm strategies for overdose prevention.

Case Selection

Participants reported several factors that influence case selection. About 50% (n=5) of the participants reported looking at demographic trends such as age, race, and sex. About 50% (n=5) of the participants reported combining multiple demographic and substance trends into a single theme and looked explicitly at decedents within that theme. For example, 1 participant stated, "Now that we're doing theme selection, we may focus on a specific drug, like, I think the next theme that we're doing is African American men between certain ages that historically used cocaine, but fentanyl was also involved in their cause of death." Around 60% (n=6) of the participants prioritize selecting cases with comprehensive data, though they noted that this is challenging due to limited data availability during the initial selection process. Other key factors influencing case selection included obtaining permission from agency partners (n=5, 50%) and ensuring cases fell within jurisdictional boundaries (n=9, 90%).

Case Data Collection and Preparation

OFR leaders reported collecting data on decedents using publicly available databases and resources provided by their health departments and from the state-level data provided. They also reported requesting data from agency partners regarding any interactions with the decedent. After data are collected, they are processed manually by the OFR leader. One participant stated, "Then those individual partners have to go in, look at the specific case and then they have to like hand-put in all of the info and then they send those to me and then I scan them into our system so that we have them electronically, and then I have to take all of those electronic copies and upload those, one question at a time into REDCap." After processing, all participants reported compiling the information into a timeline to display during case review presentations, which helped viewers to understand the decedent's story.

Reported Challenges

When asked about challenges, 90% (n=9) of the participants identified a reliance on manual processes to collect data as a significant challenge. Due to limited bandwidths, responses to data requests from agency representatives are often delayed or incomplete, which impacts the preparation of case review materials. When final requests were not fulfilled, critical data were missing from presentations. Participants also reported several technological challenges, including siloed data sources (n=4, 40%), confusing data formatting (n=7, 70%), and other technological issues (n=10, 100%), all of which impacted data collection and preparation. As a result, 90% (n=9) of the participants highlighted time pressure as a major challenge for

XSL•FO
RenderX

preparing for the OFR process. One participant explained this time pressure stating, "Lots of times for overdose fatality review, and this is true for me also, this is one part of my job, right? It's part of my FTE, it is not my full FTE, so there are directions that I'm pulled for other projects that can sometimes limit the time that I have available to work on this."

Desired Future State

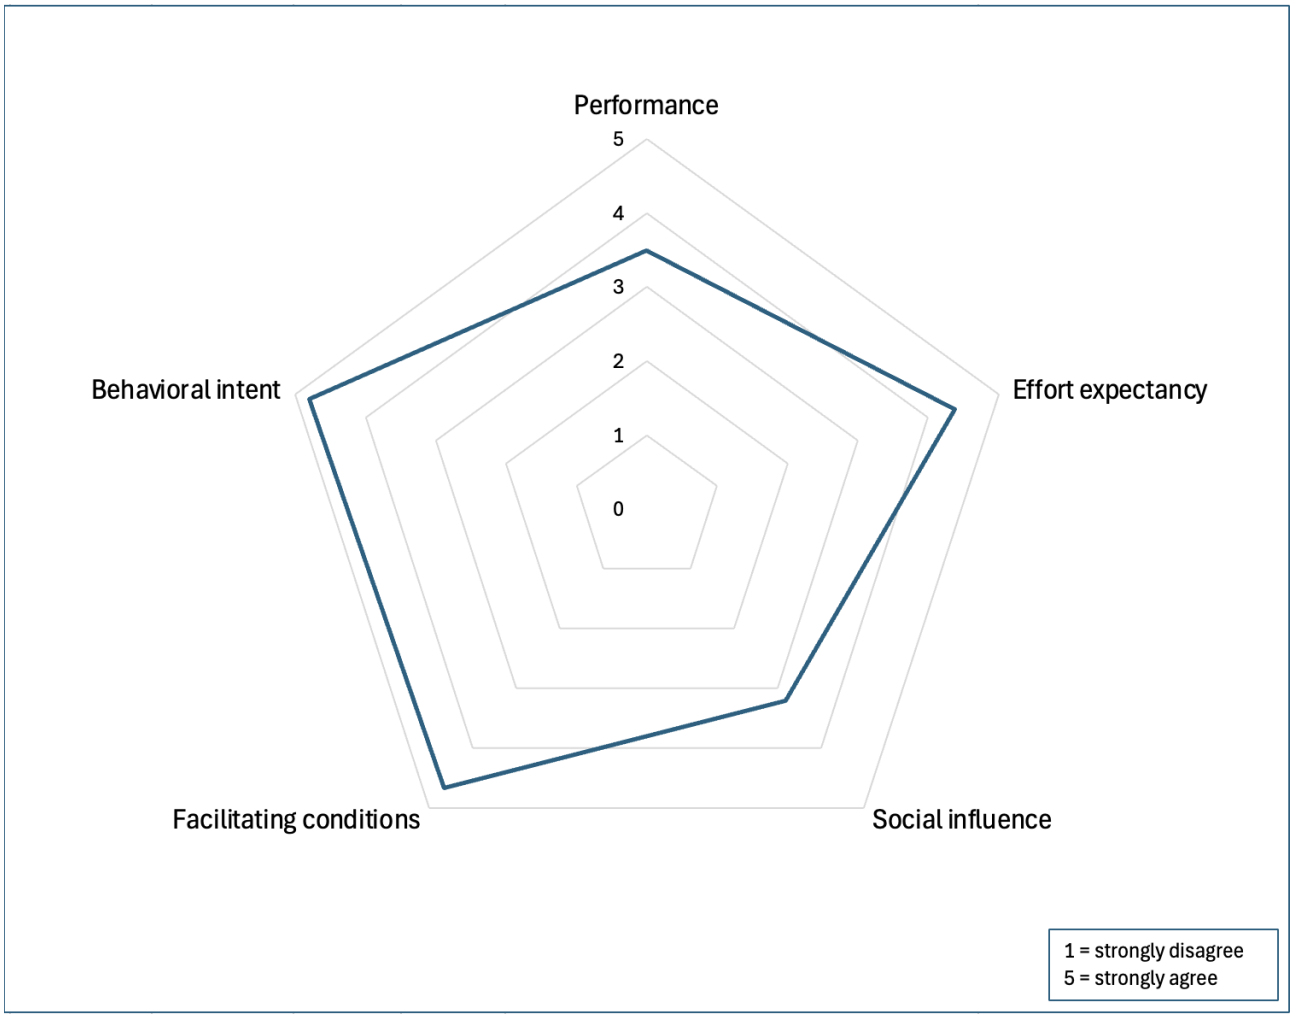
Half (n=5) of the participants indicated that easier access to current data sources would be helpful, specifically mentioning simplified access as well as fewer lags to be able to identify and respond to current trends. One participant stated, "I think something that local public health and us specifically have always sort of struggled with is being able to keep up with that data…having it be a little easier for us to get local data and more quickly, that is an issue that is huge for us. We see things, and we hear about these trends, but we don't necessarily always know that that's happening until all of a sudden, it's like, hey, we're seeing this, you know, all across the county, and is that something we could have caught sooner had we been able to access that data quicker."

Participants mentioned that additional data would help them. About 70% (n=7) of the participants desired health care data, most commonly substance use disorder treatment data; however, these data are protected by federal statute, which adds complexity to accessing and sharing them. About 50% (n=5) of the participants desired criminal justice data, whether they did not have access to it or did not often receive it when requested. Participants mentioned that they worked with multiple law enforcement agencies and regularly received data from some but not others. Additionally, 2 participants mentioned that they had not been able to perform next-of-kin interviews due to barriers in setting up interviews. Other desired data sources included childhood information from school districts or Child Protective Services and input from local organizations.

About 80% (n=8) of the participants mentioned that more collaboration or support would help the OFR process. Other participants specifically mentioned that increased collaboration between health departments and local agencies would help their current workflow, create the possibility to expand their services, and address long-term sustainability of OFR.

Phase 2: Data Dashboard Design and Evaluation

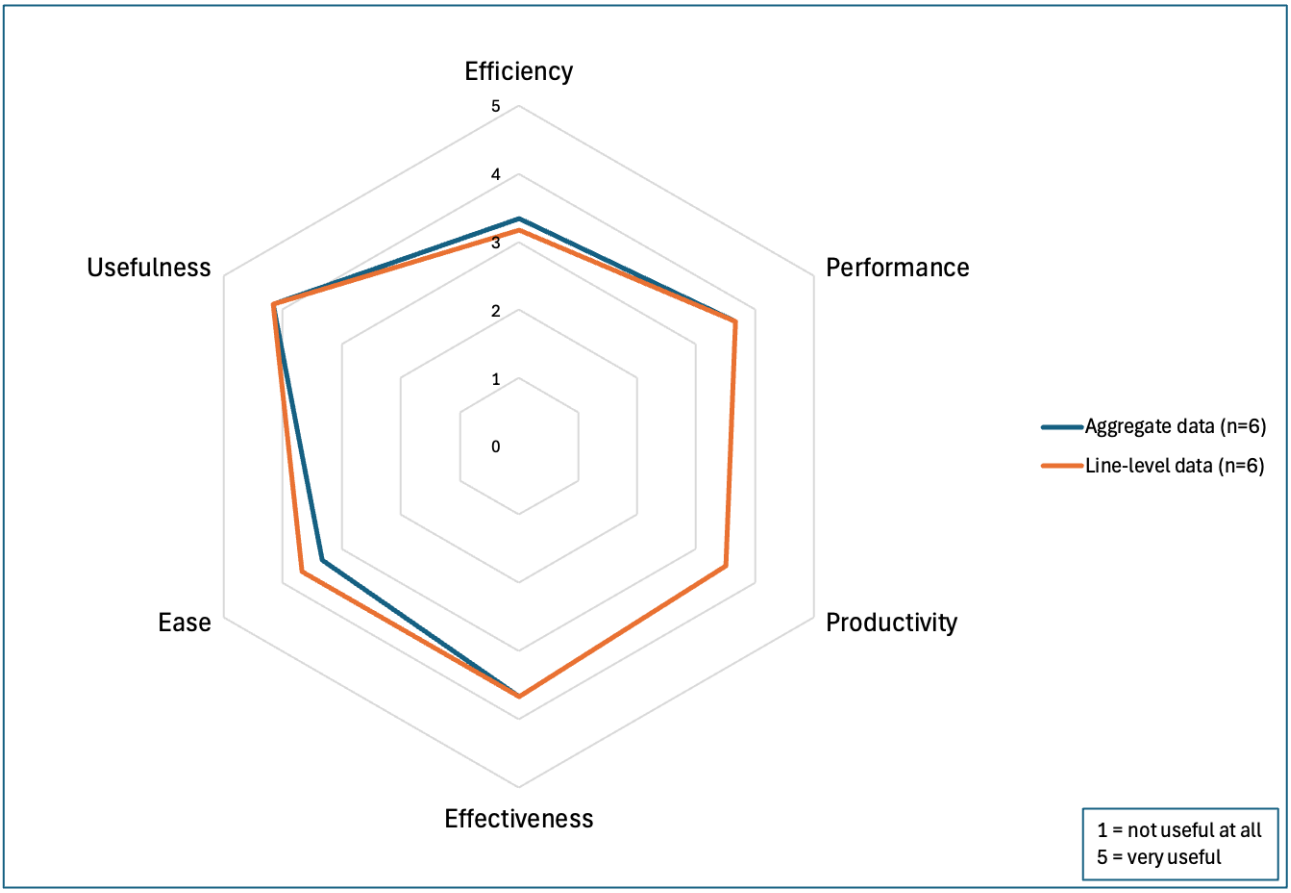
Dashboard Design



The synthetic data dashboard prototype, developed based on Phase 1 data, was refined into a high-fidelity prototype for further usability and human factors evaluation. The final prototype featured 9 theme-based aggregate data pages covering demographics, substances used, health care interactions, prehospital emergency services, social and economic factors, mortality, prescription patterns, and treatment and recovery. Select components of the line-level data and timeline are shown in Figures 1 and 2, and a full demonstration video is available in our GitLab repository [23]. The final dashboard prototype included advanced filtering capabilities, enabling users to refine data by specific time frames, substances, and death status. A total of 3 machine learning tools were integrated into the dashboard. First, the Hospital Note Topics Tool utilized latent Dirichlet allocation for topic modeling of EHR notes [25]. This tool identified prevalent themes and trends, such as patterns of substance use, health care utilization, and social determinants of health, providing users with a high-level understanding of key insights from unstructured text data. Second, the 30-Day Risk Score for Readmission and Death employed an eXtreme Gradient Boost machine learning model, which analyzed a combination of EHR notes and tabular data along with EMS and neighborhood census data to predict the likelihood of hospital readmission or death within 30 days. Third, the EMS Geographic Prediction Tool combined EMS response data with neighborhood-level census tract information to identify geographic areas at higher risk for overdose events. Additionally, the final prototype incorporated a drill-down feature, allowing users to filter patient populations by category and narrow them down to individual patients.

Surveys

A total of 6 OFR organizers participated in the Phase 2 survey, representing stakeholders from county, state, and federal agencies. Additional demographic details are provided in Table 1. All the 6 participants reported analyzing aggregate data and selecting review cases, while 4 were involved in abstracting data for case reviews. The UTAUT results indicated that the dashboard would likely be adopted if made available to participants (Figure 4), with a mean of 4.07 out of 5.00 (SD 0.65). The Perceived Usefulness Questionnaire results suggested a moderately positive perception of usefulness for the aggregate and individual-level data (Figure 5), with means of 3.61 (SD 0.82) and 3.64 (SD 0.85) out of 5.00, respectively.



XSL•FO
RenderX

Figure 5. Perceived usefulness questionnaire results for overdose fatality review leaders in Wisconsin, 2024.

Interviews

A total of 7 OFR leaders participated in semistructured interviews. Participants were specifically asked about the potential benefits of the dashboard as well as areas for improvement. The summaries of the findings are outlined below, with detailed results and quotes provided in Multimedia Appendix 2.

Benefits of the Dashboard

All the participants (n=7) highlighted improved data access as a key benefit of the dashboard. This included expanding access to currently unavailable data sources, facilitating quicker and easier access to existing data, and increasing access for less-resourced communities. Additionally, 86% (n=6) of the participants indicated that the dashboard could help to optimize workflows by reducing the manual processes and introducing time-saving features. One participant stated, “That’s helpful in just kind of like streamlining it all in one spot, because the data that I do get like from emergency department visits, I have to go through every single entry, and then like, figure it out from there. So, this is quite nice to just have it in one spot where I can look at it, write it down, we’re done.” About 71% (n=5) of the participants noted that the dashboard’s tools are especially valuable for organizational outreach efforts. The machine learning tools, particularly the EMS geographic prediction tool and the 30-day risk score for readmission or death, were highlighted as most useful for these initiatives. All the participants (n=7) reported that the dashboard appeared easy to navigate, with an intuitive structure and organization. About 71% (n=5) of the participants specifically mentioned the ability to filter patients for specific populations as a standout feature, distinguishing the dashboard from other available tools.

Areas for Improvement

Most participants suggested adding more data sources. Specific recommendations included sexual orientation and gender identity, medical comorbidities such as chronic pain, and presenting data as rates instead of counts to better represent minority group trends. Concern about the accuracy and timeliness of the data was expressed by 71% (n=5) of the participants. The SMDC cohort, which is limited to patients with hospital encounters linked to other data, excludes individuals seen only by EMS or those without EMS or hospital contact. One participant expressed this concern, stating, “I like the way that it’s laid out, but because it’s only people who are going to the ED, I don’t know that we can draw conclusions about folks that are at risk of overdose, generally speaking.” The current data were also identified as a critical need for the dashboard. Participants proposed several technological enhancements to improve the dashboard’s usability. Specifically, 43% (n=3) of the participants suggested the ability to export data from the dashboard, while 57% (n=4) recommended adding other technological features such as additional filters and hover-over tips for ease of use. Other important but less commonly cited concerns included a training or learning curve (n=3, 43%), having jurisdictional access (n=2, 29%), adding to stigma or bias (n=2, 29%), having too many years aggregated in the dataset to be reflective of current trends (n=2, 29%), and the dashboard data being deidentified and therefore not being

XSL•FO
RenderX

able to be connected to data about individuals from other sources (n=2, 29%).

Discussion

Principal Findings

This study is the first to systematically assess the cognitive workload of OFR leaders and apply those findings to the design of a user-centered data dashboard prototype. Using validated instruments (NASA-TLX, UTAUT, and Perceived Usefulness Questionnaire) and qualitative interviews, we identified substantial cognitive demands associated with data aggregation, case selection, and abstraction across multiple agencies. Guided by these findings, we developed and tested a prototype dashboard using synthetic data modeled on the SMDC to streamline data access and visualization. Participants reported improved usability, reduced time burden, and high potential for adoption in future OFR workflows.

Interpretation and Implications

Our results highlight that OFR leaders face high mental and temporal demands due to fragmented data sources and reliance on manual processes, a challenge consistent with prior studies on multiagency data integration and decision-making in public health surveillance [26]. Previous dashboards have been implemented at the state or regional level to visualize aggregate overdose trends, yet few, if any, have incorporated both population- and individual-level data or been explicitly designed around the OFR workflow. By linking health system, emergency response, and correctional datasets within a privacy-preserving synthetic environment, our approach extends beyond traditional epidemiologic dashboards to directly support operational review teams. The integration of predictive modeling tools, such as 30-day readmission and EMS geographic risk scoring, further distinguishes this work from prior descriptive dashboards by introducing prospective, data-driven decision support [7,8]. These findings align with recent public health informatics initiatives emphasizing human-centered design, cognitive workload reduction, and automation to improve decision-making efficiency [27,28].

Our SMDC data dashboard serves as a comprehensive tool for extracting, transforming, and visualizing overdose data. It was designed to refresh with recent case information from multiple sources; incorporate automation for case matching, data formatting, and quality checks; and offer easy navigation to streamline current workflows. The dashboard helps automate the current workflow challenge of siloed data sources and includes additional data that participants found valuable. It integrates key data variables from multiple agencies, with options to filter the data by important demographic and substance-related factors. The automated timeline feature compiles data from all sources in our dataset, visually representing the events leading to an overdose death. Phase 2 participants saw the dashboard's potential to reduce time pressure and reliance on manual processes. Additionally, in larger cities where reviewing every case is impractical or impossible, OFR leaders typically hand-pick cases to analyze in detail. By linking all cases and presenting the data in aggregate, this system enhances the understanding of overall trends and helps to better inform recommendations.

Many participants indicated that they would use this dashboard as an additional tool, rather than replacing their current methods. This likely explains our Phase 2 survey findings, which revealed a discrepancy between the tool's effectiveness and efficiency. This preference highlights a key concern raised in Phase 2 interviews that cannot be resolved in future dashboard versions: the deidentified nature of the SMDC data prevents integration with other data sources, such as next-of-kin interviews, a crucial part of the case review process. Other areas of improvement discussed in Phase 2 interviews can be resolved.

Phase 1 participants emphasized a desire for increased collaboration and support. Some mentioned this in the form of improved relationships between the health department and other agencies. Expanding the sectors involved in OFR processes and broadening the information available for case reviews may highlight previously unseen gaps in care. Emergency department utilization is common among those who misuse opioids and other drugs, and the number of emergency department visits is associated with an increased risk of drug overdose [29]. Our dashboard aims to establish and improve data sharing between OFR teams and health care systems, which has been identified as an important prevention strategy implementation [30].

Our findings underscore the potential of informatics-driven tools to enhance collaboration among public health, health care, and community agencies. By reducing cognitive workload and manual data handling, such tools can accelerate case review preparation, standardize data access across jurisdictions, and allow OFR teams to focus more on interpretation and prevention strategies. The use of synthetic data generated through large language models also represents an innovative method for tool development when working with sensitive, multiagency datasets. As counties nationwide expand their OFR infrastructure, the approach demonstrated here offers a transferable model for building and evaluating data dashboards that are secure, scalable, and adaptable to local contexts.

Limitations

The general process reported by participants in the interviews is mainly consistent with the process in the OFR Practitioner's Guide and the Public Health and Safety Team toolkit, which are guiding frameworks for health departments when creating OFRs and holding case review meetings [31]. However, the feedback in this study was collected from local OFR leaders in Wisconsin, and therefore, these findings may not be generalizable to other systems. Limitations inherent to the SMDC include its inclusion criteria and its deidentified nature. All data variables included in the prototype dashboard are included in the SMDC; however, the SMDC does not include all data variables important to OFR leaders when presenting cases. Finally, addressing challenges in the OFR process with new technology may not ultimately lead to better outcomes. Substance misuse is both a complex medical condition and an evolving public health issue. In order to make meaningful progress and improve outcomes, sustained collaboration across health care systems, public health agencies, and communities

XSL•FO
RenderX

will be essential to reform policies, reduce disparities, and improve medical care.

The existing OFR process is built on a thorough, team-based approach, but it includes several cognitively demanding tasks, and there are multiple challenges to timely data preparation. Increased collaboration, access to standard, centralized tools, and comprehensive data could build upon the rigorous work already being done by OFR teams in order to further augment and automate workflows to reduce manual work. We designed a user-centered data dashboard to help reduce the cognitive workloads identified from surveys and incorporate the desired data sources and workflows gathered from the interviews. Evaluative feedback indicated many potential benefits as well as some areas for improvement. This insight will guide the development of a real-time data dashboard accessible to OFR leaders in their review process.

Conclusions and Broader Implications

Despite these limitations, this study demonstrates a replicable, human-centered approach for modernizing OFR workflows through data integration and visualization. The combination of cognitive workload analysis, synthetic data modeling, and dashboard-based decision support provides a foundation for scalable OFR modernization across states. Beyond overdose prevention, this framework illustrates how human factors and data science methods can be combined to enhance other multidisciplinary public health review processes. Future work will focus on deploying the dashboard with live SMDC data, expanding data sources, and assessing real-world impacts on timeliness, data completeness, and prevention outcomes.

Abstract

Background: Irritable bowel syndrome (IBS) is a common chronic gastrointestinal disorder that impairs bowel functions and patients' overall quality of life. IBS-focused digital health technologies (DHTs), including online health resources and mobile health (mHealth) apps, have recently proliferated for patient use. However, research exploring patients' experiences with navigating, adopting, or using commercial or publicly available DHTs for IBS self-management is limited.

Objective: This study aims to explore the user experiences and decision-making of patients with IBS as they navigate, adopt, and use diverse DHTs for disease self-management.

Methods: We conducted virtual semistructured focus group interviews to explore the experiences of patients with IBS using DHTs, including their perspectives on design and features, their decision-making process in using DHTs, and recommendations for improving user experience and uptake, given the heterogeneous nature of these tools. Canada-based patients with IBS who were using or had used mHealth apps to manage symptoms were recruited through purposive sampling from previous IBS-related studies. Discussions were transcribed verbatim, and inductive thematic analysis was performed using NVivo (version 14; Lumivero). A modified version of the Expanded Unified Theory of Acceptance and Use of Technology (UTAUT2) model was applied to guide the interpretation of the dynamic relationship between the influences on participants' decisions regarding DHT use.

Results: Among the 8 participants (all female; mean age 55.3, SD 13.5 years), two themes were identified: (1) uncertainty impacts the trustworthiness of DHTs, and (2) influences that drive the decision-making process to adopt and use DHTs. The observed influences aligned with the constructs of the UTAUT2 model (performance expectancy, effort expectancy, social influence, facilitating conditions, hedonic motivation, price value, and habit), with the addition of trust and risk in participants' decision-making. Digital health literacy and patient engagement were also raised as crucial components of participants' experiences and perspectives on DHTs.

Conclusions: Findings of this study highlight the current landscape of digital health in IBS and existing gaps and challenges for patients in navigating, adopting, and using DHTs for IBS self-management. While DHTs were generally viewed positively for their value and potential, patients with IBS consider several coexisting factors and trade-offs in their decision-making. Further

XSL•FO
RenderX

investigations on the influences on and perspectives toward DHTs could enhance future development and iterations of these tools and improve patient confidence and uptake.

Introduction

Digital health has revolutionized health care and disease management by leveraging technology and digital devices to improve self-management. With a growing public focus on health and well-being, more patients with chronic diseases rely on digital health, especially online health resources and mobile health (mHealth) apps [1,2], for answers, guidance, and management support.

Irritable bowel syndrome (IBS) is a disorder of the brain–gut connection that impacts patients' daily activities and well-being and is characterized by abdominal pain, bloating, altered bowel habits, and psychiatric comorbidities [3-5]. As there is no known cure for IBS, greater knowledge of the syndrome and relevant self-management options are critical in alleviating symptoms and improving quality of life [6,7]. However, IBS self-management strategies—such as lifestyle and dietary modifications and brain–gut behavior therapies [8,9]—are often coupled with challenges around accessibility, adherence, affordability, and productivity loss for patients [10-12]. Digitizing health information and support could offer alternative models of delivery and potentially address these issues by improving access to information and treatments, reducing health-related costs, and enabling and empowering patients [13-16].

In the context of IBS, digital health technologies (DHTs) encompass a diverse range of tools that support dietary, psychological, behavioral, and educational aspects of self-management. Commonly used dietary-focused tools include low fermentable oligosaccharides, disaccharides, monosaccharides, and polyols (FODMAP) diet apps, which are supported by evidence for improving symptom control and dietary adherence [17]. Psychological and brain–gut behavior apps have also demonstrated effectiveness in reducing IBS symptom severity and improving quality of life [18,19]. In addition, patients frequently use general symptom trackers, medication apps, and online educational resources of varying quality. This heterogeneity underscores the importance of understanding not only whether patients use DHTs, but also the specific domains these tools address, as each represents a difference in therapeutic mechanisms and levels of evidence within IBS care.

Our understanding of DHTs for IBS remains limited. Although several studies support the benefits of DHTs for patients with IBS [20], there is limited evidence on their experiences in a consumer context. Existing studies that qualitatively evaluate DHTs, although informative, have been limited to specific DHTs under controlled conditions [21-23] and otherwise lacked the sociodemographic context that could otherwise impact uptake and use. Other studies suggest acceptance of DHTs is determined by users' hedonic motivations, user-system fit, and perceived utility and intuitiveness of the technology [24-26]. However, it is uncertain how these influences or other priorities influence this specific patient cohort. Currently, it is difficult to assess other considerations and consequences for the real-world application of DHTs for the people with IBS. This study is an initial investigation to explore the experiences of patients with IBS in navigating, adopting, and using online health resources and mHealth apps to support self-management, and to identify key influences in their decisions to consider DHTs.

Methods

Ethical Considerations

This study was reviewed and approved by the University of Calgary Conjoint Health Research Ethics Board (REB23-1273). A qualitative study design with semistructured focus groups was used to explore the experiences and decision-making processes of patients with IBS regarding DHTs, including their adoption, use, and suggestions for improving these tools. The study methodology was reported in accordance with the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist (Multimedia Appendix 1) [27].

Positionality

The study team comprised 5 women with research experiences in health systems (AD, NH, MVM, JS, and DAM), including one (AD) with lived experiences of IBS. AD and NH, a postdoctoral fellow and research associate, respectively, were skilled in qualitative methods. AD and DAM, a health economist and health services researcher, also had experience in IBS-related research. MVM and JS, a senior scientist and scientific director, respectively, had applied research expertise and experience in primary care. All but one each have a PhD; NH has a master's degree. Information on AD's personal experience and professional background in IBS was shared with study participants prior to the focus group sessions. Some participants had an existing relationship with AD from previous research studies.

Participants

Participants were recruited through purposive sampling from previous IBS-related studies conducted by the study team. Past participants who had provided consent to be recontacted for future studies were invited by email. Convenience sampling was attempted using the study team's social media networks and the University of Calgary's research recruitment board;

XSL•FO
RenderX

while 2 individuals were recruited through this method, neither participated in the focus groups. All participants were adults with IBS living in Alberta and British Columbia, Canada, who (1) had been formally diagnosed by a health care professional and (2) had been using or had used mHealth apps to manage their symptoms. Participants who satisfied the selection criteria received an information document regarding the study and provided written consent before the focus group sessions.

The study team a priori aimed for at least 4 focus groups, with 3 participants per group, which was expected to be sufficient to reach code saturation [28-30]. While focus group size typically ranges from 6 to 8 participants, smaller groups with 3 participants were considered to allow more opportunities for engagement and account for the potentially low recruitment yield [28]. The recruitment process ended following the exhaustion of all recruitment strategies, resulting in 8 participants and 3 focus groups. Some degree of saturation was present in participants' responses through repeated codes and themes.

Data Collection

Participants completed a survey before attending the focus group session to provide details of their existing supports, demographic information, year of IBS diagnosis, symptoms, treatment history, and dietary adjustments (Multimedia Appendix 2). The survey and data were managed using Qualtrics Experience Management (Qualtrics LLC) and the University of Calgary's secured online cloud server. Survey data were analyzed and summarized using Microsoft Excel by Darren Zhang.

Focus groups were conducted virtually using Microsoft Teams. AD moderated the focus group discussions, with the support of NH as a scribe. Sessions lasted approximately 2 hours, were audio-recorded using the recording feature in Microsoft Teams, and were transcribed verbatim using the transcription service Rev (Rev.com, Inc); the transcripts were subsequently reviewed and cleaned by Darren Zhang.

Instrumentation

Participants' IBS symptoms were assessed in the survey using the IBS Symptom Severity Score (IBS-SSS); scores ranged from 0 to 500 and were categorized as mild (75-175), moderate (176-300), or severe (>300) [31]. A focus group guide was created and reviewed by the study team to support AD in facilitating semistructured sessions (Multimedia Appendix 3). The following topics were discussed in the focus groups: (1) participants' experiences navigating digital resources to self-manage IBS, (2) their experiences adopting and using DHTs to self-manage IBS, and (3) their perspectives on influences and improvements regarding the uptake of online resources and mHealth apps.

Data Analysis

Coding was performed and managed using NVivo (version 14; Lumivero). NH and AD coded the transcripts as primary and secondary coders, respectively. Because little research has explored this topic, inductive thematic analysis was used to identify and evaluate relationships, patterns, or themes, allowing data to serve as the foundation of the results [32]. Initial codes were generated to indicate recurring features within participants' responses, and related codes were then collated into groups that subsequently defined underlying themes [32]. Following thematic analysis, the findings and their relationships were visualized based on the Expanded Unified Theory of Acceptance and Use of Technology (UTAUT2) framework model [26].

Applied Framework

The UTAUT2 framework model is an extended version of the original UTAUT model to evaluate the acceptance of new commercial technologies [26,33]. With its consumer-use context, this model was chosen to provide valuable and holistic insight into patients' acceptance of DHTs, including adoption and use, for IBS self-management. The key constructs of the UTAUT2 model [26] included performance expectancy, defined as the extent to which the individual expected the performance or benefits of the technology; effort expectancy, defined as the level of effort or ease in using the technology by the individual; social influence, defined as the extent to which the individual perceived the value of others' acceptance of the technology; facilitating conditions, defined as the extent to which the individual believed that support or resources were available to facilitate the use of the technology; hedonistic motivation, defined as the extent of the individual's motivations or pleasures experienced in using the technology; price value, defined as the cost-benefit or trade-off between the perceived value or benefit of the technology and its associated monetary cost; and habit, defined as the extent to which the individual developed a habitual or perpetual use of the technology from previous experience and learning.

Also, we modified the UTAUT2 model to include "trust" and "risk" as key constructs based on our thematic findings. Although they were not included in the original UTAUT2 model [26], previous studies have recognized and incorporated them into their own models [34-36]. Based on these studies [34-36], "trust" was defined as the extent to which an individual perceived the technology or its associated qualities as likable or trustworthy, and their willingness to believe that the technology would meet their expectations, and "risk" was defined as the extent to which an individual perceived the technology to be associated with potential consequences or harm to themselves.

Additionally, DHT-related key constructs are influenced by user characteristics. In the expanded UTAUT2 model, Venkatesh et al [26] recognized how a user's demographic characteristics, specifically age, gender, and experiences or familiarity of existing technologies, moderate the impacts of the key constructs and ultimately the acceptance and use of the technology.

Results

Participant Characteristics

Of the 11 participants recruited to the study, 8 attended the focus groups, all of whom had participated in past research studies. One individual was lost to follow-up prior to the focus group sessions, and the remaining 2 could not attend the sessions due to scheduling conflicts. Participant characteristics are summarized in Table 1.

Postsecondary certificate or diploma above bachelor level	4 (50)
Master's degree	2 (25)
Identify as, n (%)	
Born outside of Canada	3 (38)
Persons with disabilities	2 (25)
2SLGBTQI+[a]	1 (13)
Racialized or visible minority	1 (13)
Indigenous	0 (0)
I have children or grandchildren aged 18 years or younger living at home	0 (0)
New to Canada (less than 5 years)	0 (0)
Other	1 (13)
None of the above	3 (38)
Years since IBS[b] diagnosis, mean (SD)	12.9 (10.6)
Types of IBS, n (%)	
Mixed	2 (25)
Constipation-dominant	5 (63)
Diarrhea-dominant	1 (13)
Unsure	0 (0)
IBS-SSS[c], mean (SD)	197.7 (84.8)
Types of digital tool used, n (%)	
Mobile health apps	7 (88)
IBS-related podcasts	4 (50)
Mobile tracking apps (eg, physical activity and daily living activities)	6 (75)
Websites	6 (75)
Support groups	1 (13)
Types of mobile health apps (n=7), n (%)	
Diet-related apps	2 (29)
IBS-specific apps	6 (86)
Mental health or emotional well-being apps	1 (14)
General gastrointestinal and health apps	2 (29)
Cognitive-behavioral therapy and/or gut hypnotherapy apps	1 (14)

[a]2SLGBTQI+: two-spirited, lesbian, gay, bisexual, transgender, queer/questioning, intersex, and others.

[b]IBS: irritable bowel syndrome.

[c]IBS-SSS: IBS Symptom Severity Score; ranges from 0 to 500, with mild (75-174), moderate (175-299), and severe (300-500) symptom severity.

All participants identified as women and had tertiary-level education. The mean age was 55.3 (SD 13.5) years, and participants had lived with an IBS diagnosis for an average of 12.9 (SD 10.6) years. Five of 8 (63%) participants reported constipation-dominant IBS, 2 (25%) reported mixed IBS, and 1 (13%) reported diarrhea-dominant IBS. The average IBS-SSS

XSL•FO
RenderX

was 197.9 (SD 84.8), indicating mild symptoms. Participants had managed their IBS symptoms using one or a combination of the following DHTs: a total of 7 (88%) had used mHealth apps, 6 (75%) used mobile tracking apps, 6 (75%) used websites, 4 (50%) used IBS-related podcasts, and 1 (13%) used support groups. Among all types of mHealth apps used (n=7), 6 participants (86%) reported having used IBS-specific apps, 2 (29%) diet-specific apps, 2 (29%) general gastrointestinal and health apps, 1 (14%) mental health and/or emotional well-being apps, and 1 (14%) cognitive-behavioral therapy and/or gut hypnotherapy apps.

Themes of Navigating, Adopting, and Using Digital Health Technologies

Two themes were identified from participants' experiences and decision-making around navigating, adopting, and using DHTs for IBS self-management: (1) uncertainty impacts the trustworthiness of DHTs, and (2) underlying influences drive the decision-making process to adopt and use DHTs.

Theme 1: Uncertainty Impacts the Trustworthiness of Digital Health Technologies

A sense of uncertainty was prevalent among participants when navigating, adopting, and using DHTs for their symptoms of IBS. While participants were generally positive toward DHTs with hope and expectations of effective self-management and symptomatic relief, the coexisting challenges and risks contributed to varying levels of distrust.

Participants expressed uncertainty toward the effectiveness, utility, and understanding of DHTs. Because of the self-directed nature of the navigation process through their mobile devices and the internet, participants were aware that not all DHTs would be effective or suitable for them, and some recounted their experiences of finding suitable DHTs through trial-and-error.

> *[. . .] As we know, it is hard to know if anything's working. It's hard to know if anything works for the symptoms that we're experiencing. So that does come into it as well, but it's not a science, it's sort of a bit of a feeling about whether you're going to continue with something and whether it's worth it.* [Participant #48]

> *I just found and tried and listened to whatever. And then if it wasn't in my wheelhouse then I just discarded.* [Participant #29]

In contrast to those with positive experiences, other participants with subpar experiences using DHTs expressed challenges and frustration in finding what they needed to manage IBS. The lack of guidance around appropriate and trustworthy DHTs left some feeling alone and overwhelmed by the amount of information online or the number of mHealth apps to consider.

> *We just kind of have to search and go online and try to look at reliable resources [. . .] I've got family help too that they're in the tech side of things, so I get some help from them from looking at different options. But basically, you do it on your own.* [Participant #37]

> *You're feeling crummy. You need a resource, you need some help, but trying to wade through everything or do a Google (search) is just so overwhelming.* [Participant #9]

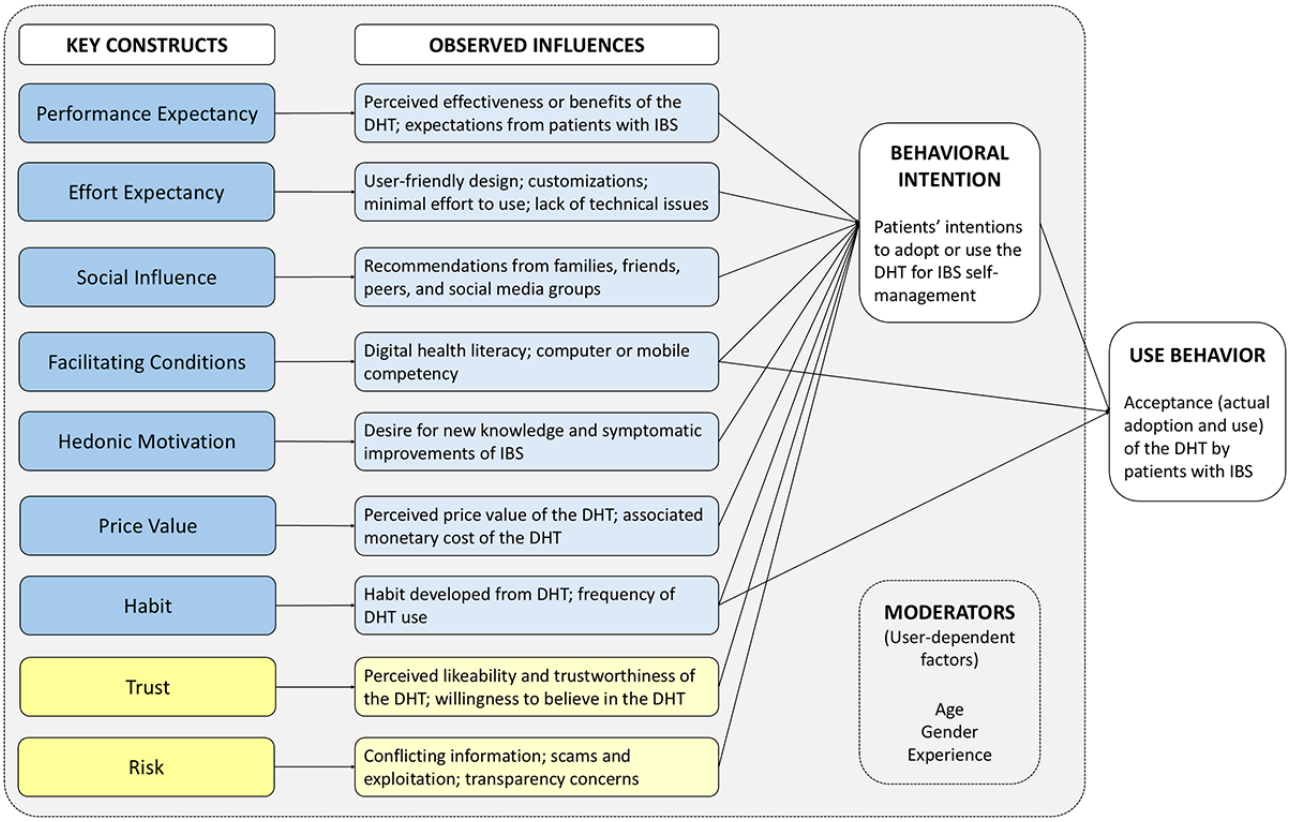
Uncertainty toward the DHTs' intentions was raised, including fear of scams or malicious attacks from illegitimate websites and privacy and data exploitation from mHealth apps. Furthermore, participants discussed the accuracy of online information from the internet and their concerns about consuming IBS-related misinformation and disinformation.

> *I agree with (Participant #9) regarding credentials and if (doctors are) trying to sell stuff. I know there's some doctors out there who do that too. So yeah, just mindful of people trying to market products versus people with credentials who are trying to debunk misinformation or provide just evidence backed information.* [Participant #14]

> *I don't like even giving my credit card information or any other personal information out into the internet. You just never know who's out there and what's going to happen to it.* [Participant #37]

During these discussions, digital health literacy was raised as an essential skill and a common barrier for patients with IBS to assess, process, and understand digital health information and technologies.

> *It's not about (like) or dislike, it's always questioning what I found, is it true or not, and how to explore further to be sure that these things are true because I'm not a great researcher [. . .] because of lack of medical background. So I am always hesitant to trust this or that information. It's not disliking, but it's a concern whether it's right direction to move or not.* [Participant #4]



Theme 2: Influences That Drive the Decision-Making Process to Adopt and Use Digital Health Technologies

Overview

Participants alluded to several influences that contributed to their decision to use DHTs, which were contextualized using the modified UTAUT2 model (Figure 1). Applying the model to this cohort illustrates the model's relevance and the complexities of DHT acceptance among patients with IBS. The observed influences (key constructs), as proponents or opponents to their decision-making process at varying degrees, collectively impact participants' intentions and/or the actual adoption or use of DHTs. Furthermore, the influences may have been externally moderated by participants' demographics, including age, gender, and experience or familiarity with DHTs. Selected quotes are provided to illustrate the influences and their relation to key constructs from the UTAUT2 model (Multimedia Appendix 4).

XSL•FO
RenderX

Figure 1. Relationships of identified influences in the decision-making process of patients with irritable bowel syndrome (IBS) on the use and acceptance of digital health technologies (DHTs) based on the modified Expanded Unified Theory of the Use and Acceptance of Technology (UTAUT2) model. "Trust" and "risk" were not part of the original UTAUT2 model and were included as a result of the study's findings.

Performance Expectancy

Based on their prior knowledge, participants expressed varying levels of preconceived expectations toward the DHTs' performance. Aspects of participants' knowledge prior to using the DHTs included past experiences and associated emotions, user-system fit, health and disease knowledge, social influences and recommendations, and preexisting familiarity or trust toward the tool. Most participants therefore evaluated the performance of mHealth apps based on one or multiple outcomes: (1) the perceived severity and/or frequency of IBS symptoms before and after use, (2) changes to overall mood before and after use, (3) feelings toward the DHT, and (4) the ability of addressing concerns specific to the user. Online health resources, many of which served to disseminate disease knowledge and information, were evaluated differently by participants compared with apps. Participants instead focused on the accuracy, readability, accessibility, and perceived value of the information when assessing performance. One participant also noted the expectation-reality discrepancy among peers, contrasting high and unrealistic expectations of a fast, curative "fix" with DHTs designed for regular, long-term disease management.

Effort Expectancy

Most participants emphasized the importance of user-friendly DHT designs in successfully maintaining user engagement. Some described their experiences with poorly designed mHealth apps as frustrating or overwhelming (eg, rigid features, complicated functions requiring more user effort), and were subsequently discouraged from using the app further or to its fullest potential. Poor user design included features such as health monitoring functions requiring frequent data inputs or stringent timing, lacking customizable functions for personalization, and features with technical difficulties or lacking updates to address bugs. Conversely, apps with a more simplistic and seamless design reducing user effort, along with more customization capabilities, were viewed favorably. One participant considered it a priority to improve patient-centered aspects in DHT designs.

Participants unanimously agreed that patient engagement is critical for DHTs to ensure they are relevant and well-designed to address the needs of patients with IBS. Some participants considered that patients could engage in varying stages of development, such as the design and testing phases. The unanticipated burden of incorporating DHTs into their lifestyles—despite their intended use to improve patients' quality of life—further underscores the need for patient partners in the health research and technology space.

Social Influence

Many participants acknowledged their social circles as valuable support for their IBS diagnosis and management. They specified the type of support they received from their family and friends, specifically in navigating online resources, accessing the appropriate health care professionals, and recommending mHealth apps. However, some felt that certain DHT recommendations from their social circles were unhelpful or irrelevant to their circumstances because of limited knowledge or understanding of IBS. Others also were hesitant to fully embrace their support altogether, citing the social stigma around the condition.

XSL•FO
RenderX

In contrast, peer support groups were viewed favorably as a knowledgeable resource because of shared lived experiences with IBS. Most participants sought IBS support—often through social media platforms—for information regarding IBS-specific professional support, symptomatic management strategies, tools, and resources. One participant explained that peer recommendations could also help patients with IBS in decision-making about using mHealth apps by considering aspects or barriers from another perspective, such as evaluating the price relative to its value or benefits.

Facilitating Conditions

Participants' level of digital health literacy and competency with a device (eg, computer or mobile device) were identified as facilitating conditions contributing to user experiences with DHTs. Participants recognized the importance of digital health literacy in navigating, processing, and critiquing online health information. Many participants were considered to have higher digital health literacy because of their educational or professional backgrounds. Participants also acknowledged the role of computer and mobile competencies required for accepting and using DHTs, along with the significant learning curve for digital competency among older populations.

Hedonic Motivations

Most participants mentioned that their decision to adopt and use DHTs stemmed from a desire and willingness to learn about IBS and emphasized the importance of new and updated information available on these tools. Some participants had thoroughly researched and exhausted common IBS-related recommendations; DHTs that regularly provided new content were highly desirable and therefore maintained user engagement. Conversely, most participants struggled to fully engage with DHTs that lacked new content or variety, as they no longer felt the need to continue using these DHTs. Some participants also noted their interest in other IBS topics areas, such as mental health and community engagement.

Price Value

Participants frequently evaluated the cost-benefit trade-offs of DHTs—the monetary cost relative to their perceived values and benefits—in their decision-making process. Most participants first opted for services or apps that were free to download and use, but some also considered DHTs with paid business models. However, DHTs following a subscription business model were perceived by participants as the least desirable, with the accrued cost to maintain full access outweighing the potential benefits.

Habit

Participants correlated their habit or frequency of using DHTs with the DHTs' perceived utility, with greater frequency and established positive habits to be associated with symptomatic improvements and user satisfaction. Conversely, DHTs that were seldom used were deemed less useful, thus discouraging participants from using them even further.

The habit of DHT use depended on the features available, specifically reminders, and the digital platform. Some participants noted that customizable reminder functions prompted more consistent engagement from their experiences and were considered especially useful for certain DHT characteristics (eg, symptom and diet tracking and exercise programs); however, one participant mentioned that they did not need to be reminded to use their DHTs. Participants agreed that, given their frequent use of mobile devices (eg, smartphones), mHealth apps are more advantageous in maintaining user engagement. In contrast, participants perceived online websites or programs differently; they were viewed as cumbersome to locate, input login credentials, and search for the content. The integration of lifestyle with digital devices served as an antecedent factor that influenced participants' level of DHT acceptance and engagement.

Trust

In the context of the UTAUT2 model, trust in a DHT influences users' intention or willingness to use it and subsequently, whether the DHT is used for IBS (Figure 1). When navigating online health resources, participants positively associated medical or academic credibility with trust. Participants often referred to reputable medical websites (eg, Mayo Clinic and WebMD) for health information to improve their knowledge and IBS self-management. Academic and research institutions were also viewed favorably, and the involvement of a credible institution in the development of DHTs heavily weighted in favor of participants' decision-making. Some participants also acknowledged digital health literacy as a contributing factor toward trustworthiness of DHTs, as the ability to critically assess the information and sources provided greater confidence in recognizing credible websites and apps and placing trust in them.

Risk

In the acceptance and use of DHTs, participants weighed the potential risk associated with using DHTs as part of the trade-off with perceived benefits. Conflicting information, transparency concerns, and fear of financial and data exploitation were commonly raised by participants when navigating or using DHTs. For mHealth apps, concerns were primarily related to the handling and security of personal and health information. Regarding online resources, participants recognized the prevalence of conflicting information on the internet and the potential risks posed to unsuspecting users seeking clinical guidance. Participants also recounted their experiences with suspected scams, specifically websites that offered paid products and services to allegedly treat or cure IBS. One participant correlated their familiarity with the DHT and the DHTs' risk, associating less familiar DHTs with lower trustworthiness and greater risk.

Discussion

Principal Findings

Overview

Our findings highlight the importance of certain characteristics from both DHTs and users with IBS in determining intentions and success in navigating, adopting, and using DHTs, with many attributes aligning with the UTAUT2 framework [26]. Participants expressed an overarching theme of uncertainty towards DHTs in their abilities to ameliorate symptoms, which is based on their levels of and balance between perceived trust

XSL•FO
RenderX

and risk. Other relevant user-specific attributes include digital health literacy and digital competency (facilitating conditions), desire for new knowledge (hedonic motivation), habitual use of DHTs (habit), and recommendations from social circles (social influence). DHT-specific characteristics include considerations around the design and features that influence perceived effectiveness (performance expectancy), user experience (effort expectancy), and value (price value). These considerations holistically illustrate the experiences and perspectives of patients with IBS using DHTs and their underlying and multifaceted influences. Addressing barriers and leveraging facilitators is essential for developing effective DHTs, improving user experience and health outcomes, and promoting innovation within the digital health care space [37-39].

Building Trust and Addressing Uncertainties of Digital Health Technologies

Trust is a juxtaposing force to fear of uncertainty and a critical component of successful implementation, adoption, and use of DHTs. However, the unprecedented evolution of the digital health landscape poses several challenges, including limited regulations, guidelines, and a lack of robust evidence base for efficacy, safety, and impact [40,41]. Furthermore, other limitations (eg, technological, costs, and transparency concerns) add to the DHTs' "black box" nature, which could discourage users from accepting or engaging with DHTs when they are not being fully informed.

In a 2018 scoping review, trust in digital health systems was influenced by several elements, including quality, efficiency, self-efficacy, accessibility, reputation and users' recommendations, and fear of data exploitation [42]. Many of these enabling and inhibiting elements of trust align with the key constructs of the applied UTATU2 model, further highlighting the complexity and interconnectedness of patient trust in adopting and using DHTs. Participants' trust in DHTs was also compromised by their fear and the potential risk of harm through scams, malicious digital attacks, and exploitation. Similarly, Catapan et al [43] found commercial and data exploitation concerns to undermine the trustworthiness of digital health in a cohort of patients with chronic kidney disease.

Participants' hesitancy toward DHTs must also be understood within the broader digital misinformation landscape. Research has shown that IBS-related content on online platforms, such as YouTube and TikTok, is made accessible in the absence of a vetting process, and can be inaccurate, promotional, or lack scientific grounding [44,45]. Likewise, online dietary guidance for IBS often suffers from poor readability and inconsistent quality [46]. Patients with chronic, fluctuating symptoms such as IBS might be particularly vulnerable to online "cures," unregulated wellness products, or misleading health claims [47]. In this context, skepticism reflects an adaptive response to navigating oversaturated but often unreliable digital health information. Recognizing health misinformation as an external driver of uncertainty reinforces the need for credible and evidence-based DHTs that patients can trust.

Reducing the uncertainties of DHTs and improving patient trust require a large-scale, coordinated, multidisciplinary approach involving technology developers, patients, researchers, health care professionals and institutions, and government bodies. First, improving the technological systems and processes of DHTs for quality, data security, and transparency is needed, with patients and researchers involved to assess effectiveness, utility, value, and feasibility [38]. Second, improving health care system infrastructures to better respond and adapt to DHTs will further facilitate general trust in DHTs among patients and health care professionals [38]. Lastly, stronger regulatory practices and guidelines should be implemented to improve transparency by ensuring that commercial and publicly available DHTs meet efficacy, safety, and privacy standards. While governments have the capacity and means to implement laws and regulatory measures, professional health associations and bodies could also play a pivotal role in supporting health care professionals in navigating and using DHTs alongside their patients. For example, Torous and Roberts [48] argued for the American Psychiatric Association to provide digital health–related resources and guidelines to patients and clinicians. However, while advancing transparency and patient trust is crucial, it is also important to avoid overregulation, which could subsequentially limit or delay DHT innovation, adoption, and use [48].

Existing Gaps in Digital Health Literacy

Digital health literacy is a factor in participants' decision-making on adopting or using DHTs (facilitating condition) and a crucial determinant of health—especially in one's ability to navigate and critically assess health information online and leverage the benefits of effective DHTs [49]. Our sample was highly educated, which may have influenced their ability to evaluate the quality of online sources effectively without additional support. However, digital inequality is an ongoing issue; patients with lower levels of digital health literacy are more likely to struggle with navigating and using DHTs, considering that high levels of reading comprehension are expected [39,46,50]. Limited understanding of content, benefits, and risks in adopting health technologies hinders patients' ability to make informed decisions about DHTs, and by extensions, to fully trust them.

Improving digital health literacy requires a collaborative approach involving patients, health care professionals, and policymakers. Strategies include the availability of educational or digital health literacy programs [51] and adapting online information and resources to a broader audience [52]. Technology developers should also tailor their content and design based on the target users' characteristics, such as digital health literacy levels, and improve transparency around privacy and security to mitigate harm and build trust. By facilitating the conditions in which patients are equipped with the skills and confidence to effectively use DHTs, they could fully leverage these available resources.

The Financial Barrier to Digital Health Technologies

Unsurprisingly, affordability was raised as a common barrier for participants to access support, especially mHealth apps with paid models or in-app purchases. While paid apps may be perceived more positively than free apps [37], affordability, or the lack thereof, could impact patients' adherence to them [53]. In addition to the existing socioeconomic burdens of IBS [54],

XSL•FO
RenderX

patients could be especially more conscious of the financial trade-off of adopting and using cost-associated DHTs. Participants' preferences for one-time payment models over subscription models aligns with similar findings from a patient cohort with rheumatoid arthritis [55], suggesting that certain payment models for DHTs could also influence patients' decision-making process. Although Xie et al [56] suggested technology developers consider subscription plans to improve affordability and users' willingness to pay, this approach might instead deter patients with chronic diseases requiring sustained DHT use. More research is warranted to better understand the preference of patients with IBS for DHTs with certain business models to ensure accessibility and acceptance.

The Value of Patient Engagement in Digital Health Technology Development

Content and user-centered designs were important aspects of DHT acceptance and use [57]. As part of their hedonic motivations, participants valued new and varied content in DHTs and considered limited and outdated content as a major deterrent. Health information–seeking behaviors are prevalent in people with IBS [58], which could be attributed to a desire and hope for relief or a cure [47]. Furthermore, IBS is a complex disorder involving individualized brain–gut interactions and requires personalized medicine [9]. As a result, the accuracy, variety, and customizability of the content are considered invaluable for patients to explore self-management strategies from a multidisciplinary perspective [59].

User-centered design is an iterative and collaborative process that requires a foundational understanding of the target users and the context of their intended use [60]. The outcome of such design is heavily dependent on comprehensive research and observations, feedback, and recommendations from lay individuals and experts at all stages of development (eg, initial design, evaluation, and user feedback) [60,61]. Patient engagement in digital health research and development is, therefore, fundamental to constructing a successful user-centered design in DHTs for optimal efficacy and impact [61].

However, patient engagement remains limited in digital health and technology innovation [62], given existing challenges around digital health literacy, accessibility, and trust and transparency concerns [39]. Careful planning and considerations are also needed to leverage patients' inputs effectively; patients are most often involved in usability testing, where DHTs are mostly finalized which consequently leaves little flexibility to implement feedback [62]. Although there has been encouraging efforts to further engage patients with IBS in digital health research and implementation science [63], more is needed to fully ascertain the implications of DHTs and develop robust evidence specific to this population group.

Strengths and Limitations

This study is the first to explore the experiences of patients with IBS in navigating the digital landscape for self-management using the UTAUT2 model. Our findings contribute to the limited existing literature by providing insight into how DHTs can support IBS symptom management while addressing concerns related to distrust and digital literacy. We also identified key barriers and facilitators that impact patient experience and outcomes and provide recommendations for improvement based on patient perspectives.

This study also has several limitations. The transferability of our findings may be limited due to the small sample size and the presence of self-selection and sampling bias. First, our recruitment method used purposive sampling, where individuals decided whether to participate in the study. Our sample was highly educated, demonstrated high levels of digital health literacy, and showed great interest and motivation in health research and therefore was not representative of the general population with IBS. Second, all participants identified as women, which may be due to a combination of potential gender-related differences in IBS prevalence [64], mHealth app use [65], or the gender disproportion of the recruitment pool from previous IBS studies. This, however, poses the challenge of evaluating gender-based differences in this study, especially when gender is a moderating variable in both the original and expanded UTAUT models [26,33]. Third, all but one participant lived in a single Canadian province; their access or experience with health services and other non-DHT support may be different from other regions of Canada or worldwide. Lastly, coding saturation could not be fully attained in this study due to the insufficient sample size. While we have identified the most prevalent themes, having additional focus groups would further capture the themes comprehensively [30]. This would also avoid data bias and ensure the content validity, replicability, and transferability of the study [66]. Nevertheless, this study achieved its aim of building a deeper understanding and appreciation of patient experiences, perspectives, and decision-making around DHTs used for IBS that could serve as an antecedent for future studies and a guide in developing more patient-centered resources and supports.

Future Directions

Given the central role of digital literacy in our findings, future research should prioritize developing and evaluating educational or digital literacy programs specifically designed for patients with IBS. Identifying the unique barriers these patients face can guide the development of effective educational interventions. Additionally, longitudinal studies examining how enhanced digital literacy impacts the adoption and sustained use of digital tools would be valuable.

An emerging aspect in digital health is the rapidly expanding role of artificial intelligence and large language models (LLMs), such as ChatGPT, in supporting patient decision-making. Early evaluations suggest advanced LLMs can provide clinically aligned guidance, summarize complex medical concepts, and support initial health information–seeking more effectively than traditional search engines [67-69]. For patients with IBS, LLMs could serve as navigational tools that help filter misinformation, translate evidence-based information into patient-friendly language, and direct users toward credible DHTs or reputable resources. At the same time, concerns regarding bias, hallucinations, privacy, dependence on the quality and reliability of available training data and prompts, and lack of transparent regulatory oversight highlight that these tools remain imperfect and require careful integration into IBS self-management

XSL•FO
RenderX

[70-72]. Because LLM outputs are only as trustworthy as the data and sources on which they are trained, they may inadvertently reproduce inaccuracies or amplify misinformation. As AI-driven tools become more embedded in digital health, understanding how patients with IBS engage with them and how these tools can be responsibly implemented will become a critical future next step in this research. As AI-enabled tools and LLMs become increasingly integrated into consumer-health information-seeking behaviors, future work should also examine how these systems can support digital health literacy and help patients with IBS navigate an often-confusing online environment. Understanding how patients with IBS engage with these emerging technologies will be essential for designing safe and supportive digital self-management tools.

The evidence base on the feasibility and implementation of digital health technology for IBS is still lacking but necessary for real-world application. Understanding certain DHT features and attributes in patients' decision-making process could serve as a guide for future research and projects to understand and prioritize key objectives. Comprehensive economic evaluations should consider the direct and indirect costs of adopting DHTs in patients' self-management practices, as cost was considered a major barrier among participants.

Another fundamental step in this field is to improve patient engagement in health research and technology development. User-centered design was highlighted as a crucial component for the success of DHTs, and the need for greater involvement of patients in developing DHTs. Patient partners in future research and commercial development of DHTs, especially in the design and testing phases, will help ensure these tools are intuitive and meet patients' needs. Patient engagement will also be valuable in providing opportunities to quantify the significance of the identified influences in this study; this information could offer further insight into patients' decision-making process and how they weigh their considerations holistically.

Conclusion

This study highlights the complexities of the digital landscape in the context of IBS. While there is optimism toward DHTs in enhancing self-management, concerns about digital health literacy, trustworthiness, access, and cost must be addressed. With user-friendly, accessible, trusted, and cost-effective tools, the effectiveness and adoption of digital health solutions can be enhanced, and the digital health user experience optimized. It is evident that integrating DHTs in IBS self-management is a multifaceted, complex task that requires comprehensive and interdisciplinary collaboration among technology developers, health services, health professionals, and patients. More efforts are needed to address the identified barriers and leverage facilitators to improve health outcomes and quality of life for patients managing IBS or other chronic diseases.

Acknowledgments

We would like to express our gratitude to our patient research partner, Chantel Wicks, for her support and contributions to participant recruitment, and to student volunteer Darren Zhang for analyzing and summarizing the prefocus group surveys for this study.

Funding

This research was supported in full by the IMAGINE (Inflammation, Microbiome, and Alimentation: Gastro-Intestinal and Neuropsychiatric Effects), a Canadian Institutes for Health Research (CIHR) Strategy for Patient-Oriented Research (SPOR) Chronic Disease Network (funding reference number: 1715-000-001), with funding from several partners. No other financial arrangements were related to the research or assistance with manuscript preparation. DAM is supported by the Svare Chair in Health Economics, Value and Impact.

Data Availability

The datasets generated or analyzed during this study are not publicly available, as participants did not provide consent to share their individual data.

Authors' Contributions

AD and NH contributed equally as co–first authors. AD, DAM, MVM, JS, and NH conceptualized and designed the study. AD and NH collected the data. AD and NH analyzed the data. AD and NH wrote the first draft of the manuscript. All other authors provided revisions to subsequent drafts. All authors contributed to and approved the final manuscript.

Conflicts of Interest

DAM reports personal fees from the Office of Health Economics, Analytica and Novartis, and meeting expenses from ISPOR—The Professional Society for Health Economics and Outcomes Research—and Illumina. AD, MVM, JS, and NH disclose no conflicts of interest.

Abstract

Background: Adolescents face a variety of potential harms in the online environment, including exposure to distressing illegal material, cyberbullying, image-based abuse, and "sextortion." Various agencies provide on-demand helpline and information services for children and adolescents to support them with navigating online (and offline) harms.

Objective: This study examined whether a chat-based conversational agent (chatbot) might be a useful additional tool for meeting the needs of adolescents at risk from online harms. We developed a prototype chatbot—including both conversational and menu-driven user options—and evaluated users' trust in the chatbot. In this context, trust relates to perceptions of the chatbot's usability and the value of the information and support it provides.

Methods: Participants (n=224; mean age 16.8 years) interacted with the chatbots and evaluated them in terms of user trust: perceived usability and utility (ie, relevance of support resources provided).

Results: Most participants (conversational chatbot: 141/224, 63% and menu-driven chatbot: 142/224, 63%) showed a willingness to click on the chatbots' recommended support links. Participants with higher trust in the chatbots were more likely to click the links for recommended support services (with extreme evidence for large effects: δ=0.73, 95% credible interval [CrI] 0.46-1.00 and δ=0.78, 95% CrI 0.50-1.07, for the conversational and menu-driven chatbots, respectively; Bayes factor [BF_{10}]>50,000), and participants who clicked the links, compared with those who did not, reported higher rates of positive attitudes toward their decision (with extreme evidence for large effects: δ=0.87, 95% CrI 0.58-1.15 and δ=0.84, 95% CrI 0.54-1.12, for the conversational and menu-driven chatbots, respectively; BF_{10}>3,000,000). The conversational and menu-driven chatbots differed little in perceived trust or effectiveness.

Conclusions: Chatbots represent a promising additional tool to help adolescents access mental health–related support services and navigate online harms. However, establishing trust is critical.

Introduction

Overview

Chat-based conversational agents—chatbots—are used in many contexts globally. Research on technology in the health care and service sector has found that the use of chatbots (compared to traditional systems, such as web interfaces or menu-based systems) can lead to a more positive user experience (ie, users feeling more comfortable and better understood) [1-4]. This is often attributed to chatbots facilitating a more conversational and interactive form of communication, making users feel more

XSL•FO
RenderX

engaged and better supported [4]. Developing these feelings of engagement and support is essential. In health care and mental health support contexts, individuals often need to share personal information with a chatbot (eg, their medical history or symptoms) to receive customized recommendations [5-8]. This process relies on users feeling secure in sharing sensitive information [2,9-12]. Effectively, the successful adoption of human-technology systems (like chatbots) relies on people's trust in these systems [3,6,13-19]. Trust in human interactions is grounded in shared emotional connections and the confidence a person has that others will prioritize their interests [19,20]. However, trust in technology and artificial intelligence (AI) systems operates differently due to the absence of genuine empathy [11,19,21]. Instead, trust in human-technology interactions is more transactional, being influenced by factors such as functionality, performance, helpfulness, predictability, and reliability [13,19]. Specifically, trust in conversational chatbots has been defined as the users' willingness to provide confidential information and to accept and act on the chatbot's recommendations [17]. In this study, we tested adolescents' feelings of trust toward, and perceptions of the utility of, 2 chatbot systems, providing proof-of-concept evidence for the potential utility of these chatbots in providing support to adolescents at risk from online harms.

Developing trust involves both cognitive and affective processes. To facilitate cognitive trust, a system must meet expectations and be perceived as useful. In contrast, affective trust is related to emotional connections, such as making a user feel secure and comfortable [22,23]. Cognitive trust, grounded in reasoning, is associated with practical aspects of an information system (ie, usage-related factors), such as functionality, ease of use, and the quality and relevance of its recommendations [16]. When users consider using new technology-based services, they can engage in a rational decision-making process, weighing potential benefits against drawbacks [22,24]. Building and reinforcing cognitive trust occurs when users experience tangible, positive outcomes (eg, when they perceive that the new system makes tasks easier). When users feel their needs are met, they are more likely to trust the system and continue using it [25-28]. Cognitive trust positively influences the acceptance and usage of technology; conversely, technology with low cognitive trust is less likely to be adopted [22,29]. Thus, developing an online safety chatbot that meets users' needs is essential for establishing and sustaining cognitive trust and for the ultimate success of the system.

Affective trust is not based solely on objective measures of performance but rather on feelings associated with security, comfort, and satisfaction [22,30]. Affective trust can help reduce the psychological distance, or perceived emotional gap, between a user and the information system [3,30-32]. Compared to basic information systems (such as a web or menu-style interface), chatbots, with their more natural interaction and personalized conversational approach, can reduce psychological distance by making users feel more comfortable and supported, encouraging users to share personal information and accept support recommendations from the chatbot [3,17,33,34]. Even adding a basic human-shaped symbol, compared to a machine-like symbol, to a chatbot has been found to enhance affective trust, reduce psychological distance between the user and the chatbot, and increase users' intentions to comply with chatbot recommendations [3].

Cognitive and affective trust often reinforce each other [22,35,36]. When a person believes a technology is useful, they become emotionally engaged with it. When they are emotionally engaged, they are more likely to view the system as useful and credible. Importantly, when users trust a chatbot, they are more likely to follow its recommendations, making trust a critical factor in predicting users' behavioral intentions, their willingness and motivation to follow advice [3,17,37-39]. A person's behavioral intention serves as an informative, though admittedly imperfect, predictor for actual behavior [40-43]. Several studies show a positive link between a stated positive intention to use an AI service (such as a chatbot) and actual usage [26,44]. Thus, investigating trust-related factors and how they relate to potential help-seeking behavior in the context of an online safety chatbot is essential for predicting how users might perceive and interact with this potentially helpful tool, as well as their willingness to accept and act on its recommendations, in a real-world setting.

The Case for an Online Safety Chatbot for Adolescents

Adolescents encounter many challenges staying safe online. The online and social media environments present a range of risks, including cyberbullying and exposure to inappropriate content, which can have serious consequences for adolescent well-being [45]. The pressures of negative online interactions can contribute to increased levels of stress, anxiety, and depression among adolescents [46,47]. The "Digital Lives of Aussie Teens" report by the e-Safety Commissioner [45] found that adolescents in Australia spend, on average, 14 hours online each week (researching topics of interest and engaging with social media, entertainment, and gaming) and, among those aged 14-17 years, just over 50% reported negative experiences in the past 6 months. Such incidents include being contacted by strangers, receiving threats and abuse, and being exposed to inappropriate or unwanted content. In addition, one-third reported negative online experiences stemming from instances of bullying that occurred at school. Although many adolescents do seek help from friends and family, a considerable portion do not share their concerns or report harmful incidents to authorities (eg, law enforcement and the school), the online platform (eg, social media platform and gaming websites), or support services (eg, helplines, mental health professionals, and counsellors). Nonetheless, a large majority (75%) of adolescents expressed a need for online safety information, with schools and reputable websites for digital well-being being their preferred sources for accessing this information. Importantly, an online safety chatbot can serve a dual purpose, not only supporting those who may have experienced harm but also reducing the risk that they may unintentionally be causing harm to others due to their limited understanding of legalities, consent, and privacy rights. By providing guidance and information on these topics, the chatbot can contribute to the promotion of responsible online behavior among adolescents. The vulnerability of adolescents to online threats, and the potentially harmful impact of such experiences on their development and mental health, highlight the need to address cyber safety

concerns among youth and ensure they have easy access to reliable information from trusted sources.

Yourtown [48], which operates Commonwealth-funded services for children across Australia, has reported that the use of on-demand helplines and websites by minors has steadily increased between 2018 and 2023. This paper suggests that chatbots could be a useful additional tool for helping address cyber safety and related mental health concerns among adolescents [49]. Integrating an online safety chatbot service into a school program could not only raise awareness of the risks associated with negative online interactions but also serve as an important resource for students seeking help. This online safety chatbot can provide direct links to information tailored to the students' concerns on issues such as cyberbullying, grooming, image-based abuse, and "sextortion," online gambling, eating disorders, and substance abuse—as well as counselling services, mental health resources, and trusted helplines. This tool could be particularly important in reaching those who may feel embarrassed or hesitant when talking to others, or who lack adequate support from family members or peers, leaving them without necessary guidance on these issues. An online safety chatbot service available on school websites could help schools bridge this gap by providing a readily accessible platform where students can seek help anonymously. By offering an additional avenue to access trustworthy information, an online safety chatbot can empower vulnerable adolescents to address their concerns proactively and confidentially and direct students to appropriate mental health support. It can also complement school and community efforts to promote online safety and well-being among young people.

Given the sensitive nature of online safety concerns, especially where adolescents may be coping with distressing emotions, a chatbot service can provide a safe and confidential space for adolescents to share their concerns [31]. This would allow the online safety chatbot to offer tailored recommendations that can be delivered empathetically and securely to help young people navigate the issues they are experiencing. This would be particularly helpful for those who may feel more comfortable asking about sensitive issues or sharing personal information to a dedicated online safety platform rather than a human [50]. However, as noted previously, the efficacy of a chatbot service is likely to be associated with users' trust in the chatbot, which, in turn, will affect how receptive users are to the chatbot's recommendations for further support.

This Study

In technology design, creating user-friendly systems is essential, particularly in sensitive information-sharing contexts [2,3,6]. When implementing an online safety chatbot in schools to help address online harms, it is important to include aspects of cognitive trust (eg, perceived utility) and affective trust (eg, feeling comfortable with its use). Several trust-related factors can influence how likely someone is to adopt and engage with a chatbot [3,16-19,26,51]. These include perceptions of the accuracy of the information the chatbot provides, how easy and user-friendly the chatbot is to interact with, and how well its suggestions align with a user's needs. The chatbot's ability to provide relevant recommendations based on the user's input, such as offering resources related to their specific concern, is important to building and maintaining trust. Additionally, feelings of trustworthiness, security, and positivity during interactions with the chatbot play a key role in impacting users' overall perception and willingness to continue using it [2,3,10-12,52]. Essentially, a user's perception of the chatbot's reliability and the more helpful and comfortable they feel with the chatbot, the more likely they may be to trust it and follow its recommendations for additional help. In this study, we included 6 measures related to trust in chatbots, tapping both cognitive and affective trust (accuracy, user-friendliness, relevant recommendations, trustworthiness, security, and positivity).

Menu-Driven and Simple Conversational Chatbot

To examine the potential for developing an online safety chatbot for a school or community setting, participants interacted with both a conversational and menu-based chatbot using a scenario-based activity (as explained further in the Methods section). A menu-driven chatbot offers users preselected options, guiding users through structured pathways based on their selections. In contrast, a conversational chatbot enables users to input questions or concerns using natural language. There are 2 main types of conversational chatbots: "simple chatbots" and "smart chatbots." Smart chatbots use advanced algorithms and AI to understand and respond to user inputs in a more flexible and natural manner. In contrast, a simple conversational chatbot, the system used in this study, simulates simple conversations, providing tailored responses and recommendations based on user textual input. They leverage advanced machine learning models to understand user input (trained on input phrases and rules) to establish user intent but then rely on predefined responses to provide answers to user input. Phrases like "Sorry, I did not understand" appear for inputs that do not match preselected intents, particularly in contexts where a less constrained chatbot may respond with unhelpful or inappropriate responses. There have been many examples in recent years of chatbots responding poorly, although none more famously than @TayAndYou [53]. The choice to implement a simple chatbot in this study was to minimize the risk to adolescents inquiring about sensitive topics.

Examining users' ratings for trust-related factors across the 2 chatbots allowed us to compare which method of interaction and design approach might better align with students' needs and preferences when seeking help navigating online safety issues. This study, being exploratory and intended as a proof of concept, investigates multiple research questions and considers alternative viewpoints. For example, students might trust a menu-driven chatbot more because it is predictable and easy to navigate with clear menu options, but this might feel less interactive and personalized compared to a conversational chatbot [54]. However, a simple conversational chatbot, though potentially more flexible and engaging, may be limited when handling complex sentences or questions. This could affect the accuracy of its responses, potentially impacting trust in the chatbot. A preference for a menu-driven chatbot or a conversational chatbot may depend on whether students prioritize a structured interface or a more conversational interaction.

XSL•FO
RenderX

Past research on technology adoption suggests perceptions of an online safety chatbot's utility may be influenced by gender-specific factors [16], highlighting the importance of considering these differences. For example, findings suggest that females tend to have a favorable view if they perceive the technology as practical, while males might need extra motivation to engage [55,56]. Thus, we examined potential gender differences in students' trust and their engagement with the chatbot's recommendations, as this may inform an online safety chatbot's marketing and design to better cater to the preferences of different gender groups, enhancing its effectiveness.

In sum, this study examined whether a chatbot might be a useful additional tool for meeting the needs of adolescents at risk from online harms. Specifically, in this proof-of-concept work, we evaluated users' (1) perceptions of efficacy for 2 types of chatbot, (2) trust in our chatbots, and (3) preferences for chatbot design features.

Research Questions

Textbox 1 outlines the study's research questions, which examine students' help-seeking behavior and their perceptions of trust and usability in chatbot systems. The questions focus on the relationships among key trust factors, behavioral intention to use chatbots, and differences between conversational and menu-driven designs. Additional areas of inquiry include user preference, personalization, anonymity, prior experience, gender differences, and common usability challenges, providing an overall framework for understanding trust and user experience in chatbot-based support.

Textbox 1. Research questions examining students' trust, usability perceptions, and behavioral intentions toward conversational and menu-driven chatbot systems.

Research questions

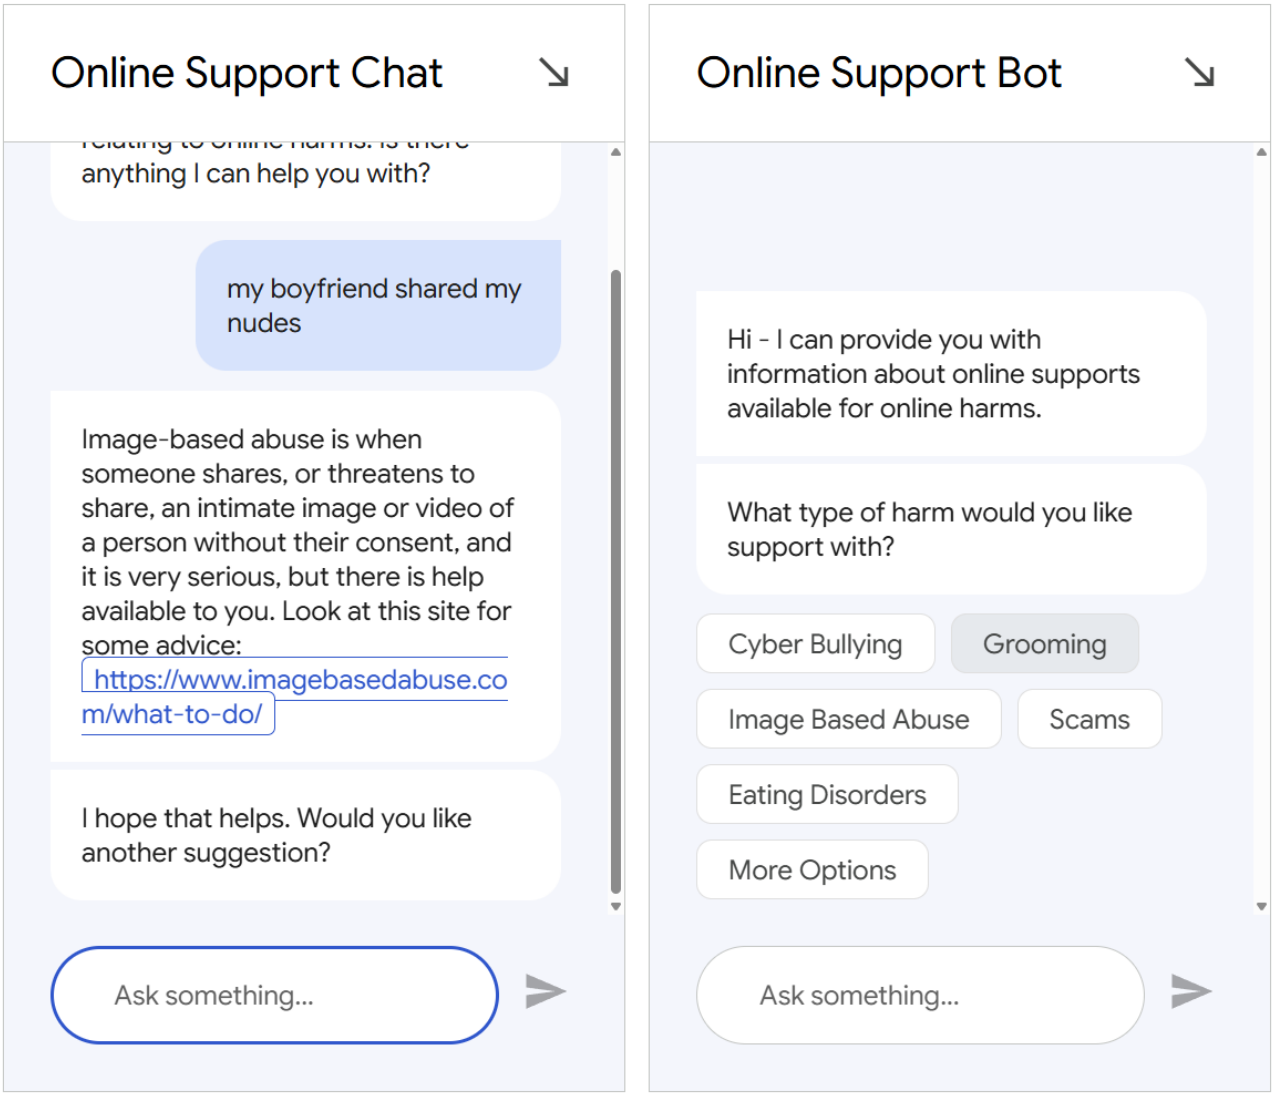
- How likely are students to seek help from outside their family and peer group?
- Do perceived accuracy, usefulness, ease of use, security, comfort, and credibility show a positive correlation, indicating that they may work together to contribute to trust in chatbot systems? Does this differ between conversational and menu-driven chatbots?
- Is there a relationship between a higher trust score (combined scores on perceived usefulness, ease of use, security, comfort, and credibility) and behavioral intention to use a chatbot (measured by clicking on a help link and positive feelings about the action)? Does this differ between conversational and menu-driven chatbots?
- Do conversational chatbots have a higher overall trust score than menu-driven chatbots, indicating that they are perceived as more trustworthy (based on perceived usefulness, ease of use, security, comfort, and credibility ratings)?
- Does perceived usefulness differ between conversational and menu-driven chatbots?
- In terms of perceived ease of use, is there a preference for conversational chatbots over menu-driven chatbots?
- Overall, do users prefer a conversational or menu-driven chatbot, and what factors influence users' preferences? (Qualitative)
- Is there a preference for personalization of the conversational chatbot? Is a face or name important?
- Is there a preference for strict anonymity in a chatbot system?
- How does prior experience with conversational chatbots affect users' perceptions of ease of use, comfort, and overall trust (trust score) in a conversational chatbot?
- What are the common difficulties encountered by users when using conversational and menu-driven chatbots, and how might these difficulties relate to user experience ("ease of use") and trust in the system ("trust score")? (Qualitative)
- Do trust scores differ according to user gender identity? Does gender impact a user's behavioral intention?

Methods

Ethical Considerations

All procedures were compliant with the relevant laws and institutional guidelines and have been approved by the appropriate institutional committee (March 26, 2024; project no: H0029893). Privacy rights for human subjects were observed, and informed consent was obtained prior to data collection. All data were collected anonymously and stored securely in line with the university research data governance guidelines. Participants completed the survey within their "home room" group at school, within the presence of a school staff member. A member of the research team was also present to answer questions from participants. The information sheet also provided guidance on contacting the school counselling team or 1 of 2 listed independent support lines (Beyond Blue and Headspace) if the survey caused any discomfort or raised concerns for participants.

Participants



A total of 224 participants (131 female, 93 male, and 0 selecting a different identification), with a mean age of 16.8 years, completed the study. Participants were recruited from a local school, and both participant and parent or guardian information sheets were prepared and communicated to the relevant parties through the school communication system. This same system also provided a facility for parents or guardians to provide consent for participants. The school collected the list of students for whom consent was provided, and this list was later used to provide access to the survey to students who met the consent requirements.

XSL•FO
RenderX

Materials

The chatbot was developed using a co-design process, leveraging 2 focus groups at a local school that teaches grades 11 and 12. The first focus group comprised members of the pastoral care team at a school, and the second was a cohort of students. This design process is detailed in Roehrer et al [57]. The focus groups considered what harms were of greatest importance to be included, what resources were of most value, and general design considerations, including what the chatbot's opening line to users should be. The chatbot design did not attempt to mimic a young person's vocabulary or style in alignment with similarity-attraction theory [58] but aimed to use simple casual language that would be understandable at a 13-year-old reading level. The focus groups highlighted the importance of nonjudgmental advice that was factual and trustworthy. The chatbot included slang and other terms used by young people within its training data to understand inputs, but its responses did not include such terms and prioritized simple plain English responses that directed users to support resources and services. The chatbot was built on the Google Dialogflow platform [59] based on the outputs of the design requirements and in 2 variants, 1 menu-driven and 1 conversational (Figure 1). The survey was delivered to participants using the Qualtrics platform, accessed through a web link provided to them in the classroom at the time of the survey. The chatbot variants were embedded within the survey, with a randomized order of presentation of the 2 chatbot types. Following the survey, lunch was provided on the school campus for students who participated in the survey.

Figure 1. The 2 variants of the chatbot created within the project: the conversational chatbot (left) and menu-driven chatbot (right). The conversational chatbot allows the user to enter free text and engage in a conversation. The menu-driven chatbot prompts users to select response from prespecified lists.

Procedure

After reading the task instructions, participants were asked to enter their gender and age into text boxes. In addition, they were asked a single question about their general help-seeking behavior, "When something worries you, how likely are you to seek help from sources outside of your family or peer group?" (7-point scale: "very unlikely" to "very likely"). The main task consisted of 2 parts. In the first part of the task, participants engaged with the first chatbot (eg, conversational chatbot). They began by reading the first vignette, which provided context for

XSL•FO
RenderX

the interaction with the chatbot. Participants entered into a simulated "conversation" with the first interactive chatbot, assuming the role of the character in the given scenario. Based on the details shared by the participant, relevant hyperlinks to appropriate websites, such as eSafety [60] and the Butterfly Foundation [61], were embedded within the "conversations." These interactive clickable links led directly to real-world websites. For example, if the conversation related to cyberbullying, participants received a hyperlink directing them to eSafety. Additionally, the chatbot offered the option for another link to a different but relevant website. Participants received instructions at the start of the study that these hyperlinks were interactive. After engaging with the first vignette, participants proceeded to a second vignette, repeating the process (using the same interactive chatbot). After completing both interactions, participants responded to a set of 8 questions aimed at capturing their thoughts related to their experiences with the first chatbot. The following questions were asked for conversational and menu-driven chatbots following an interaction with that system and were aimed at capturing behavioral intention. Question 1: "For either vignette, did your character choose to click a support link?" (This was aimed at capturing behavioral intention). Question 2: "How did your character feel about this decision? e.g., did they feel positive about their decision, or did they have some reservation?" The participants then answered 6 questions on various aspects of trust-related factors. Participants were instructed to consider the perspective of the person seeking help while responding to these questions. The following questions related to trust with responses collected on a 5-point Likert scale, ranging from "strongly disagree" to "strongly agree": (1) "The interaction with the chatbot resulted in a recommendation for a relevant service" (perceived usefulness), (2) "Overall, I felt the chatbot provided accurate information" (perceived accuracy), (3) "The interaction with the chatbot felt user-friendly" (perceived ease of use), (4) "The interaction with the chatbot felt secure in terms of privacy" (perceived security), (5) "I felt that the interaction with the chatbot was a positive experience" (perceived comfort), and (6) "I found the chatbot to be trustworthy" (perceived credibility). Higher scores indicate an increased likelihood of trust in the chatbot. In the second part of the task, participants engaged with a different chatbot (eg, menu-driven chatbot). As in the first part, participants read 2 new vignettes, and engaged in a "conversation." Participants then answered the same set of 8 questions as in the first part. This approach allowed us to collect information on participants' engagement with the 2 distinct interactive chatbots (conversational and menu-driven), their perceptions of those interactions, and the likelihood of seeking further advice through a suggested helpline.

At the end, participants were presented with a final set of questions designed to gather their feedback and impressions directly comparing the 2 chatbot systems: Question 1: "After engaging with both systems, which did you find most helpful?" (Response options: conversational, menu-driven). Question 2: "After engaging with both systems, which did you find easier to use?" (Response options: conversational, menu-driven). Question 3: "If you wanted to find out more about support services and information related to online harms, which system would you prefer to use?" (Response options: conversational, menu-driven, neither). Question 4: "Do you believe the conversational chatbot should be personalised, for example, having a face or a name?" (Response options: yes, no, unsure). Question 5: "Do you think a chatbot service for information related to online harms should be strictly anonymous?" (Response options: yes, no, unsure). Question 6: "Before today, have you used a conversational chatbot before?" (Response options: yes, no, unsure). Question 7: "Please share your thoughts on what specific features would increase your comfort level when it comes to sharing personal information with a chatbot." Question 8: "Did you encounter any difficulties using either of the systems today?" For Questions 3, 4, 5, 7, and 8, participants were provided a text box to add any additional information.

Analysis Strategy

We used the *jamovi* [62] packages to run Bayesian analyses to examine our data. This approach provides 2 key advantages for our purposes. First, unlike null hypothesis significance testing (NHST), Bayesian analyses can quantify evidence for the null hypothesis. When a NHST approach returns a nonsignificant result, all that can be concluded is that there was no evidence of a meaningful difference between groups or association between variables. In contrast, a Bayesian approach allows researchers to draw meaningful conclusions about equivalence across conditions or the absence of associations between variables. Second, a Bayesian approach allows for targeted *t* tests and chi-square analyses without inflating the risk of Type I error [63]. When interpreting Bayes factors (BFs), we relied on Lee and Wagenmakers' [64] criteria, where evidence for the alternative (or null) hypothesis can be categorized as follows: 1-3=anecdotal, 3-10=moderate, 10-30=strong, 30-100=very strong, and >100=extreme. For Bayesian *t* tests, effect size measures are reported as δ, the population equivalent to Cohen *d* [65]. An adapted summative content analysis was performed on the survey responses, using the comments to drive the units of meaning, providing labels and then grouping labels into a final category [66]. Our analyses were largely exploratory, but the preregistration for our analysis strategy can be found here at the Open Science Framework [67].

Results

Overview

A key aim of this study was to examine aspects of trust in both a conversational and menu-driven online safety chatbot. As individuals typically require trust before they comply with recommendations [11,21], establishing and maintaining trust is an essential component to ensuring adolescents are receptive to its suggestions for related online e-safety resources.

Willingness to Seek Help From External Sources

Establishing whether young people are open to seeking help beyond their close friends and family circle is important, as this informs the need for and development of effective external support strategies. When participants were asked about the likelihood of seeking help outside their family and peer group, of the 224 participants, 39% (87/224) reported it was likely (collapsed across slightly, moderately, and very likely), 42%

XSL•FO
RenderX

(94/224) said it was unlikely (collapsed across slightly, moderately, and very unlikely), with the rest (n=43) being unsure. Thus, over one-third of students showed openness to seeking external help when needed. We measured students' willingness to follow a chatbot's recommended service by including clickable hyperlinks in their chatbot interactions and asking participants about their link-clicking behavior. We considered those who clicked on a help link might also be more likely to seek help when presented with that opportunity in real-life. When engaging with both the conversational and menu-driven chatbots, a substantial majority of the 224 participants reported they clicked on a help link (141/224, 63% and 142/224, 63% for the conversational and menu-driven chatbots, respectively). As students were no more or less likely to press on a help link via a conversational or menu-driven chatbot, this suggests that the type of interface (as they currently stand) does not influence help-seeking behavior. Although females were, numerically, more likely than males to click on help links provided by both the menu-driven (90/131, 69% vs 52/93, 56%) and conversational chatbots (87/131, 66% vs 54/93, 58%), the evidence in favor of these representing meaningful differences was anecdotal (BF_{10}<2.10).

Considering an individual's attitude, whether positive or negative, toward a behavior is important, as it can indicate the likelihood of engaging in that behavior in the future [42]. Positive feelings associated with a behavior often suggest a higher chance of repeating that behavior. Therefore, a positive feeling toward clicking a link in this study might suggest a tendency to seek assistance via a chatbot-suggested link in real-world situations. Bayesian independent samples 2-tailed *t* tests found that, for both the conversational ($BF_{10}=1.29\times10^7$) and menu-driven chatbots ($BF_{10}=3.73\times10^6$), there was extreme evidence that students who clicked on the provided link, compared with those who did not, felt more positive about their choice. For both the conversational (mean 3.50, SD 0.78 vs mean 2.76, SD 0.92; δ=0.87, 95% credible interval [CrI] 0.58-1.15) and the menu-driven chatbots (mean 3.49, SD 0.85 vs mean 2.82, SD 0.63; δ=0.84, 95% CrI 0.54-1.12), these differences exceeded the threshold for large effects. These findings suggest that choosing to click on a link while interacting with either the conversational or menu-driven chatbot is associated with a higher level of positivity regarding that decision, in contrast to choosing not to seek help via the link.

Trust and Trust-Related Factors

Trust is an important factor in users' willingness and motivation to follow advice (ie, behavioral intentions; [6,17,26]. Thus, we were interested in how trust relates to clicking on chatbot-suggested help links. We expected that higher overall trust in the chatbot should relate to a greater likelihood of clicking on a suggested help link. A Bayesian independent samples 2-tailed *t* test (1-tailed/2-tailed) showed extreme evidence (BF_{10}=87,421) for a large effect (δ=0.73, 95% CrI 0.46-1.00) such that, for the conversational chatbot, those who clicked on a help link (mean 3.68, SD 0.75) had a higher trust score (using the mean of the 6 trust-related factors) than those who did not click (mean 3.14, SD 0.65). Similarly, for the menu-driven chatbot, there was extreme evidence (BF_{10}=543,051) for a large effect (δ=0.78, 95% CrI 0.50-1.07), where those who clicked on a help link (mean 3.76, SD 0.73) had a higher trust score compared with those who did not (mean 3.22, SD 0.53). These findings are consistent with the idea that trust relates to a person's inclination to use the chatbot's suggested help features.

We compared participants' perceptions of menu-driven and conversational chatbots across various trust-related factors. As trust is a multifaceted concept, it is important to first consider the relationship between these factors and their potential collective impact on trust in chatbots. Key trust-related factors influencing chatbot adoption, which are essential for developing and maintaining trust, include the accuracy of information based on user input, user-friendliness, appropriateness of recommendations (eg, directing users to relevant help sites for specific concerns such as cyberbullying), and feelings of trustworthiness, security, and positivity toward interactions with the chatbot. The internal consistency of the trust-related factors in our study was high, with a Cronbach α coefficient of 0.88, indicating good reliability among the measured items (Tables 1 and 2). We found extreme evidence for moderate-to-strong correlations between all trust-related factors for both menu-driven and conversational chatbots, highlighting the factors' interconnectedness.

Table 3 displays the means and SDs for, and Bayesian 2-tailed paired samples *t* tests comparing, each trust-related factor across chatbot types. Across these comparisons, 3 key findings emerge. First, for most trust-related factors, there is evidence of equivalence across chatbot types, indicating that users did not report trusting one chatbot over the other. This evidence was strong for perceptions of security and trustworthiness, moderate for users' feelings of positiveness toward the chatbots and for the perceived relevance of the recommended information, but only anecdotal for perceptions of the accuracy of provided information. Second, there was moderate evidence that users viewed the menu-driven chatbot as more user friendly than the conversational chatbot, though the effect size only approach the cutoff to be considered small. Finally, there was anecdotal evidence suggesting that overall trust scores may have favored the menu-driven chatbot over the conversational chatbot. However, this interpretation requires 2 caveats: the effect size here was trivial, and any difference likely reflects differences in perceived user-friendliness. Together, these findings suggest that users generally reported equivalent trust for conversational and menu-driven chatbots, but that the conversational chatbot may need to be refined to improve usability.

Table 3. Mean (SD) for, and Bayesian paired samples 2-tailed t tests comparing, trust scores for the menu-driven and conversational chatbots.

Variable	Menu-driven chatbot, mean (SD)	Conversational chatbot, mean (SD)	BF_{10}[a]	δ (95% CrI[b])
Accuracy	3.54 (0.93)	3.42 (0.96)	2.46[a]	0.12 (–0.01 to 0.25)
User-friendly	3.62 (0.91)	3.45 (1.00)	3.09	0.18 (0.05 to 0.31)
Secure	3.51 (0.89)	3.48 (0.93)	10.65[a]	0.04 (–0.09 to 0.17)
Trustworthy	3.50 (0.91)	3.50 (0.94)	13.18[a]	0.01 (–0.12 to 0.14)
Positiveness	3.51 (0.88)	3.44 (0.93)	6.42[a]	0.08 (–0.05 to 0.21)
Recommended relevant	3.70 (0.90)	3.59 (1.02)	3.49[a]	0.11 (–0.02 to 0.24)
Overall trust	3.56 (0.71)	3.48 (0.76)	1.45	0.16 (0.03 to 0.29)

[a]Indicates Bayes factor (BF_{01}) expressing evidence in favor of the null/equivalence across chatbot types.

[b]CrI: credible interval (around the effect size).

XSL•FO
RenderX

When examining gender effects on overall trust, Bayesian independent samples *t* tests revealed anecdotal (BF_{01}=2.40; δ=0.19, 95% CrI –0.07 to 0.45) and moderate evidence for the null (BF_{01}=5.12; δ=0.09, 95% CrI –0.17 to 0.36) for the menu-driven and conversational chatbots, respectively. Thus, for both types of chatbot, female and male users reported similar levels of trust (mean 3.62, SD 0.63 and mean 3.48, SD 0.82, for female and male users rating the menu-driven chatbot; and mean 3.51, SD 0.70 and mean 3.43, SD 0.84, for female and male users rating the conversational chatbot).

User Preferences

Despite evidence of greater user-friendliness when considering the trust-related factors, when participants were asked directly which chatbot was easier to use, there was no difference between the conversational (118/224, 53% of participants) and the menu-driven (106/224, 47%) chatbot, with a Bayesian binomial test revealing moderate evidence in favor of the null (BF_{01}=8.70). However, when asked which chatbot was most helpful, there was anecdotal evidence supporting a preference for the conversational (131/224, 58%) over menu-driven (93/224, 42%) chatbot (BF_{10}=2.10).

Taken together, our findings suggest that although there were subtle differences in user-friendliness and overall trust between the menu-driven and conversational chatbot systems, these differences were not substantial enough to practically impact users' perceptions of trust across chatbots. Trust levels for each chatbot were consistently just above the neutral midpoint, indicating a generally positive perception. When students were explicitly asked which chatbot they would prefer to use if they were to seek help, a majority appeared to favor the conversational chatbot (92/224, 41%), over a menu-driven chatbot (74/224, 33%) or choosing neither system (58/224, 26%). However, a Bayesian multinomial test run in the *JASP* statistics package [68] provided anecdotal evidence for the null (BF_{01}=1.96), suggesting there was no statistical evidence for a preference regarding chatbot type.

Students provided 245 comments when indicating their preference for a chatbot. Slightly more commentary was provided regarding the conversational chatbot (n=88 in comparison to n=75 that specifically focused on the menu-driven chatbot), and of these 88 comments, a total of 66 were comments that supported the use and features of the conversational chatbot. These codes directly mentioned easy or easier use or interaction or understanding (n=12), being friendlier (n=1), more realistic (n=8), more relatable (n=2), more helpful (n=5), like a person/human (n=6). The codes also mentioned a greater flow of conversation (n=6) and the ability to frame the issue in their own words (n=14). Students also spoke about the conversational chatbot's ability to tailor the conversation or interaction to their specific problem (n=5). Students spoke of the perception of the conversational chatbot taking the burden of the problem (n=4) and helping them navigate to meaningful resources (n=4). Of the 75 menu-driven chatbot comments, a total of 65 were in support of the use and features of the menu-driven chatbot. These codes directly mentioned easy or easier use or interaction or understanding (n=10), being efficient (n=5), more realistic (n=8), access to resources (n=11), more helpful (n=5), quick access to information (n=3), and helpful when interacting due to a menu, prompt, or list of options (n=8). Students found the menu-driven chatbot less invasive (n=5), found that the menu prompts helped frame the issue they were facing (n=6), and preferred the option of not having to type (n=5). Concepts of "trust" were directly mentioned (n=6); however, these were either in the context of not trusting AI, "AI doesn't feel supportive or trustworthy," or in defining what a trusted person would look like ("Trusted person would be patient").

Students differed in terms of their prior experience with chatbots similar to the conversational one used in this study, with the majority of participants (134/224, 60%) reporting no previous interaction with a similar conversational chatbot, while 33% (73/224) had prior experience, and 7% (17/224) were uncertain about their past interactions. A user's degree of prior experience with similar chatbots may adversely affect participants' perceptions of the conversational chatbot regarding overall trust and user-friendliness. However, prior experience did not affect either overall trust (BF_{01}=13.04) or perceptions of user-friendliness (BF_{01}=9.35; Table 4 provides descriptive statistics).

Table 4. Mean ratings of overall trust and user-friendliness for the conversational chatbot, according to prior experience with conversational chatbots.

Measure	Response	Rating, mean (SD)
Overall trust	Yes	3.44 (0.82)
Overall trust	No	3.49 (0.75)
Overall trust	Unsure	3.52 (0.62)
User-friendliness	Yes	3.37 (1.07)
User-friendliness	No	3.47 (0.97)
User-friendliness	Unsure	3.65 (0.86)

Unsurprisingly, anonymity emerged as a significant concern among students, with 69% (155/224) expressing a preference for anonymous interactions with an online safety chatbot; only 10% (22/224) preferred nonanonymous interactions, while 21% (46/224) were undecided. These results confirm the importance of user privacy to adolescents in an e-safety context. When asked about personalizing a conversational chatbot, such as giving it a face or name, 39% (88/224) favored personalization, 34% (75/224) preferred a nonpersonalized chatbot, and 27% (61/224) were uncertain, demonstrating no significant preference for personalization of the chatbot. Thus, while some users may want a more engaging and relatable interaction with the chatbot,

XSL•FO
RenderX

others do not perceive the need to add human-like characteristics in this context.

Students directly mentioning the conversational chatbot included some concerns or issues with the conversational chatbot (n=11). These comments were focused on unhelpful responses from the chatbot (output did not make sense from input given, n=5), causing the student to hesitate in interaction (due to needing to type out the issue, n=1), perceiving to not provide advice (n=1), causing greater distress (due to misunderstanding from the chatbot, n=1), or uncomfortable (n=1), hard (n=1), and artificial (n=1) to interact with. Student comments directly mentioning the menu-driven chatbot also included concerns or issues with the menu-driven chatbot (n=6). These comments focused on the menu-driven chatbot's inability to handle or misunderstand student queries (n=3), the perception of the platform as more closed off (n=1), unhelpful (n=1), and limited in the range of topics it could offer advice on (n=1).

Of the remaining 82 comments (total comments n=245), students spoke about a negative view of turning to AI. Some students did not feel they could trust (n=3) or turn to AI (n=2), and some felt that using AI for help with online harms was inappropriate (n=8). Some students preferred to turn to people they trust (n=9) or look up the information themselves (n=5). Some students stated they did not prefer either chatbot (n=10). While others did not have a clear answer (n=2) or did not know which chatbot they preferred (n=10). However, some identified that both chatbots were appropriate/relevant resources (n=5). A few students expressed feeling confused (n=2) or frustrated (n=1) by the responses provided by either (or not specifically named) chatbots. The students identified the potential serious consequences of chatbots failing to provide correct or meaningful interaction during crises (n=2). Students directly spoke about improving the conversational chatbot (n=10), noting its limited conversation abilities and the need for trust in the interaction (n=6), as well as a more human-like approach to engage users (n=2). Additionally, students spoke about the need for the chatbot to provide advice, not just links (n=5), and felt that better options were already available (n=4). Thus, overall, students identified the importance of improving chatbots for more meaningful interactions and advice, highlighting the need for trust and a human-like approach.

Summary of Key Findings

A substantial percentage of respondents (87/224, 39%) expressed a willingness to seek help outside their family and social circle when dealing with online harms, and approximately 60% (conversational chatbot: 141/224 and menu-driven chatbot: 142/224) of respondents engaged with our chatbot systems. When dealing with chatbot systems, our results highlight 2 related issues of importance. First, trust was strongly associated with willingness to click links provided by our chatbots. Perceptions of trust were generally similar across chatbot types and for male and female participants. Second, most respondents (155/224, 70%) expressed a preference for anonymity when dealing with chatbot systems. Thus, to be effective, and capitalize on adolescents' willingness to seek external support, chatbot systems must be able to build and maintain trust with users, and it will be necessary to assure users of their continued anonymity.

Discussion

Overview

Adolescents' vulnerability to online dangers, and the associated potential negative impacts on their mental well-being, highlight the urgent need to address cyber safety issues among young people. It is essential to provide young people easy access to trustworthy information and support. Chatbots represent a promising tool in addressing cyber safety concerns, offering convenient access to established and reputable support services, and helping link students with appropriate clinical support providers. We explored whether trust in chatbot systems was influenced by the design of the chatbot. Examining students' perception of 2 chatbot systems, a menu-based and conversational chatbot, in terms of key trust-related factors could inform the development of an effective user-centered chatbot in the educational online safety context.

Trust and Chatbot Efficacy

Individuals usually need to feel trust before following recommendations [11,17-19,21]. Thus, establishing and maintaining trust in an e-safety chatbot is vital to ensure adolescents are comfortable using the system and receptive to its suggestions for online safety resources. Comparing adolescents' perceptions of trust for menu-driven and conversational chatbots allowed us to examine which interaction method and design approach better suited students' preferences. As trust is multifaceted, we evaluated how key trust-related factors (ie, perceived accuracy of information, user-friendliness, appropriateness of the chatbots' recommendations, and feelings of trustworthiness, security, and positivity toward the interaction) impacted overall trust across chatbot systems. Both chatbots were viewed more positively than negatively in terms of overall trust, indicating that they are both viable options for a trusted online safety chatbot. When students were directly asked which chatbot they would prefer for seeking help, there was some evidence for equivalence, suggesting no meaningful difference between the 2 options, despite a higher number of students endorsing the conversational chatbot over the alternative. Student comments supported the endorsement of the conversational chatbot, highlighting its "conversational nature" and "interactive" elements that simulated real-life conversations, "it was easy to communicate with and share my deepest and darkest thoughts" and "You are able to describe what you need help with in greater detail." The perceived ability for the conversational chatbot to emulate person-to-person interaction facilitated some preference for this mode of delivery, "the conversational one was easier to understand and felt like i was talking to someone rather than clicking a menu." However, there remains room for improvement based on the mean trust ratings.

Help-Seeking Behavior

Over a third of participants were open to seeking help beyond their friends and family, indicating that many young people could benefit from support provided by an online safety chatbot.

XSL•FO
RenderX

Further, there is a positive link between the intention to use tech tools, like chatbots, and their actual usage [44]. Thus, to assess users' readiness to engage with the chatbot's recommended resources, we included clickable help links to external support sites and asked users whether they clicked a link. The majority of students reported clicking a support link, with no difference between chatbot systems, indicating the interface type did not impact the likelihood of accessing recommendations for further assistance. Links were perceived by students as being helpful, with one student mentioning, "it provides useful links for kids/teens in a way that makes them feel more comfortable without seeking outside help." However, another student suggested integrating the links into the conversation, "the links should be embedded into script rather than just being a plain link, it is not a big step but it definitely makes you more likely to click on a link." There was some, albeit weak, evidence that males were less likely than females to click on help links, aligning with the well-documented gender disparity in help-seeking behavior [69]. Although participants in this study reported identifying as either male or female, it is also important to consider the perspectives of gender-diverse populations, as this at-risk group often faces extra challenges and unique concerns. Understanding specific gender-related issues that could hinder help-seeking is important for developing an inclusive online safety chatbot that caters to all young people. Unfortunately, gender-diverse populations were under-represented in our sample.

Trust was an important factor in user behavior within chatbot interactions, as the level of trust students had in the chatbot was related to the likelihood of clicking a link (engaging with a linked support service) within the chatbot interaction. Additionally, we found choosing to click on a link was related to a higher sense of positivity regarding that choice, as opposed to opting not to press a link. The underlying mechanism here can be interpreted in different ways. One possibility is that a feeling of positivity arises from the decision itself, suggesting an associated sense of satisfaction in taking a proactive step toward seeking help. Alternatively, it could reflect a preexisting state of positivity or readiness to engage with the provided resources, influencing the decision to press the help link. Further examination of these mechanisms might provide greater understanding of users' decisions to seek help and their interactions with a chatbot, particularly concerning the inclusion of links to external support resources and how they perceive these resources. This may inform strategies aimed at improving the chances of adolescents accessing online support when needed.

Design Implications: Empathy, Personalization, and Anonymity

To explore students' interest in an online safety chatbot, we used a simple conversational chatbot, which operates with predefined outputs that are matched to conversational intents. Thus, although the current results serve as a useful proof of concept, the data from this study also highlight potential areas of improvement, particularly in terms of increasing cognitive trust (through accuracy and user-friendliness) and affective trust (through empathetic responses and personalization). The simple conversational chatbot appeared to struggle at times when handling students' written input. One student expressed this frustration: "Sometimes I found it hard to specifically say the situation and get the bot to understand." An inability to handle requests effectively may have lowered trust in the chatbot's competence and would seem like a substantial issue in applied settings. As another student noted, "it just kept saying "please re-phrase that" or "thats [sic] not relevant to the issue" when it was." These issues will need to be addressed to improve user experience and effective delivery of online safety support. User-friendliness could be improved by training the underlying machine learning model on training data from adolescents to better establish the user intent. The current chatbot was primarily trained on adults, with input from only a handful of younger adults, and based on comments made during the focus groups conducted during the co-design process. Additional sampling of several hundred, or thousand, students could create a much larger training dataset to produce a more robust model of user intent (the ethics approval for this study precluded the evaluation data being used as a training dataset for the model). While a menu-driven chatbot's simple interface with clear options makes navigation easy, predictable, and reliable, its standardized interactions may reduce emotional connection with users. In contrast, a conversational chatbot can be more emotionally engaging due to its capacity for natural language and empathetic responses. The simple conversational chatbot used in this exploratory study was focused on delivering support links and had limited natural interaction and empathic capabilities. Based on feedback from students (ie, the intended users of the chatbot), it seems that there was a desire for a more empathetic and personalized chatbot. For example, one student stated:

> *The understanding of certain kid/teens phrases or slang… more of a response aside from a brief description and a link, something like what snapchat AI would respond with more care and emotion.*

Future research should explore enhancing empathetic interactions, such as using warmer language and including more reassuring phrases, as prior studies indicate the potential benefits of a strengthening the user connection with the chatbot [2,70-74]. By incorporating these improvements into future designs, we may create an engaging and informative system, leading to a positive user experience and effective delivery of online safety support.

Personalization features, such as giving a chatbot a face or name, have the potential to enhance user engagement and satisfaction by creating a more personalized and human-like experience [30,71]. However, our current findings indicate that while some users want a more engaging and relatable interaction with the chatbot, others do not see the need for human-like characteristics. One student stated, "I think that if the chatbot was personalised it would help develop more of a connection with those seeking support and as though they aren't talking to a robot" while others preferred a nonpersonalized chatbot, explaining:

> *Having a non personalised Chatbot makes the information feel more trustworthy and reliable…" and "Giving the chat bot a face would also make it*

XSL•FO
RenderX

harder to communicate your problems, I believe it should be similar to a confessional booth.

This was surprising, as studies have found including a human-like visual cue in a chatbot can improve trust and reduce the psychological distance between the user and the chatbot [3,33,71,75]. However, the opposition, or hesitation, to personalization among some participants may stem from concerns related to privacy—known as the "valley effect," where users become increasingly concerned about privacy as technology becomes more human-like in its interactions [76,77]. Thus, if personalized features were to be incorporated in future designs, there may be a need to clearly address concerns related to privacy to ensure users feel comfortable and trusting in their interactions with the chatbot.

Anonymity was a significant concern among the students, with an overwhelming preference that an online safety chatbot should be anonymous. When users feel confident that their conversations are confidential, they are more likely to engage openly and honestly with the chatbot. One student noted that "Having the chatbot clearly anonymous will encourage openness" while another explained, "Anonymity is essential for someone to share their true, unfiltered opinions on the internet, to a 'secure' bot or to another person." Many users may be dealing with sensitive issues, such as online harassment, image-based abuse, substance abuse, or mental health challenges. They may feel a sense of shame or embarrassment if this information becomes known. As one student noted, "Having this privacy could encouraged [sic] those that may be embarrassed by their situation or not willing to share when their name is attached to it." Another mentioned, "…it provides the person in need with a safe outlet whilst also giving them a reliable source that they dont [sic] have to be ashamed about." The sharing of personal information can facilitate better support and guidance tailored to their individual needs. A chatbot service can provide a safe, confidential space for adolescents to share their concerns to help them navigate their problems. On a related note, it will be vital that data security measures ensure the privacy and confidentiality of any data supplied by users accessing a chatbot system like this in applied settings. Any misuse of data provided by users would not only be extremely unethical, but would rightfully damage users' trust in the chatbot system and consequently negate its efficacy.

Limitations

Given that this is a proof-of-concept study, there are limitations to the generalizability of the results obtained. Some of these limitations relate to the number and nature of vignettes explored and to the nature of the sample tested. Obviously, a chatbot may be accessed as a source of support by individuals experiencing a wide range of personal circumstances, and our stimulus and participant sampling does not provide a comprehensive representation of population of interest (eg, our data do not speak to how user characteristics like ethnicity, gender diversity, or sexual orientation affect the actual or perceived utility of the chatbot). Moreover, although our data are promising and serve as a proof-of-concept, promising findings in controlled, simulated testing environments do not guarantee efficacy in field settings. Thus, although our data provide initial support for the utility of chatbots in supporting the needs of adolescents at risk of online harms, further work is required to establish the generalizability of these findings. Further, there are aspects of trust and of chatbot technology that require additional attention. A trust-related factor we did not examine, but that requires attention, is that trust in technology systems can be influenced by the credibility of the organization involved, and their knowledge base (ie, that provides advice and guidance) [78]. In the context of health-related services, trust in the health information provider is crucial in increasing compliance with professional advice [79,80]. If the associated organization lacks credibility, people are less likely to follow recommendations [11,21]. However, as adolescents have identified schools and reputable online safety websites as their preferred sources for accessing online safety information [45], a school- or community-based system has the potential to gain students' trust. Thus, in the context of an online safety chatbot, its association with reputable institutions like schools and government-funded organizations dedicated to online safety (eg, Butterfly Foundation, Headspace) may improve access to quality support for cyber safety issues.

Another issue is that chatbot technology continues to evolve, as large language models (LLMs) provide an opportunity to create more lifelike and realistic dialogue. These LLMs are advanced AI models trained on vast amounts of text data, which could be selected to be appropriate and realistic for an adolescent audience. They are capable of ingesting and then generating human-like text across a wide range of topics. While LLMs are not specifically chatbots, they can be used as the underlying technology for conversational agents. They excel at generating coherent and contextually relevant responses to user input, even in complex conversational scenarios. LLMs are highly versatile and can be fine-tuned for specific tasks, including chatbot applications, content generation, and language translation. Such chatbots, as with the curated set of resources used in the chatbot in this study, will require maintenance, as LLMs are only aware of resources and supports contained within their training datasets. Currency and relevancy of support provided will be an ongoing challenge for each chatbot architecture.

Conclusion

Young people understand the value of obtaining more information about online risks, not only to deal with their own negative experiences but also to support others in similar situations [45]. This information also plays a role in promoting responsible online behavior, as teens might unknowingly cause harm due to their limited understanding of legalities, consent, and privacy. An online safety chatbot has the potential to serve as a valuable supplementary cyber safety resource alongside school support systems, such as pastoral care or school psychologists, with the aim to increase accessibility for adolescents navigating online safety challenges. Integrating a chatbot into schools' digital libraries, resources, or a student portal, can promote a collaborative approach to e-safety education and support. Online safety chatbots guided by a framework of trustworthiness can support users in navigating online risks and accessing valuable resources. In designing and deploying an online safety chatbot, it will be essential to build trust to ensure users feel emotionally connected and comfortable

XSL•FO
RenderX

with its use in navigating online risks. This technology-driven approach may be particularly helpful for those who prefer digital interactions or feel apprehensive seeking help directly from others. An online safety chatbot can offer a confidential and easily accessible space where adolescents can seek guidance and access information from reputable organizations dedicated to young people and online safety.

Funding

This project was funded through the eSafety Commissioner’s Online Safety Grants Program.

Authors' Contributions

JS, JP, and ER acquired the funding from the eSafety Commissioner’s Online Safety Grants Program. JS, JP, ER, MC, JDS, and PW conceived the studies, drafted the original paper, and edited the final manuscript. JS, ER, and JDS collected the data. JDS, MC, and ER performed the analyses.

Abstract

Background: Periorbital measurements such as margin to reflex distances, palpebral fissure height, and scleral show are critical in diagnosing and managing conditions like ptosis and disorders of the eyelid. However, deployment of automated periorbital measurement algorithms in structured research workflows remains limited by the lack of integrated capture and data management infrastructure.

Objective: We developed and evaluated Glorbit, a lightweight, browser-based application for automated periorbital distance measurement using artificial intelligence (AI). The objective was to evaluate end-to-end workflow feasibility of the platform under simulated, operator-run conditions.

Methods: The application integrates a DeepLabV3 segmentation model into a modular image processing pipeline with secure, site-specific Google Cloud storage, supporting local preprocessing and cloud upload through Firebase-authenticated logins. The full workflow—metadata entry, facial image capture, segmentation, and upload—was tested. After the session, the participants completed a Likert-style survey.

Results: Glorbit successfully ran on all tested platforms, including laptops, tablets, and mobile phones across major browsers. A total of 15 volunteers were enrolled in this study in which the app completed predefined workflow steps in all simulated, operator-run sessions. The segmentation model produced outputs on all images, and the average session duration was 101.7 (SD 17.5) seconds. Simulated experience scores on a 5-point Likert scale were uniformly high.

Conclusions: Glorbit is a cross-platform application that supports structured periorbital image capture and automated inference within a unified workflow. In simulated, operator-run testing, the platform demonstrated successful execution of predefined workflow steps across devices. These findings support the technical feasibility of the system as a research-oriented data collection framework and may inform future evaluations in broader research settings.

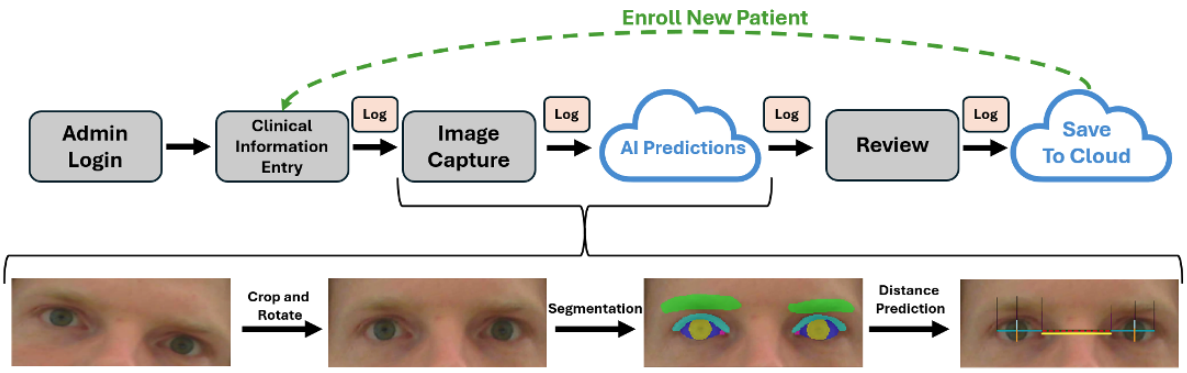
Introduction

Periorbital measurements such as margin to reflex distance 1 and 2 (MRD 1/2), palpebral fissure height, and scleral show are essential components of clinical assessment in a range of conditions, including ptosis, thyroid eye disease, and congenital craniofacial conditions [1-3]. These measurements guide surgical decision-making, track disease progression, and serve as important inputs for diagnosis [4-7]. However, manual measurement of these distances incurs substantial intergrader variability, even when trained graders performed the analysis [8,9].

Previous work has demonstrated that automated periorbital measurements from facial photographs can achieve clinically acceptable accuracy by using deep learning–based segmentation approaches [10,11]. For example, a trained DeepLabV3 model achieved mean absolute errors consistently below established intergrader variability thresholds for key measurements, including MRD1, MRD2, and intercanthal distance, with 86% of the measurements falling within intergrader thresholds. This approach also outperformed the benchmark method PeriorbitAI, successfully processing 100% of the images across diverse disease populations, including thyroid eye disease and craniofacial conditions, compared to 59%-85% success rates for PeriorbitaAI [10,12]. However, due to the lack of deployable infrastructure capable of integrating image capture, processing, and secure data management, both of these algorithms (and others) cannot be integrated into routine data collection workflows for research use.

In response to this gap, we developed Glorbit, a web-based application for artificial intelligence (AI)-based periorbital distance measurement and metadata capture. Rather than introducing a new periorbital measurement algorithm, the primary contribution of Glorbit lies in system integration or in the unification of image capture, local preprocessing, AI inference, metadata collection, and secure, site-specific data storage within a browser-based interface. This contribution is orthogonal to algorithm development, and as such, we focus exclusively on assessing workflow operability of the application rather than measurement accuracy, reliability, or readiness for clinical use. In this paper, we describe the system architecture and image processing pipeline and present a small, simulated feasibility study assessing end-to-end workflow execution and participant-perceived enrollment experience under controlled conditions.

Methods



Ethical Considerations

The simulated enrollment study was designed to evaluate technical operability and workflow execution rather than performance under real world clinical constraints. No direct identifiers (eg, name, date of birth, medical record number) were collected, and each participant was assigned a deidentified patient ID. Verbal consent was obtained in accordance with an institutional review board–exempt protocol (STUDY2025-0731). All captured images, derived measurements, and metadata were deleted following data analysis. No participant images or metadata were retained in persistent cloud buckets. Participants were not compensated.

System Overview and User Flow

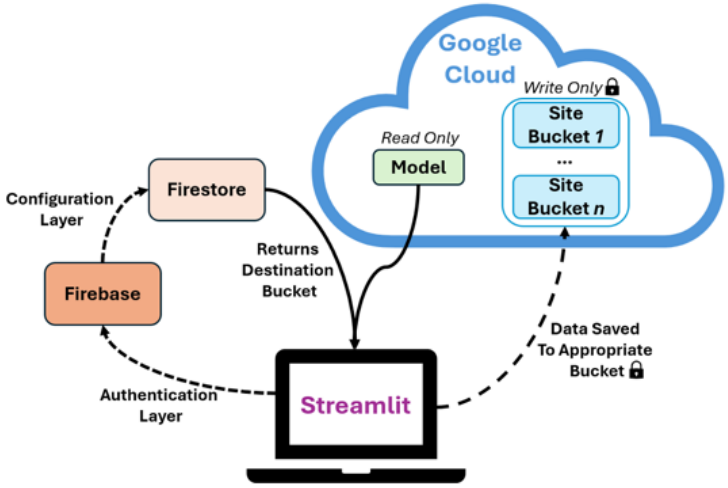
Glorbit is a browser-based application designed to support structured periorbital image capture and automated distance inference for research use. Upon login, authenticated users are presented with a structured form to collect brief patient history and visit metadata. This information is stored temporarily in session state within the browser. After submission, users proceed to an image capture page, where a webcam or device camera is used to capture a frontal facial image. The image is processed locally to generate segmentation and AI-derived distance measurements, which are then displayed for user review. Once confirmed, the image and associated metadata are uploaded to a secure, site-specific cloud storage location. Logging is integrated throughout the pipeline to capture system events, errors, and upload status. See Figure 1 for an overview of users' steps throughout the application.

Figure 1. Glorbit application workflow and artificial intelligence (AI) processing pipeline. The top row illustrates the user-facing app interface: a user logs in, enters clinical metadata, captures an image, reviews AI-predicted periorbital distances, and uploads results to cloud storage. Cloud-shaped nodes denote steps involving remote model inference or cloud-based data storage. All user actions, including reverse navigation, are logged. The bottom row depicts the backend image processing steps: cropping and rotation based on facial landmarks, semantic segmentation of key anatomical regions, and automated distance prediction using landmark geometry.

XSL•FO
RenderX

Image Processing Pipeline

Each captured image undergoes a predefined processing pipeline for anatomical alignment, cropping, and segmentation, as described by Nahass et al [10]. MediaPipe FaceMesh landmarks are used to rotate and align the image to a horizontal eye-level axis [13]. A region of interest is then cropped around the eyes and periorbital region. The aligned image is passed to a trained DeepLabV3 segmentation model for periorbital anatomic segmentation, followed by the geometric calculation of periorbital distances from the segmented output (Figure 1) [14]. In the event of a model failure, the app handles the error, logs the failure, and prompts the user to try again. The periorbital distance prediction model integrated into Glorbit was selected from prior work and was used without modification; evaluation of measurement accuracy, repeatability, and robustness was outside the scope of this study, which focused on platform feasibility and workflow execution.



Clinical Data

Glorbit captures a structured set of clinical metadata alongside each image to support contextual analysis and downstream modeling. At minimum, users are required to input a deidentified patient ID, age, and sex to proceed with the workflow. Optional fields include ethnicity (selected from a site-customizable dropdown list), relevant comorbidities (eg, thyroid eye disease, craniofacial conditions, prior eyelid surgery), visit type (new or follow-up), and image conditions (eg, use of tape, lighting notes). Sites may also enable the entry of laboratory values when available. Supported laboratory measurements include levels of alanine aminotransferase, aspartate aminotransferase, hemoglobin A_{1c}, estimated glomerular filtration rate, thyroid-stimulating hormone, thyroid-stimulating immunoglobulin, albumin-to-creatinine ratio, and calcium, with standardized units displayed next to each input. All metadata are stored alongside the captured image and the AI-derived periorbital distances in the designated site-specific cloud storage bucket. Only the required fields must be completed to advance to image capture; all other fields are optional and may be tailored to institutional needs.

Data Handling and Storage Architecture

The app frontend is built in Streamlit and deployed as a Docker container to ensure reproducibility. Firebase Authentication manages secure login, with role-based access control and per-site credentialing. Firestore is used to assign each user's upload path based on their authenticated credentials, enabling dynamic configuration of storage destinations. This allows a single instance of the app to be deployed across multiple locations without requiring hardcoded site-specific settings or local reconfiguration. Glorbit stores the following data elements: (1) cropped facial images, (2) AI-predicted periorbital measurements, (3) session-level metadata entered by the operator, and (4) system logs generated for debugging and audit. All data are encrypted at rest and in transit, and access rules are configured through Google Cloud Identity and Access Management policies. Glorbit is designed to operate on consumer-grade hardware and can be accessed on laptops, tablets, and mobile phones with integrated webcams. A graphical schematic of data movement from the operator's perspective can be found in Figure 2.

Figure 2. System architecture for secure authentication, configuration, and cloud-based storage within the Glorbit platform. Users authenticate via Firebase, after which Firestore provides site-specific configuration, including the destination storage bucket. The local Streamlit app reads artificial intelligence model weights from a centralized, read-only location in Google Cloud and writes collected data to site-specific, write-only buckets. All data transfers are protected using encryption at rest and in transit, as indicated by lock icons. Access control is governed via Google Cloud's Identity and Access Management framework.

Security Design

The primary data elements with potential status as Protected Health Information within the Glorbit workflow are cropped images of the periorbital region. While the removal of the full face reduces identifiability, we treat these cropped images as sensitive biometric data. To protect this information, all uploads utilize technical safeguards, including encryption in transit (TLS) and at rest (AES-256) via Google Cloud's native encryption [15-17]. Each deployment site is assigned a unique Google Cloud Storage bucket with Identity and Access Management roles that can be configured to restrict access by

XSL•FO
RenderX

site. Firebase Authentication enforces user-specific logins, and Firestore assigns site-level write access dynamically. Full event and error logging is implemented for auditability. The platform architecture incorporates technical safeguards commonly required for Health Insurance Portability and Accountability Act (HIPAA)-compliant workflows; however, compliance is conditional upon the specific deployment environment. Specifically, when deployed within an institutional environment governed by a Business Associate Agreement with the cloud provider, the system provides the necessary infrastructure to maintain a HIPAA-compliant data pipeline when appropriately configured [18,19]. In the absence of a Business Associate Agreement between an institution deploying Glorbit and the cloud provider, Glorbit is not HIPAA-compliant.

Internal Testing: Cross-Platform Compatibility

Glorbit was tested by a member of the study team (GRN) across multiple operating systems (Windows, iOS, ChromeOS), browsers (Chrome, Firefox, Safari), and device types (laptop, personal computer, smartphone, tablet) to assess basic cross-platform compatibility. Testing focused on verifying that core workflow components, including authentication, metadata entry, camera access, image capture, and execution of the image processing pipeline, functioned consistently across platforms. A workflow failure was defined as the inability to successfully complete any predefined step, including authentication errors, camera access failure, image capture failure, segmentation, or inference errors, resulting in missing outputs, upload errors, or logging failures. Failures were identified through user-facing error messages hardcoded into the pipeline, as well as through a review of system logs confirming completion of each stage. In addition, controlled negative-input scenarios such as the absence of a detectable face in the camera frame were manually tested to confirm appropriate system behavior, including user-facing feedback and event logging. These checks were performed to validate control flow and error handling rather than to quantify measurement accuracy. This testing was performed under natural indoor lighting conditions with 5 trial runs on each combination.

External Testing: Survey and Simulated Enrollment Testing

To evaluate participant-perceived enrollment experience, we conducted a simulated enrollment study with 15 adult volunteers (age ≥18 years) at the Illinois Eye and Ear Infirmary. Each session was conducted by a trained study operator (GRN) using a 2021 MacBook Air in a private room under natural indoor lighting conditions. The operator followed the standard Glorbit workflow, including metadata entry and facial image capture. Failures of the workflow were assessed using the same protocol as described earlier.

Following the simulated interaction, participants completed a brief anonymous survey assessing their experience immediately following the interaction. The survey included 5 Likert-scale items (1-5) evaluating perceived intuitiveness, perceived efficiency, clarity of workflow steps, self-reported confidence in the displayed outputs, and perceived potential usefulness in a clinical context. All responses were stored without any identifiers. This survey was intended to capture participant-perceived workflow clarity and general impressions following an operator-run simulated interaction; it was not designed to assess operator usability, measurement validity, or clinical readiness. Any reported confidence in the displayed outputs following the simulated interaction reflect participant perception only and does not represent validation of measurement accuracy.

Results

App Walkthrough and Cross-Platform Compatibility

Screenshots of the core workflow of Glorbit are shown in Figure 3, illustrating the minimalistic, stepwise interface. To assess platform execution, Glorbit was internally tested across multiple browsers, operating systems, and device types. Across all tested platforms, core workflow components, including authentication, form entry, camera access, image capture, execution of the image processing pipeline, and system logging, were executed without observed workflow interruption across tested configurations.

Table 1 shows the evaluated platforms and devices. In addition, controlled negative input scenarios were manually evaluated, including cases in which no face was detectable within the camera frame. In these scenarios, the system generated appropriate user-facing feedback and recorded the event in the application logs.

XSL•FO
RenderX

Figure 3. Screenshot of the Glorbit app interface. (A) The form used to input patient metadata, including demographics and comorbidities. (B) Face alignment guide with a live camera view for guided image capture. These two steps represent the only direct patient interactions aside from the final review and submission step.

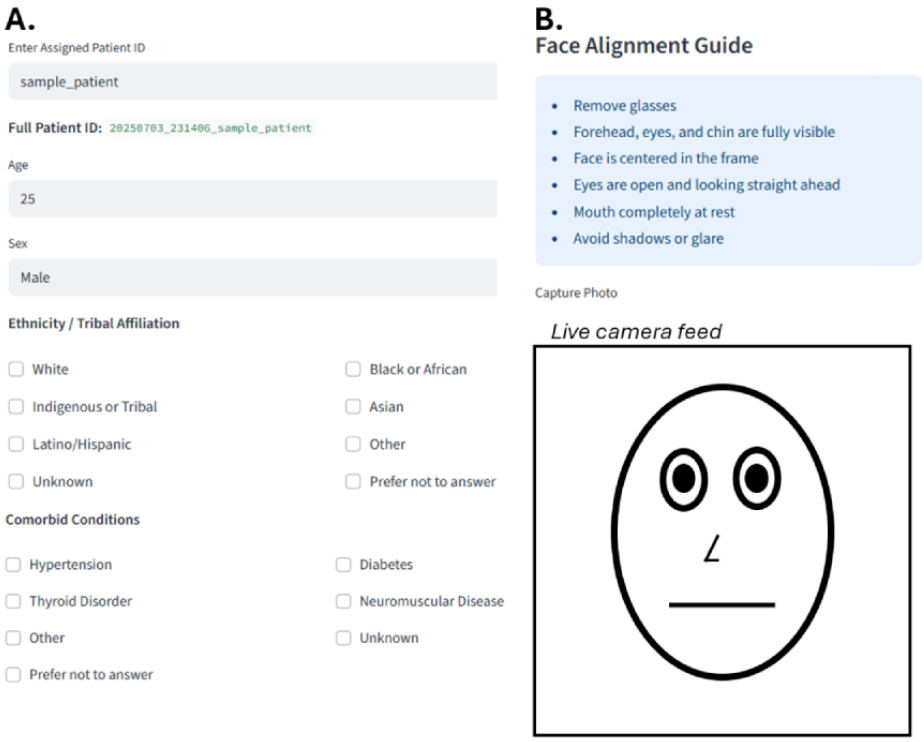


Table 1. Summary of the operating systems, device types, and camera sources that the workflow feasibility of Glorbit was evaluated on. Five execution runs were completed for each configuration.

	Operating system	Device type	Browser	Camera source
1	Windows	Desktop PC	Chrome	USB webcam
2	Windows	Desktop PC	Firefox	USB webcam
3	macOS	MacBook	Chrome	Integrated webcam
4	macOS	MacBook	Firefox	Integrated webcam
5	macOS	MacBook	Safari	Integrated webcam
6	ChromeOS	Chromebook	Chrome	Integrated webcam
7	iOS	Smartphone	Chrome	Front camera
8	iOS	iPad	Chrome	Front camera

Simulated Enrollment Performance

We enrolled 15 adult volunteers in a simulated enrollment study to assess the workflow operability of Glorbit under simulated operating conditions. Participant demographics are summarized in Table 2. The group's mean age was 32.6 (SD 11.0) years, was 67% (10/15) female, and spanned 5 self-identified ethnic groups.

In all 15 cases (100%), the app completed the predefined workflow steps (metadata entry, image capture, segmentation, and upload) in all the simulated sessions conducted by a trained operator. The segmentation model generated outputs in all cases, and no image processing or upload failures were observed under the tested conditions. The average session duration, measured from initial form entry to final upload, was 101.7 (SD 17.5) seconds on consumer-grade hardware (Figure S1 in Multimedia Appendix 1). Logging was successful in all cases, with system events and session metadata stored as expected.

Participant Perception of Glorbit

Following each session, participants completed a brief anonymous postusage survey to assess their perceived experience during the simulated interaction. These responses reflect participant perceptions following an operator-run simulated interaction and do not represent an evaluation of clinician usability, workflow performance in routine practice, or validation of measurement accuracy. Average responses were high across all 5 items (Table 3).

Participants rated the app as intuitive and efficient (both 5.0, SD 0.0), with high self-reported confidence in the displayed outputs (4.9, SD 0.3) and a high perceived comfort in a hypothetical clinical context (4.9, SD 0.3). Participants also reported clear understanding of each step in the data collection workflow (4.8, SD 0.4). Across all participant responses to all questions, 93.3% (70/75) of the responses were 5, 6.7% (5/75) of the responses were 4, and no 3 or lower were observed. The implications of this ceiling effect are discussed in the Limitations section.

Table 3. Summary of participant feedback from postsession surveys in the simulated enrollment study. Each participant (N=15) rated 5 statements on a 5-point Likert scale (1=strongly disagree, 5=strongly agree).

Statement	Average rating, mean (SD)
The Glorbit app was intuitive and easy to use.	5.0 (0.0)
The process of capturing and uploading patient data was fast and efficient.	5.0 (0.0)
I would feel comfortable using this tool in a clinical setting.	4.9 (0.3)
I understood each step of the data collection process.	4.8 (0.4)
I have confidence in the displayed outputs.	4.9 (0.3)

Discussion

Principal Findings

Many periorbital distance prediction algorithms have been developed in recent years, but their utility as broader research tools remains limited by the absence of deployable infrastructure [9,12,20-22]. In such contexts, there is a need for lightweight and secure systems capable of image capture, processing, and storage that can be employed within structured data collection workflows. To meet this need, we developed an internet browser–based app, Glorbit. Glorbit does not introduce a new periorbital measurement algorithm; instead, its primary contribution lies in the integration of existing periorbital measurement models into a unified system that supports image capture, inference, metadata collection, and secure storage. Periorbital distance measurement is a property of the underlying AI model rather than the deployment platform itself, and therefore, evaluation of this was outside the scope of this study, which was designed to assess the workflow operability of Glorbit.

In a simulated study of 15 participants, Glorbit completed predefined workflow steps (metadata entry, image capture, segmentation, and upload) in all simulated sessions conducted under operator-run conditions. These findings reflect successful technical execution of the workflow under simulated conditions and should not be interpreted as evidence of field readiness or validated clinical usability. The uniformly high survey ratings reflect participant-perceived workflow clarity following an

XSL•FO
RenderX

operator-run simulated interaction and do not represent an evaluation of clinician usability, workflow performance in routine practice, or clinical utility. Glorbit provides error messages and logs all user movement in the event of a failure (which were not observed in the simulated user study). This error handling is intended to provide administrators with detailed diagnostic information for troubleshooting workflow interruptions during future testing or deployment.

Additionally, the complete end-to-end workflow duration through Glorbit was short, with a mean session time of 101.7 (SD 17.5) seconds, inclusive of clinical metadata entry and user review of AI generated outputs. For contextual reference, prior studies have reported longer durations for traditional periorbital measurement workflows, including assisted measurement using ImageJ toolkits (327, SD 116 s) and purely manual measurement (804, SD 204 s) [23]. These previously reported values were obtained under different study designs and are provided here for qualitative context rather than as a direct efficiency comparison. Additionally, these timing results were obtained during simulated, operator-run enrollments and may not generalize to routine clinical or real-world research settings.

To date, several mobile apps have been developed for facial measurement. However, these tools primarily focus on interpupillary distance and do not include integrated metadata capture or cloud upload functionality for research workflows [24,25]. Glorbit is designed to include a combination of site-specific secure cloud storage and a modular architecture that can be deployed across institutions without requiring local IT infrastructure. Table 4 summarizes selected functional characteristics of Glorbit and other facial measurement tools, emphasizing deployment features rather than measurement accuracy or clinical validation.

Table 4. Comparison of Glorbit to existing facial measurement platforms.

Platform	Cloud storage[a]	Measurement type[b]	Open source	Primary function
Glorbit	Yes	MRD[c]1, MRD2, PFH[d] (48 distances)	Yes	Integrates inference, metadata forms, and storage
MediaPipe [13]	No	Facial landmarks	Yes	Google tool for face mesh detection
OpenFace [26,27]	No	Facial landmarks	Yes	Academic tool for facial behavior analysis, can extract 68 landmarks

[a]Cloud storage reflects availability of integrated cloud upload functionality.

[b]Measurement type describes the anatomical features or distances quantified by each system.

[c]MRD: margin to reflex distance.

[d]PFH: palpebral fissure height.

In addition to serving as a storage repository for providers, the captured data could potentially be used as future training data to create patient-specific models. One of the most persistent barriers to equitable AI is poor model generalization to underrepresented populations, often due to data captured under different conditions being out of distribution to the original training set [28-32]. Glorbit is designed to facilitate ethically governed data collection across diverse sites, which may support future efforts to improve model generalization. If integrated into research workflows, structured image and metadata capture could support the development of more representative, generalizable models through real-world data acquisition and iteration. Further strengthening the motivation for large-scale collection of high quality data is the developing field of Oculomics, which aims to leverage deep learning to make predictions about systemic health from images of the eyes [33-37]. While most current Oculomics research focuses on retinal imaging, recent studies have shown that external eye photographs can also be used to predict systemic biomarkers such as alanine aminotransferase, aspartate aminotransferase, and hemoglobin A_{1c} [38-40]. With the increasing number of foundational ophthalmic deep learning systems, having specific multimodal datasets available for finetuning may support future development and evaluation of downstream predictive models.

An important consideration for potential future deployment of tools like Glorbit in clinical settings is the protection of patient privacy and compliance with institutional and national data governance requirements. While the platform utilizes cropped periorbital images to minimize identifiability, these data elements are treated as sensitive biometric information requiring protection. Consequently, deployment within a regulated clinical environment would require the establishment of a Business Associate Agreement between the deploying institution and the cloud service provider to ensure HIPAA security requirements are met. Glorbit's architecture is designed to incorporate technical safeguards (access control, end-to-end encryption, and audit logging) commonly required for HIPAA-compliant workflows when governed by such an agreement [18,19]. However, institutional oversight remains a necessary component of medical AI deployment, as the software's compliance status is conditional upon the host site's administrative and security configurations. To promote transparency and allow for local adaptation and compliance with patient protection laws on a per nation basis, Glorbit is fully open-source.

Limitations

This study represents an initial feasibility evaluation and should be interpreted in that context. The simulated enrollment involved a modest number of participants (N=15) and was designed to assess workflow operability, system stability, and platform execution rather than to formally evaluate usability using standardized instruments or to assess performance across diverse clinical users and settings. As such, measurement validity, repeatability, and robustness of the underlying periorbital distance prediction models were not assessed here. Although

XSL•FO
RenderX

the simulated enrollment cohort included participants from multiple self-identified ethnic groups, the small sample size precluded meaningful subgroup analysis as well as drawing conclusions regarding reliability in real-world settings. Taken together, this study does not assess demographic-specific measurement accuracy, robustness across lighting conditions, or device-related biases—all important factors in computer vision applications. These factors represent known risks for facial analysis systems and will require dedicated, adequately powered evaluations in future studies.

In addition, sessions were conducted by a trained operator on a convenience sample, and participant feedback reflects perceived clarity and comfort following observed system interaction. As such, these ratings should be interpreted as indicators of basic workflow acceptability rather than sensitive or discriminative measures of usability performance and may not generalize to a larger population. Additionally, survey responses demonstrated strong ceiling effects, likely reflecting the controlled, operator-run nature of the simulated enrollment sessions. Future assessments of user experience (as opposed to participants) should incorporate standardized usability instruments and comparative study designs.

Finally, operator-facing usability and workflow burden were not formally evaluated in this study and would require evaluation in clinician-operated studies. Similarly, while the system architecture was engineered to permit offline use with local data storage, these capabilities were not evaluated here. Future work should include larger, clinician-operated evaluations across multiple sites to further assess usability and performance under routine clinical conditions.

Acknowledgments

The study team would like to gratefully acknowledge Alexander Schönjahn from Quina Care. We also thank our funders.

Funding

This study was supported by an unrestricted grant from Research to Prevent Blindness, a donation from the Cless Family Foundation, and the National Institutes of Health P30 EY001792 core grant. The funding organizations had no role in the design or conduct of the study; collection, management, analysis, or interpretation of the data; preparation, review, or approval of the manuscript; or decision to submit the manuscript for publication.

Authors' Contributions

GRN conceived the study, designed the system architecture, implemented the application, conducted testing, analyzed data, and drafted the manuscript. JvdE contributed to study design, manuscript writing and editing, and served as the primary global health liaison for deployment planning. BB assisted with coding and technical implementation. SH and JDE supported user interface development, usability testing, and manuscript editing. BK and CB facilitated ethical compliance and institutional review board processes. RVPC, PS, JWL, DY, and AQT provided critical oversight, domain expertise, and manuscript review. All authors approved the final version of the manuscript.

Conflicts of Interest

SH reports stock or stock options in Horizon Surgical Systems. PS reports consultancy for Oyster Point Pharma and Viatris and is a board member of the American Society of Ophthalmic Plastic and Reconstructive Surgery; he also reports stock or stock options in Lodestone Pharmaceuticals. AQT reports grants from the Illinois Society for the Prevention of Blindness and consultancy for Genentech/Roche. No other disclosures are reported.

Abstract

Background: Artificial intelligence (AI) is increasingly recognized for its potential to transform cancer care. However, much of the existing evidence of its efficacy comes from controlled settings. There remains a need to complement this knowledge with insights into how AI tools are perceived and used in real-world clinical settings, as well as how their use impacts clinical practice.

Objective: This study aimed to explore key factors influencing clinicians' acceptance of AI tools and examine how AI adoption and use impact clinical workflows in cancer care.

Methods: We used purposive sampling for recruiting oncology-related health care professionals and collected data using web-based semistructured interviews to gather their perceptions. Data were thematically analyzed and interpreted through the lenses of sociotechnical systems theory and the Unified Theory of Acceptance and Use of Technology.

Results: Participants largely accept and perceive AI tools as beneficial to clinical practice. Unified Theory of Acceptance and Use of Technology constructs were reflected in our data as determinants of intention to adopt AI tools. Trust appears as an influential factor in shaping attitudes toward AI tools. Acceptance is found to both precede AI tool use and to grow following successful integration. The use of AI tools is perceived to yield operational benefits, such as reduced workload and time savings, and clinical benefits, such as increased diagnostic reliability and reduced patient recall. Minimal disruption to clinical workflows following integration of AI tools was reported for some cancer screening applications and organ-at-risk segmentation, whereas greater disruption was anticipated for 3D cancer screening. Although accountability and lack of explainability are highlighted in literature as barriers to AI adoption, participants do not view these as significant obstacles in image-based diagnostic contexts. Additionally, negative impacts, such as overreliance on AI and reduced critical review of AI results, arise in association with the use of AI tools.

Conclusions: Participants perceive AI tools to deliver benefits to clinical cancer care. However, their adoption relies on their alignment with clinical needs and seamless integration into clinical workflows. To encourage clinician acceptance, the identified concerns must be addressed. Future work should focus on training programs, co-design with clinicians, and exploration of mitigation strategies for emerging adverse effects, such as automation bias and potential skill erosion.

Introduction

Background

Amid the staggering number of cancer incidences worldwide, artificial intelligence (AI) promises a better future, improving efficacy through faster and more accurate health care decisions [1,2]. This promise can make a huge difference in oncology, where the fight against cancer places a high demand on health care resources, while also being challenged by a workforce shortage. AI is increasingly integrated into various stages of cancer care, including tumor detection, diagnosis, clinical decision-making, risk stratification and prognosis, treatment planning, drug response prediction, and clinical research [3,4]. Although AI has transformative potential in health care and an increasing number of AI products on the market, the number of clinically implemented AI tools is still relatively low [5]. In oncology, evidence of AI's clinical impact is still limited [4], and there is a lack of understanding regarding how AI is perceived, accepted, and used by clinicians in real-world settings. Juluru et al [6] draw attention to the difficulty of deploying AI tools into the workflow of clinical practice, which poses a challenge to their adoption. While different workflow models have been evaluated in controlled settings, Verma et al [7] highlight that a clear gap exists between research and clinical environments, emphasizing the need for more focus on the role

XSL•FO
RenderX

and impact of AI in clinical settings. To bridge this gap, empirical studies are needed to investigate the integration of AI tools into clinical workflows [8] and verify the benefits of AI tool use in the real world [9].

AI can be defined as the ability of machines to perform cognitive functions usually associated with the human mind, such as perceiving, reasoning, learning, interacting with the environment, problem-solving, decision-making, and even demonstrating creativity [10]. These qualities set AI technologies apart and present unique challenges and opportunities that influence user acceptance. In this study, AI tools refer to AI systems, primarily, but not exclusively, based on machine learning and deep learning techniques, designed to perform clinical tasks relevant to cancer care. The value of AI tools in practice can only be fully realized if such technologies are integrated into routine clinical workflows [11,12] and if clinicians are willing to accept and use them [13]. As prior research has shown, user acceptance plays an integral part in any technology's success [14,15]. Acceptance of AI by clinicians is crucial for its successful integration into clinical practice. AI acceptance depends on how clinicians perceive its impact on their work processes and professional environment [13]. Despite the growing body of research, few studies have examined cancer care-related firsthand perspectives. Furthermore, most prior work has emphasized technical performance, leaving a gap in understanding how AI integrates into real-world clinical workflows. Finally, while acceptance models (eg, Unified Theory of Acceptance and Use of Technology [UTAUT]) and sociotechnical perspectives (eg, sociotechnical systems [STS] theory) have been applied separately, their combined use offers a rich account of how technical, social, and organizational factors jointly influence AI adoption.

This study, therefore, explores clinicians' perceptions of the use of AI in clinical practice. It aims to identify factors that influence clinician acceptance and the successful integration of AI into routine workflows. We ask the following research questions:

1. What are the perceptions of health care professionals on the integration and use of AI in oncology clinical practice?
    a. How does the adoption and use of AI tools impact the clinical workflow in cancer care settings?
    b. What factors influence clinician acceptance of AI tools in cancer care settings?

We draw from the STS theory and the UTAUT as lenses for interpreting our data. This study contributes an empirically grounded understanding of AI acceptance and integration from the perspective of clinicians. It identifies and consolidates key factors influencing adoption while highlighting the complex interplay between organizational dynamics, human factors, technological characteristics, and environmental factors that shape AI implementation into clinical practice.

User Acceptance in AI Adoption

The goal of technology adoption is for the technology to be used to address specific needs, and effective utilization depends on user acceptance. Nonacceptance of technologies by users results in failed technology adoption efforts [16]. Electronic health records (EHRs) offer an example of how health care technologies, if not well accepted or integrated, can negatively affect clinical practice. EHR systems were initially introduced to streamline documentation and improve efficiency, yet many clinicians report that they increase administrative burden, fragment workflows, and contribute to burnout [17,18]. Studies have shown that simple tasks, such as medication renewal, may involve more than 20 steps within the EHR system, requiring clinicians to spend substantial time on manual work [17]. In some cases, physicians spend nearly half their workday on desktop medicine rather than direct patient care, with additional hours spent documenting outside of normal work hours [19]. This slows down workflows and leads to cognitive overload and clinician dissatisfaction [20]. The example with EHRs demonstrates how poorly designed or inadequately integrated technologies can become burdensome rather than supportive.

These concerns also apply to the use of AI in health care. If AI tools are not transparent or explainable, clinicians may be unable to understand or trust the decisions AI tools make, making them reluctant to adopt or rely on such systems [21-23]. This is important in clinical environments where accountability and patient safety are critical. Studies show that the lack of publicly available information on the development, validation, and ethical considerations of approved medical AI tools poses serious transparency gaps that hinder clinicians' ability to assess their safety and reliability [21]. Similarly, Marey et al [22] indicate how the lack of transparency in complex AI systems, in the case of cardiovascular imaging, poses significant barriers to clinical acceptance. The latter highlights the need for sufficient training of clinicians on AI products [22]. Furthermore, clinician acceptance of AI is strongly influenced by concerns around trust [23]. Clinicians may resist relying on AI tools in their daily practice if such tools introduce uncertainty or misalign with clinical judgment, which eventually results in reducing workflow efficiency and deterring use [13,23].

A Sociotechnical Perspective

We draw on STS theory to understand AI adoption in oncology. STS emphasizes the interdependence of social subsystems (people and organizations) and technical subsystems (infrastructure, tools, and processes), and the principle of joint optimization: outcomes are best when both subsystems are aligned [24-26]. This lens highlights how AI integration depends not only on technical performance but also on human roles, organizational dynamics, and external influences such as regulations and other environmental factors [26]. Applying STS allows us to examine AI adoption beyond technical efficacy, focusing instead on how AI reshapes clinical workflows and how clinicians, organizations, and technologies co-adapt in practice.

A Model for User Acceptance

Individual user acceptance has been studied for many years, and many frameworks and models have been developed that effectively explain the factors that influence acceptance and use. In this work, we use the UTAUT. Developed by Venkatesh et al [27], UTAUT synthesized 8 technology acceptance models including technology acceptance model (TAM), theory of

XSL•FO
RenderX

planned behavior, motivational model, the combination of TAM-theory of planned behavior, theory of reasoned action, social cognitive theory, the model of PC utilization, and innovation diffusion theory, and proved to have higher explanatory power over all 8. UTAUT has been used in many studies exploring the acceptance of various technologies, including those used within health care. As proposed by Venkatesh et al [27], UTAUT has 4 core constructs—social influence, effort expectancy (EE), performance expectancy (PE), and facilitating conditions—defined as:

- PE refers to the degree to which an individual believes that using the system will help him or her attain gains in job performance [27].
- EE is the degree of ease associated with the use of the system [27].
- Social influence (SI) is the degree to which an individual perceives that important others believe he or she should use the new system [27].
- Facilitating conditions (FC) refer to the degree to which an individual believes that organizational and technical infrastructure exists to support the use of the system [27].

Attitudes, understood as the organization of one's beliefs about an object, that incline them towards certain actions [28], are also argued as determinants in some literature sources. PE, EE, and social influence are all direct determinants of behavioral intention (BI). BI, in the context of this study, refers to a person's intent to use AI tools. BI, in turn, determines actual AI tool use. EE, social influence, and PE are moderated by additional constructs: Gender, Age, Experience, and Voluntariness. Experience pertains to the individual's experience with the new technology. Facilitating conditions, on the other hand, are a direct determinant of actual use [27]. In this study, UTAUT constructs inform our understanding of how AI acceptance takes shape within health care institutions.

Methods

Study Design

Given our aim to identify key factors that shape clinician acceptance and the impact of AI integration in clinical practice, this study used a qualitative research design and semistructured interviews to elicit perceptions and opinions on AI use in real-world settings. Semistructured interviews gained popularity for their flexibility and versatility, allowing the researcher to be structured, yet free to explore other relevant ideas that might come up during the interview [29,30]. They are well-suited to research questions aimed at addressing whether a proposed service is warranted**,** how to implement it, how it is performing, or how it can be improved [29]. The interview guide is provided in Multimedia Appendix 1.

We adopted purposive sampling to ensure the inclusion of participants with relevant expertise. The following selection criteria were applied: (1) the person works in oncology or other cancer care-related fields; (2) the work area has implemented, is evaluating AI tools for implementation, or has considered AI tools; (3) the participant is familiar with AI and its uses in cancer-related care. This approach was chosen to specifically target individuals with direct experience or informed perspectives on the use of AI in cancer care. The study included 18 health care professionals involved in cancer care and a medical AI research and development expert. Participants were recruited using professional networks, referrals from prior interviewees, and institutional platforms such as official websites, professional associations, and digital publications. Our sample primarily included professionals using, implementing, or evaluating AI tools for some cancer care-related tasks, as well as those exploring AI tools that could be suitable for use in their clinical areas. A small number of nonusers were also included. Nonusers can offer valuable insights into technology acceptance studies because these participants may elucidate on reasons for nonacceptance. It is also worth noting that some clinicians are involved in research. Table S1 in Multimedia Appendix 2 details the characteristics of the study participants.

Data Collection

Interviews were conducted online, primarily via Zoom, except for one interview using Microsoft Teams, based on a participant's preference. Interviews took an average of 42 minutes of discussion ±3 minutes for introductions. Interviews were conducted in English (n=12) and Swedish (n=7). All interview sessions were recorded using an independent recording device (Olympus digital voice recorder) to ensure audio quality and data security. Transcription and translation were carried out using our university-approved (adhering to the university's policies) tool, which provides initial automated transcription and translation called Amberscript. This was human-checked together with the recording of the interviews to make sure that the content is transcribed properly and translated. This was done by 2 double checkers to make sure of the validity of the data. We have taken additional steps to double-check with some ambiguity regarding the translation of some Swedish-related terminologies. Only one participant was concerned about being misquoted, and the transcript was approved by that participant after reviewing it. Analysis was performed in English.

Data Analysis

The data were analyzed thematically, following Braun and Clarke's [31] reflexive thematic analysis (TA). TA is applied to qualitative data to identify, analyze, and interpret patterns of meaning [32]. This is achieved systematically through the iterative process of familiarizing oneself with the data, generating codes from the data, generating initial themes, reviewing the themes, and defining and naming themes. We followed this approach, inductively generating codes and subthemes directly from the data. Since we were using a reflexive TA, saturation was not sought. As discussed by Braun and Clarke [33], the concept of saturation as a rationale for sample size does not align with reflexive TA. In line with their arguments, in our study, the following make it difficult to claim saturation: the semistructured nature of interviews, the lack of homogeneity in our sample, and the inductive nature of our analysis. Instead, we used information power [34] to judge the sufficiency of the collected data. The quality of our dialogues with the specifically purposively sampled group of participants yielded rich data that is relevant to our research aim. The

XSL•FO
RenderX

findings align with existing organizational and technology acceptance theories relevant to our research questions. Even though we performed cross-case analysis, we consider the number of participants (n=19) to provide sufficient relevant information, given that implementation and use of AI tools in clinical cancer care is at its early stages and the availability of relevant participants is still sparse.

TA was conducted using NVivo (version 14; Lumivero) and yielded 378 codes. Both authors reviewed the codes and the themes. This involved discussing the codes and deciding their suitability within allocated subthemes and later assessing for fit within the theory-based themes. The inductively generated codes were subsequently organized into higher-order themes aligned with STS theory. In this way, STS theory served as an interpretive lens, not a coding framework. Table S2 in Multimedia Appendix 3 shows how the subthemes map to STS theory components. Although this study does not quantitatively measure acceptance as is commonly done with the technology acceptance model, our results nonetheless align well with UTAUT constructs; hence, the framework was subsequently applied to discuss the results and provide deeper insights into clinician acceptance. The codebook is provided in Multimedia Appendix 4.

Researcher Reflexivity

The authors do not work in the medical domain. Both authors have a technical background; their knowledge, therefore, informed the development of interview questions and the flow of discussions and influenced the interpretation of results. To mitigate potential bias, the authors iteratively checked codes and themes and held continuous discussions.

Ethical Considerations

Ethical approval for this study was granted by the ethical adviser of Karlstad University (HS 2023/1591) before data collection. An information sheet and consent form covering both participation and interview recording were sent to participants at least 4 hours before the scheduled interview. At the start of each session, the study was introduced, and participants were allowed to ask questions before proceeding. The consent form is provided in Multimedia Appendix 5. Participants were provided a lunch voucher (≈€20 [US $19.44]) only after the interviews, as a gift in appreciation for their participation. Most of the participants accepted the voucher; however, a few declined.

Results

Study Themes

Participants were asked to share their perceptions and opinions on the adoption and use of AI in their professional context, and more broadly in cancer care. Their responses inform 6 themes formed from 28 subthemes. The main themes include General AI Adoption Perceptions to set the stage for the participants' perspectives on AI, then Social Subsystem (Organization), Social Subsystem (People), Technical Subsystem, Impacts of AI integration as Indicators of Joint Optimization, and External Systems, in line with the components of STS theory. The themes are presented in Table 1, along with the associated subthemes. An extended version of this table that includes the number of coded references and the number of participants linked to each of the subthemes is presented in Table S3 in Multimedia Appendix 6.

XSL•FO

Table . Overview of themes and related subthemes. The letters G, SO, SP, T, J, and E serve as identifiers for the subthemes and their associated theme.

Theme (abbreviation used in subtheme numbering)	Subthemes
1. General AI[a] Adoption Perceptions (G)	• G1. AI[a] developments • G2. Limitations and complexity • G3. AI applications
2. Social Subsystem – Organization (SO)	• SO1. Organization-specific challenges to adopting AI • SO2. Facilitating factors at the organization level
3. Social Subsystem – People (SP)	• SP1. Need for AI awareness • SP2. Attitudes towards AI • SP3. Age-related perceptions • SP4. Trust • SP5. Involvement in shaping the solution • SP6. Responsibility and Accountability • SP7. Automation bias • SP8. Clinician autonomy, behavioral impacts, and interpersonal factors • SP9. Effect on jobs, skills, and competencies
4. Technical Subsystem (T)	• T1. AI potential • T2. Fit-for-task design • T3. Ease of use • T4. Challenges relating to data • T5. Interpretability and Explainability of AI tools • T6. Unsuccessful AI adoption efforts • T7. Effects of AI tools on workflows
5. Impacts of AI Integration as indicators of joint optimization (J)	• J1. Benefits to clinical practice • J2. Clinical benefits • J3. Continuity
6. External systems (E)	• E1. Regulatory influence • E2. Vendor stability • E3. AI and clinical guidelines • E4. Macro-level enablers

[a]AI: artificial intelligence.

General AI Adoption Perceptions

This theme captures the participants' general perceptions of AI in cancer care.

G1: AI Developments

Participants hold varying views about the developments in medical AI. While some perceive it as fast-moving, with a lot happening in a short space of time, others see it as moving more slowly than initially expected. As one participant states:

> *I'm a little surprised that we haven't… that we're not further along than we are in those applications. If you think back five years and try to predict where we would be, you would have thought we would have come further.* [P19]

However, the pervasiveness of AI in society is expected to increase exposure to AI tools, resulting in younger professionals who are more likely to be comfortable with AI use. Similarly, large language models are expected to make an impact in clinical care in the near future. One participant also calls for the health care industry to reconsider its approach and focus more on proactive care. In this area, AI can make a substantial impact, and patients can benefit more in the long term.

G2: Limitations and Complexity

A small number of participants express uncertainty about the future of AI and its promise to cancer care. They caution that, in addition to the performance of tools, institutions should also look at the decisions that established the gold standards upon which the tools are built. Furthermore, they argue that the complexity of health care deems AI incapable of handling health issues in the same nuanced way as clinicians. For example,:

> *What you realize is that healthcare is so enormously complex… this AI doesn't have human common sense. And a lot of what we do in healthcare is another kind of complex assessment of the best choice for a particular patient, taking into account other diseases, social situation, general status of the patient and the patient's wishes… there is so much that is weighed into treatment choices.* [P13]

Currently, AI tools support only a small part of the assessment process.

G3: AI Applications

Participants mention several applications of AI, both in use and under consideration, and these include uses in mammography, segmentation of organs at risk, screening for lung and pancreatic

XSL•FO
RenderX

cancer, surgery, genetic exams, patient note-taking, patient communication, and data consolidation tools.

Social System - Organization

Overview

This theme examines organizational-level factors that shape AI adoption. Participants discussed both challenges and facilitators to adoption at the organizational level.

SO1: Organization-Specific Challenges to Adopting AI

Participants describe the validation and security processes performed at the initial phase as laborious, especially as the same tools must be revalidated in different cities within the same region. They question the logic of repeating these processes. However, they acknowledge that defining boundaries, distinguishing between what is considered local and what is not, and determining whether validation in context is truly applicable to another may be challenging. Participants also highlight the need for continual validation rather than a one-time occurrence. They note the procurement process as another challenge, mainly due to bureaucracy. Participants also identify user buy-in as problematic, with the "staff on the floor," as one patient puts it, being the hardest to convince that the tools are to their benefit: :

> *we have done it this way always. So, why do we need to change how we do things?* [P1]

Participants also note issues such as a lack of motivation to learn and use new system features, and hesitation to adopt tools that have not been widely accepted, even though there is sufficient evidence to support them. Other reasons include the expectation of big impact solutions before they are worth considering. For example, one participant believes that AI in dermatology will only be truly worthwhile when an AI solution exists that can scan the entire body for suspicious lesions, rather than smaller tools that target a small surface area. Moreover, organizations are said to fail to provide clear guidance on what AI tools to use and how to use them, leaving employees to explore on their own.

Lack of clinician engagement can also be detrimental to AI adoption. In one case, radiologists have been dissatisfied with the implementation of an AI tool. They resist the AI tool because they had not been informed early in the adoption process. This is viewed as continuing to overshadow the perceptions of the involved radiologists, regardless of the same tool having been accepted in other institutions.

SO2: Facilitating Factors at the Organizational Level

According to the participants, several factors facilitate the adoption of AI tools at the organizational level. These factors include formal communication, informal social discussions, preparation, and technological orientation of organizational units. Formal communication early on is required to get people on board and reduce skepticism. Participants emphasize the importance of presenting concrete use cases and examples tailored to specific specialties that illustrate how the tools can be beneficial and where they would fit in the workflow. This approach of giving concrete examples is seen as more effective than discussing AI in broad, abstract terms. AI champions are said to play an important role in communication. Informal social discussions among colleagues also play a role in facilitating acceptance. According to participants, the talks in their social circles are concerned with which AI tools to use, which are best at performing specific tasks, and the positive impacts of having introduced AI tools, such as time-saving, which is reportedly very visible to staff.

Thorough preparation before introducing AI tools is another key factor. Participants mention the importance of conducting evaluations and validation and providing sound scientific evidence, characterized by robust methods, sufficiently large datasets, and clear presentation of results, both from internal unpublished reports and publications. According to one patient:

> *The most important thing spontaneously is that there is a good scientific basis and a good study with many included patients, where clear results have been shown. That is kind of the basis for being able to get skeptics to believe in AI.* [P13]

Participants also stress the need to analyze beforehand how implementation would affect people and their daily work. A good approach to preparedness is specifying suitable criteria. A participant from one of the Swedish regions notes that they take into consideration 5 key things: having a good use case, quality of the AI tool, economic viability, being well-integrated technically, and the possibility to validate it within the acquiring health care institution.

The technology orientation of organizational units, along with their tech-savvy experts, appears to be more willing to accept AI tools, though the same can also breed skepticism. Participants note that specialties like radiology and surgery, which are already tech-heavy specialties, may be more open towards trying AI tools, which extend upon what is typically used. Even when the clinicians have negative feedback about the performance of the specific tools they test, there is an impression that they are eager and even excited to try them. Participants highlight that there is ongoing technological development in their fields, and one should be prepared to explore new solutions. However, participants also recognize that not all colleagues are tech-savvy, and those colleagues with less technical experience may still be uncomfortable with the latest technologies. Interestingly, some participants state that while familiarity with technology makes it easier to accept AI, it also, in some ways, makes them more critical and want a deeper understanding of the underlying parts of how the tools work before they can fully accept them.

Social System - People

This theme explores the perceptions about human and social factors that influence AI acceptance and use, along with the broader impact of AI use on practice and the workforce.

SP1: Need for AI Awareness

Discussions with participants underscore the critical need to increase awareness amongst health care professionals about what AI entails, which tools are available for use, how they are used, and the potential unintended consequences that might arise from them. To enable clinicians to detect potential errors emanating from AI tools, participants emphasize the need to

XSL•FO
RenderX

enhance professionals' understanding of how AI tools function, as well as their limitations. One participant stressed that

> *You have to know what you are dealing with, of course… you have to know what you are working with to be able to use it in the intended way.* [P19]

Participants also emphasize that the AI tools can make mistakes and should not be relied upon without critical thinking.

SP2: Attitudes Towards AI

Participants communicate that attitudes towards AI tool use are largely positive. They use phrases like "happy we have it," "generally satisfied," "very positive," "healthy and reasonable attitude," "positive in general," and some express a desire to work with AI more. Positive attitudes also appear to be influenced by perceived benefits, as well as positive personal experiences with AI tools used for nonclinical purposes. Participants encourage the use of AI tools to support clinical tasks:

> *We need to look at it as a helper more, and I think we can work more with the patient if we embrace the AI products that are in development in our different areas.* [P1]

However, they also stress the need to maintain a critical perspective. To a lesser extent, negative feelings towards AI tools are also evident, emanating from a lack of communication, indifference, skepticism based on their personal beliefs about AI, and fear of the unknown trajectory of AI. Participants note that skepticism diminishes as people begin to see the performance and results of the AI tools.

SP3: Age-Related Perceptions

Participants express mixed views regarding age and AI acceptance. Some participants believe that younger professionals know more and have more positive attitudes towards using AI tools. However, a different view also exists, suggesting that there is no consistency regarding whether younger or older generations are more or less likely to accept AI. The participant further explains:

> *There are different reasons for different generations to be skeptical or hesitant to use these tools. So, it's not really the same reason for everyone. Some older people, they just don't trust this, um, for some younger people, it's not that much about trust. It's more about fear or confidence level; and not all of them [reasons] are invalid.* [P7]

SP4: Trust

There are mixed views regarding trust in AI tools. Participants note that the question of trustworthiness of AI tools remains, with concerns about how they can ascertain quality and reliability. Such concerns affect some professionals' willingness to test AI tools. Nonetheless, others use AI tools for supporting clinical work, even though they highlight that they would not trust them unquestioningly. For example, one says:

> *I think that it won't happen that I blindly trust this. But it will be like a help… like I'm on the right track. It will help me do a potentially better assessment.* [P8]

Participants also highlight that trust and openness towards AI tools are influenced by previous exposure and experience, scientific evidence, certification of tools, and thorough evaluation in the specific context of use. Some participants question why AI should be trusted less, given that health care professionals already trust and rely on many other technological tools. Still, others point out that health care professionals would rather place greater trust in their own and their colleagues' abilities over AI tools.

SP5: Involvement in Shaping the Solution

The degree to which individuals are involved in shaping AI solutions plays an important role in ensuring alignment with clinical goals. One participant states:

> *So, it's extremely important to work with the companies that have created the AI solution to improve the functionality of the solution. And I have regular meetings with the product developers at that company where they ask questions that they want answers to from a clinical perspective.* [P2]

Participants describe their involvement as ranging from no involvement to some form of feedback to demonstrations of proposed solutions, when change is required during the validation stage, or when institutions have begun using AI tools. While most participants report limited opportunities for health care professionals to be involved in the design of the AI tools they ultimately use, they emphasize the importance of doing so to reduce problems and anchor the solutions properly to the users' needs and expectations. They also highlight that, should they have been involved in design, they could have influenced how the tools work to overcome current shortfalls. Health care professionals can give suggestions when the tools fail to fulfill their needs. Participants believe that early engagement greatly influences how users react to the tool's actual use. They stress that health care professional involvement is necessary during the design stage, and as tools evolve. One participant says:

> *I really don't have specific evidence for what I'm saying now, but it is my experience for many other types of, um, just sort of software tools which clinicians are using. If the clinicians have been involved in the development or early testing of things, they are often quite positive towards the results they get, and they want to use the tools.* [P4]

However, not all participants agree with this view. A different view is that health care professionals need not be involved early in the design, but rather at a later stage, when the AI solution works at least semi-decently.

SP6: Responsibility and Accountability

Although a small number of participants note that it is still unclear who should be responsible and held accountable should something go wrong following an AI tool giving an incorrect result, several participants firmly believe that the responsibility lies with them as clinicians, and they are accountable to the patient. Given that AI tools are intended to support, and the doctors are responsible for verifying their results and making

XSL•FO
RenderX

the final decision, the issue of responsibility and accountability does not seem especially problematic. One supported this saying:

> *AI is very important, but still needs the radiologists to check their data. So, if an exam goes to the patient with the wrong interpretation, the error is from the radiologist. So, it's always on the radiologist, not on the AI.* [P10]

One participant states that it is the developer's responsibility to build a tool that minimizes the number of false positives, to use sufficiently large datasets, and to carry out performance measurements against established benchmarks. At the operational level, however, many of the participants do not appear to question where responsibility lies.

SP7: Automation Bias

A small number of participants have already noted adverse effects of AI use, such as automation bias amongst colleagues. This bias stems from over-reliance on AI tools, either by trusting AI tools more than their judgments or due to finding it so easy to click and move on as opposed to taking time to verify the results. One participant observed that younger professionals are more susceptible to believing and being influenced by AI-generated results. One said:

> *When the AI has pointed to something, there's a tendency among some reviewers to just buy the AI's decision instead of trusting their own assessment.* [P14]

Participants stress the importance of exercising caution, verifying results, applying their judgment, and the need for enhanced training to mitigate this problem.

SP8: Clinician Autonomy, Behavioral Impacts, and Interpersonal Factors

Participants highlight issues relating to autonomy. As they state, in some cases, clinicians simply resist algorithmic support even when algorithms work. Instead, they would like to feel that it's their knowledge that gives the correct answer. Regarding the assumption that the clinician determines what is correct, it is also noted that sometimes the AI tool detects cancer that may be difficult for the clinician, or even several clinicians, to spot in an image, thus a patient is assumed to be cancer-free when cancer is in fact present.

Some participants also fear that AI may overtake clinical work, reducing clinicians to passive bystanders and undermining their confidence. A participant emphasizes that it is important for one to acquire one's skillset first, build knowledge, and gain hands-on experience to trust one's own judgment. Only then can AI serve as a tool to enhance those skills, which is a far better approach than becoming overly reliant on AI from the outset. They also highlight how dependence on AI tools develops over time. For instance, they may start off skeptical and anxious to use AI tools, but later the opposite may occur, where they become uneasy when the exams have not also been reviewed by the AI tool. In support of this, one states that despite the ability to work without AI tools, a dependency forms as one uses them, and if removed, their absence is noticeably felt. Further to this, another warns that using AI tools daily carries the risk that clinicians will cease to question the results or consider alternative interpretations.

> *I guess the fear is always about relying on it too much.* [P12]

Additionally, participants highlight that the use of AI tools can impact interpersonal relationships. For example, replacing administrative staff may mean they lose support from them, not just for the tasks the AI tools fulfill, but also for the support tasks the administrative staff does in the periphery.

SP9: Effect on Jobs, Skills, and Competencies

Participants believe that while there may be a threat to administration staff, clinical staff may not have to worry about job loss for several years. Instead, AI tools are expected to serve as support and complement clinical practice. Although one participant, somewhat agrees to this, they still state a persistent concern regarding job impact:

> *But I still think that in the long run we may be working ourselves out, and that it's just a matter of time. But, it feels like it will take considerably longer than we initially feared.* [P14]

AI tools handle simple clinical tasks, and the participants stress that the physician's judgment remains indispensable, both for conducting assessments themselves and for overseeing the AI-assisted processes. Nonetheless, participants perceive a threat to skills that might weaken due to over-reliance on AI tools. Particularly, the younger generation of clinicians who may have more exposure to AI tools may not be getting sufficient hands-on experience. Participants fear that this will result in eroding their confidence in their professional knowledge. To address the issue, they suggest that a plan must be in place that will require a certain amount of work to be done by the clinician, without AI assistance. For example, a radiologist should retain the skill to delineate structures manually. Participants also suggest that younger physicians should redo by themselves the work that AI tools have performed to gain experiential practice. This should be viewed as a necessary part of education. They note that a shift is beginning to happen in medical education towards covering AI fundamentals and preparing medical students for professions that are AI-augmented. In addition, health care institutions provide tool-specific training, helping ensure the correct use of AI tools. Participants regard training to be straightforward and brief, and training sessions typically last about an hour or two. In some cases, multiple sessions are offered. However, attendance in training sessions is also limited by time constraints. In other cases, the AI tools used are deemed intuitive enough to use without prior training.

Technical Subsystem

This theme covers participants' perceptions of AI tools in terms of their potential, the effort associated with their use, and the importance of aligning them with specific clinical tasks.

T1: AI Potential

Apart from already experienced benefits, participants perceive AI as having significant potential across various areas of cancer care and enhancing their clinical practice. First, participants believe AI tools can help health care professionals in identifying

XSL•FO
RenderX

better treatments more quickly; by rapidly collating and analyzing information from various sources, AI can support the selection of the most suitable treatment arm for a specific condition. AI tools can also support compliance with required clinical standards of image taking, particularly for dermatological conditions. In addition, AI tools can aid in evaluating the need for care and improve the safety of medical procedures, as well as relieve radiologists of certain tasks, allowing them more time for other clinical activities. They are also expected to reduce health care costs. One participant explains the potential for better procedures, saying:

> *This is with skin cancer. It [AI tool] can help identify and make the correct diagnosis on the right tumors, and that you should operate on the right spot if it is [present], so that you avoid unnecessary excisions. Because even the most experienced dermatologists operate on four benign changes before they find a melanoma.* [P18]

Another highlighted the potential of AI tools in increasing patient support:

> *I think that can also be something where AI can be really helpful, to help us monitor patients throughout their chemotherapy journey.* [P12]

Second, participants believe AI can aid patients' understanding of their disease, facilitate understanding of scientific literature about the disease, and help patients feel more in control of their treatment. Thirdly, AI can assist health care professionals in staying up to date with clinical practices and developments. It is also expected to accelerate the translation of research findings into clinical practice.

Even with so much potential, participants point out that these tools still have limitations in handling certain functions that require human judgment. For instance, handling decisions on how to proceed with a patient's chemotherapy after years of treatment involves deep contextual understanding that only a physician can provide. Furthermore, clinicians are better at handling standardized and systematized nomenclature, an area where AI tools still fall short.

T2: Fit-to-Task Design

Participants point to the importance of clear use cases and AI tools that are designed for specific tasks that can support their work. One participant emphasizes that as there are many AI tools on the market,

> *It is very important that one is very clear on the suitability of the AI tool for its intended use, and are clear on the kind of testing they should do before they can use it.* [P19]

Participants stress that the tools must meet performance expectations and should have clearly defined limits and boundaries. Participants also note that AI tools should help them achieve specific goals such as improving the quality of care, using limited resources efficiently, and improving operational effectiveness. Without this alignment, there is no incentive to adopt such technologies.

T3: Ease of Use

Although a few participants note that some AI tools initially require more work, resulting in longer processes, they acknowledged that over time, these solutions eventually show improvement and positive outcomes. The longer processes are associated with the need to change work processes and make adjustments to ensure optimal functioning and fit within the workflow. The participants view this as a natural part of change. One states:

> *and there will certainly be a lot of work in the first year when we try to adjust so that it is right and good. So, there will certainly be a period now when things are slower for us and we will not be as productive, but that's part of it. There is not much to argue about. It's just that if you believe in it, you have to accept that it will take a while before all the new routines have settled in and become as good and effective as before.* [P2]

Several of the current AI tools are perceived as easy to understand and easy to use, and where errors occur, recovery requires little effort. One example is that if an AI-based segmentation tool returns incorrectly drawn structures, the radiologists, who possess the expertise to delineate them manually, can easily make corrections. Support is available for health care professionals when using AI tools. The support is provided by vendors, as well as IT departments within health care institutions. High availability and responsiveness when support is needed are appreciated and underscored by phrases like "all the time," "24/7 almost," "continuous support," and "when we have challenging questions... we turn to them."

T4: Challenges Relating to Data

Participants also raise data privacy and security as concerns. Particularly, the potential misuse of patient data sent to the cloud and shared with third-party companies is disconcerting.

> *That is one of the three major challenges that we have encountered. It is the technical implementation to get through data protection considerations, patient data considerations, cloud solutions and all that.* [P9]

However, others point to General Data Protection Regulation compliance and pseudonymization of sensitive data as providing the necessary security. Another ethical concern raised is the potential of AI tools to propagate bias, whether inherent, learned from training data, or intentional. Furthermore, inconsistencies in how colleagues input data can impact AI tool performance.

T5: Interpretability and Explainability of AI Tools

To encompass both interpretability and explainability, this section uses the concept of transparency. While most AI tools in clinical practice are admittedly opaque or "black-boxed," participants express differing views on the necessity of transparency. A lack of transparency is said to introduce uncertainty, as clinicians cannot discern what the model has taken into consideration to reach its conclusions. Some of the participants emphasize the need to understand how the models arrive at their decisions to clarify aspects that may have been missed during a clinical evaluation, or in the case of predictive

XSL•FO
RenderX

tools, to support the development of suitable interventions. However, participants also suggest that transparency is more critical in some contexts than others. For instance, with image interpretation, where clinicians can independently verify results by reviewing the same images, transparency may be less critical. On the other hand, some participants feel that they do not need tool transparency. For them, the tool's high level of performance, paired with supervision by a human expert, is deemed sufficient. For example, one states:

> *No, I don't need to know how it is done inside, how the AI have been calculating. But, of course, I have to compare and see. Do I agree? Is this the right decision? Is it really so suspicious.* [P19]

Others believe that the level of detail about how a model works would be beyond clinicians' comprehension. One participant points out that there is a trade-off between accuracy and explainability of AI tools, noting that improvements in one often come at the expense of the other. As a result, they may settle for partial explanations and experiment with different approaches to understand how the models achieve their results. Nonetheless, another believes that transparency of AI tools could offer tangible benefits to clinicians, providing peace of mind, opportunities for learning, and helping them clarify conclusions better for their patients.

T6: Unsuccessful AI Adoption Efforts

The following examples provide insight into how AI implementations can fail. Participants shared examples of unsuccessful AI adoption efforts that reveal technical- and implementation-related challenges. In one case, a commercial product, despite having been validated in advance by the purchasing health care institution, resulted in too many false positives once introduced into clinical practice. Another example involves an in-house development project that, when benchmarked against commercial alternatives, performed poorly. Even when technical infrastructure is in place, hurdles remain. One participant describes a locally deployed model as difficult to operate and poorly integrated into the existing pipeline, calling it "a pain" to manage. Custom-built systems are presented as producing minimal gains in comparison to larger commercial solutions. At the same time, the participant cautions that the success attributed to some AI tools, particularly in pathology, is often overstated, with many models still failing to generalize well between patient cohorts. They state:

> *So, so far, those claims were, I would say, highly exaggerated because, um, they usually I mean, maybe we haven't seen the right models, but it's like they would over analyze each particular sample, like in a particular cohort, it would work well. If you try to generalize it to other cohorts like the slides which we would have, then it would start to behave in a crazy way.* [P3]

T7: Effect of AI Tools on Workflows

Participants note that AI integration changes work routines, but its impact on workflow varies across contexts. Some require more adjustments than others. For example, one participant states that:

> *As far as finding breast cancer is concerned, it's a big challenge to change all our routines so that they work with the new way of examining breasts.* [P2]

This suggests that clinicians need to accept new ways of working, a process said to be challenging at first and often met with resistance. The participant highlights that workflow changes will be due to the additional steps required in the process of 3D breast cancer screening. Nevertheless, they expect a positive overall outcome eventually. Participants highlight that AI tools in one area of care can significantly alter the patient's pathway after an examination, and the clinicians must rethink how the quick AI responses will affect operations at different times in the day. In breast cancer screening, for example, the use of AI tools introduces a new process of reviewing images, where an AI tool reviews the images at one point, and radiologists review the images at another. There are different points and scenarios in the workflow where senior or junior radiologists get involved and perform their assessment. One simply puts it:

> *The main difference is that some exams go only to one doctor instead of two. So, that's the only difference in workflow.* [P17]

Others note that, initially, screening may take a little longer as images contain more information and AI-generated markings that highlight suspicious changes in a breast image. The workflow can also differ depending on the protocols or image modalities used. For instance, whether a computed tomography (CT) scan, magnetic resonance imaging (MRI), or another interface is used. Several participants feel that workflow changes are not drastic and have minimal impact on cognitive load. In one case, however, they note that an AI tool may perform its task satisfactorily, but a lack of integration with other technical systems may cause a workflow disruption. AI integration into the workflow must be well organized and accompanied by staff training to result in a more efficient process. After integrating AI tools in their work, participants note that evidence shows a positive synergy between good AI tools and experienced clinicians.

Impacts of AI Integration as Indicators of Joint Optimization

This theme reflects the outcome of AI tools and the social system as a jointly optimized system.

J1: Benefits to Clinical Practice

Participants note several benefits. The 2 primary benefits that clinicians note are workload reduction and time savings. Workload reduction is highlighted as one of the key goals of adopting AI in clinical settings, which are currently overwhelmed due to staff shortages.

> *Well, in Sweden, we have a lack of radiation oncologists. So, that means that we are finally able to do our jobs on time. Otherwise, we were always behind schedule. So now we are on schedule again.* [P6]

Participants point out that the introduction of AI tools reduces manual work and increases productivity. They explain that in

XSL•FO
RenderX

breast cancer screening, AI tools handle scans that would otherwise wait for the radiologist to review. Similarly, in segmentation tasks, the time to draw structures is significantly reduced by the automatic generation of structures compared with when they are done manually. A participant points out that:

> *The physicians love it because they say, oh, I've got all this time. I don't need to take this patient [for] three hours. Now I can do something else and take another patient.* [P16]

In speech recognition systems designed for taking health care records, the need for an administrative middleman is eliminated, resulting in quicker access to health care records for subsequent care. Participants also note that the use of AI results in increased access to information and frees up time, allowing them to work more with patients. One emphasizes that the use of AI tools improves current work processes and adds the ability to perform functions that are otherwise not possible for humans. While they may not fulfill all needs, AI tools are seen as making a difference in the care process. Furthermore, participants highlight that AI tools increase accuracy and reliability, can minimize the risk of oversight, and increase clinician confidence in performing certain tasks. Participants also highlight that in the long run, AI may contribute to reduced costs through paying fewer salaries and reducing the need for multidisciplinary team meetings where expert views of different professionals are corroborated to reach decisions about cancer patients; that is, their diagnosis, recommended treatment, and follow-up care. One participant states:

> *And this is a situation where I think this gathering of many different expert views… is going to be, if not replaced, at least assisted by AI, which will start to provide the same comprehensive advice. And perhaps often it will be just an oncologist then, assisted by AI, that makes the decision, ultimately together with the patients, rather than having this [multidisciplinary] conference.* [P4]

Though AI tools may be costly, the cost is expected to be offset by the benefits.

J2: Clinical Benefits

Participants note that the use of AI tools leads to better cancer detection, allowing clinicians to identify smaller cancers at an earlier stage. For example, one participant hares that when the AI tool they are implementing in breast cancer screening was evaluated,

> *They found 29% more cancers compared to when there were 2 radiologists, and they found slightly smaller cancers and clinically significant cancers at an earlier stage.* [P13]

Increased accuracy results in lowered patient recall. Furthermore, a participant highlights that the advanced 3D imaging technology used in breast screening can provide better detection of cancers in dense breast tissue. Using AI tools in segmentation tasks is reported by a participant as yielding better organ structures and missing fewer structures compared with manual delineation by physicians. Participants also observe that AI tools reduce inter-observer variation and perception errors. The greatest benefit, one says, is to the patients, accruing from early detection of disease and potential complications, as well as improved, timely treatment. A participant makes a similar assertion:

> *So, it [AI tool] helps the patient. It lowers the error in the exams.* [P10]

J3: Continuity

Some participants indicate a willingness to change their AI tools due to unmet needs, high costs, and unacceptable error rates. There is also the possibility that other tools are now available on the market that offer better features, better prices, or possibilities to run on on-site servers. A participant put it this way:

> *We would love some extra things that are not there, we are considering doing a new comparison… and see if there are new vendors… who are doing a better job.* [P6]

However, others have reached satisfaction with their existing AI tools and have no plans to look for alternatives. Even though some participants observed that performance has remained consistent since their tools were evaluated and validated, they see continual and long-term validation of the tools as necessary to ensure ongoing reliability and effectiveness. One participant also notes that the first version of nearly any technological tool in a complex system, such as health care, is often imperfect, and better versions tend to emerge over time.

External Systems

This theme reflects the influence of the external systems, that is, the environment, on the STS, and how they can enable or constrain AI integration efforts at the local level.

E1: Regulatory Influence

Participants highlight challenges related to regulations. One notes the complexity of regulating AI in medicine, particularly that models are learning from data and evolving over time, making it difficult to claim reproducibility of results. Others pointed to the lack of clear guidelines that pose a challenge to AI use. One participant states:

> *I think it's a problem to have unclear guidelines and guidelines that are difficult to follow. It sets the stage for people to try to circumvent them or ignore them.* [P9]

Even when guidelines exist, they are said to lack the detail required to give sufficient guidance. Participants perceive inconsistencies in how regulations are applied. For instance, while institutions are required to submit a notice to the Medical Products Agency to perform a prospective evaluation of an AI application, there is no equivalent regulation obligation when purchasing and deploying an AI application in clinical practice. This gap in regulation creates a loophole for the adoption of AI tools that have not undergone proper evaluation.

E2: Vendor Stability

Whether AI vendors will remain viable in the long term could pose a threat to the adoption and sustained use of AI tools. A

XSL•FO
RenderX

participant expresses concern that some vendors may not have staying power. This is a risk for health care institutions that often seek long-term partnerships with technology providers. This uncertainty prompts the preference for in-house developed solutions.

> *We can see, as a risk of course, for the moment. So many companies have popped up who provide us with solutions. Will they be here in 5 or 10 years, 20 years? You know… So, we need solutions that are reliable…* [P1]

E3: AI and Clinical Guidelines

Participants reflect on how they perceive the influence of clinical guidelines and AI tools in cancer care. They acknowledge that AI could give recommendations that are not entirely aligned with existing guidelines, but could still offer better options for some patients: a flexibility that is considered acceptable given the mutable nature of clinical guidelines. Participants note that AI has the potential to help interpret the results of mega-trials and rapidly analyze the vast number of publications that inform guideline development. However, they also feel that AI tools remain inferior to the expert panels who create guidelines, and that AI tools should be optimized to follow guidelines while retaining their potential benefits. Participants also felt that clinical guidelines should acknowledge the increasing use of AI:

> *I also think that the guidelines should mention it [the use of AI tools]… they need to acknowledge AI and give us some guidelines about when it's feasible to use it or not, and some of the drawbacks that they have.* [P15]

Participants also highlight the need for AI developers to stay up to date with guidelines to effect the necessary changes in model behavior, and it is seen as positive when vendors align their AI solutions with international guidelines and can tailor them to national guidelines.

E4: Macro-Level Enablers

As highlighted by participants, infrastructure and governance structures at the national level influence the implementation of AI tools. Technologically advanced countries that also have more centralized digital health systems, like Denmark, are viewed as better positioned to integrate AI tools in health care, as opposed to decentralized ones, like Sweden, that are perceived to have more challenges adopting AI tools. Participants point out the redundancy and cost associated with repeating the evaluation and validation of the same AI tool across different institutions and regions. They add that due to costs, not all regions use AI tools. They further suggest forming collaborations and cooperation between and within regions to promote mutual learning and optimize resources when exploring different AI solutions. One of them says:

> *I hope that in Sweden we can establish a collaboration between different regions and between private and county council-funded care, where we collaborate on evaluations, because there are so many different solutions, and it is difficult to test all of them. It would be great if we could create some forum where we have common procedures on how to evaluate and how to share our experiences.* [P2]

Discussion

Principal Findings

This study explores clinicians' perspectives and opinions on the use of AI in clinical practice, with the aim of identifying key factors that shape clinician acceptance and AI integration into everyday practice. We sought to answer the questions: (1) How does the adoption and use of AI tools impact the clinical workflow in cancer care settings? (2) What factors influence clinician acceptance of AI tools in cancer care settings? To interpret the results, we draw on STS theory and UTAUT as complementary frameworks. We find that the successful integration of AI tools into clinical practice requires organizational support, careful consideration of potential effects on individuals, and alignment between technical offerings and the requirements of clinicians. While perceived ease of use (EE), PE, social influence, and facilitating conditions influence acceptance, attitudes, and trust are also expected to influence an individual's BI and use of AI tools, suggesting an extension to the UTAUT model.

Workflow Impacts and Sociotechnical Alignment

The introduction of AI tools in clinical practice changes the way that care is delivered. Understanding their adoption requires understanding their impact on clinical workflows. In this section, we use STS theory to understand how workflow dynamics change as AI tools are introduced. Participants note that the core goals for adopting AI are improving the quality of care and making efficient use of resources. To achieve these goals, there is a need to optimize clinical workflows while recognizing the interdependence between social and technical elements that comprise the work system.

From the social subsystem perspective, conditions positioning the organization for successful AI adoption include prior preparation, the uptake of robust AI tools and effective technical integration, increasing awareness, careful consideration of impacts on people and their daily practice, as well as feedback, adaptation, and continual validation. Introducing AI tools must take into consideration the local infrastructure, clinical practice, and institutional dynamics that shape and are shaped by their use. Organizational readiness provides a foundation for successful adoption and integration and requires both the capacity to deploy tools and to develop the necessary competencies [35]. Organizations must provide training, and, importantly, ensure that staff have adequate time for training [13]. The key to organizational readiness lies in aligning human roles, organizational processes, and technical functionalities to achieve both adaptation and value realization.

Local validation helps ensure that an AI tool performs adequately within a specific clinical context. It includes rigorous assessment to establish the AI model's reliability, safety, and efficacy [36]. However, such validation efforts can be resource-intensive. This raises the need to reconsider how validation processes might be shared or collaboratively undertaken across institutions serving similar populations,

XSL•FO
RenderX

thereby reducing redundancy and making the process more efficient. Validation has previously been discussed as a single event that occurs prior to the tool's use in clinical practice [37]. This study also highlights the need for continual validation to ensure that systems remain reliable over time, which is especially important as AI models continue to learn from data and undergo adaptations. Local, recurring validation allows institutions to assess both the performance of the tools and the unintended consequences. Consequences such as workflow disruptions, cost inefficiencies, and bias may hinder long-term use [38]. These assessments ultimately inform institutional decisions regarding the continued use or abandonment of an AI tool. Beyond such high-level decisions, the integration of AI brings visible shifts in daily practice.

Integration of AI into routine clinical workflows presents a challenge to effective AI adoption in health care [6]. Clinical workflows change due to the introduction of AI tools, but integration also requires clinicians to adopt different routines, thus shaping the nature of work. Such changes require that stakeholders be adequately involved and informed early on to clearly understand the roles fulfilled by AI tools and the context-specific benefits to be derived from them. This early engagement increases stakeholder buy-in [37,39]. As our results reveal, there are different workflow impacts in different contexts. In breast cancer screening, apart from handling image analysis, the introduction of AI tools also alters the timing and sequence of clinician involvement, necessitating localized rethinking of roles and responsibilities, and prompting reallocation of expertise, such as that of junior and senior radiologists. Even when performing the same type of clinical task, institutions may adopt distinct workflows. The selection of an appropriate workflow is important, as variations in workflow design can lead to differences in clinical effectiveness and implementation success [40]. The speed of processing by AI tools produces results more quickly, which also alters expectations around when and how subsequent tasks are performed. Where segmentation of structures is concerned, AI tools perform the segmentation process that was previously handled manually by radiologists. Radiologists review the AI-generated structures and rectify those that are incorrectly produced. Thus, an asynchronous collaboration between radiologists and AI tools is formed. This collaboration results in more consistent structures and helps reduce inter-observer variability. It also maintains a closer alignment with clinical guidelines. However, participants also highlight that the impact of AI tools varies depending on imaging modality and clinical protocols used. For example, workflows differ depending on whether CT, MRI, or other imaging systems are used. For AI tools to be efficiently incorporated into health care practices, they must be designed with these practices in mind [7]. While many current AI users believe the workflow changes are not drastic, integration of AI tools can be challenging, resulting in workflow disruptions. Efforts should be made to integrate AI tools seamlessly into clinical workflows, as workflow disruption can increase cognitive effort and time for performing a task [41] and hinder adoption [8]. While several researchers highlight the importance of seamless integration into existing workflows, institutions may need to embrace structural changes and new clinical workflows [42].

In this study, we find that the majority of participants were not involved in the design of the AI tools acquired by their institutions, and that several users report that the tools did not fully address their needs. Tools developed without sufficient input from the clinicians who will use them tend to fail to deliver clinical value [43]. Better alignment can be achieved through early involvement of health care professionals in design activities, as useful AI tools ideally involve clinicians who can clearly define relevant use cases, based on their needs [7,43]. Nonetheless, feedback and adaptation, which involve health care professionals communicating with AI tool providers, help with aligning the AI tools with user needs. However, it is done retrospectively. This is important in STS theory, which emphasizes the significance of the interactions between people and technologies in the design and redesign of systems, key to the pursuit of optimization [44].

While the introduction of AI reshapes clinical routines and requires adjustment from clinicians, it also delivers tangible benefits that can improve workflow performance and clinical outcomes. Having put AI tools to use, several benefits are identified, such as time-saving, increased work efficiency, workload reduction, reduced inter-reader variation, increased tumor detection accuracy, and reduced patient recall. The benefits demonstrate that the integration of AI tools supports and enhances existing workflows, benefiting both clinicians and patients. The appreciation of AI tools despite some shortfalls attests to their utility. The realization of benefits, along with the participants' view that great human-AI synergy arises when AI tools are integrated with experienced clinical judgment, aligns with STS's understanding of co-adaptation between humans and technology.

AI tool design and integration should consider human factors [45,46]. The perceptions and opinions of health care professionals have given further insight into pressing concerns associated with AI adoption and use, such as trust, responsibility and accountability, interpretability and explainability, autonomy, and threats to jobs, skills, and competencies. We find that health care professionals are largely optimistic that the use of AI tools will yield positive returns for the health care industry overall. It must be noted that tensions exist between the perceived utility of AI tools and the commitment to maintain clinicians' personal autonomy, where fear of displacement and the desire to preserve professionals' authority have been highlighted. Autonomy extends beyond decision-making to encompass the preservation of clinical judgment, which is deeply informed by formal training, accumulated experience, and tacit knowledge acquired through practice. Verma et al [7] find that the clinicians' need to maintain control over AI is raised in relation to responsibility and trust but is driven by their service to patients. Similarly, our results show that most health care professionals do not perceive accountability as a dilemma; they take full responsibility for patient assessments even when supported by AI tools. They emphasize that AI tools are used only as support and that physicians take the final decision regarding a patient and remain responsible and accountable to the patient. The threat of job loss also does not appear to be a significant concern to most in the short term. An understanding of how AI tools function and their current limitations provides health care

XSL•FO
RenderX

professionals with assurance that widespread job displacement is not imminent but may be a concern for the future. To date, AI tools fulfill narrow-based tasks, whereas clinicians have expertise to handle diverse types of data modalities and have a holistic view of different diseases and patient situations [43]. Nonetheless, there is fear that fewer opportunities will exist for junior professionals and administrative workers. Although the threat may be distant for some, the concern about job security must be addressed [47]. Participants also foresee that skills may erode due to overreliance on AI. Increased reliance on AI tools means that they will have reduced hands-on practice, which may hinder their ability to perform certain tasks independently. Maintaining such skills is necessary if clinicians are to continue to oversee and verify AI-generated results. Measures, such as clinicians occasionally handling clinical tasks without AI assistance, are proposed. On the contrary, clinicians may have to adopt a different type of thinking, accepting that roles and responsibilities shift, and that they may no longer need to possess skills for certain tasks that AI tools execute exceptionally.

Trust in AI tools remains a complex issue. Although AI perceptions amongst clinicians appear largely positive, trust continues to be a concern for many. The novelty of AI in health care, lack of awareness, and uncertainty about AI's long-term impact contribute to issues of trust. Closely linked is the perceived threat to clinician autonomy, confidence in their own work, and impact on interpersonal relationships. Lack of explainability is also linked to diminished trust [7]. Trust or lack thereof influences the adoption of AI tools and human-AI collaboration [47,48]. We also find that over time, however, skepticism appears to lessen with increased exposure, experience, quality control, and demonstrated performance of AI tools. While a lack of trust results in low adoption, trusting AI tools uncritically leads to overreliance and automation bias. Automation bias, along with other cognitive biases, can undermine the effectiveness of human-AI collaboration that is essential for optimal clinical outcomes [48]. This underscores the need for further research into the implications of too much reliance on AI tools and approaches to mitigate it. As participants noted, clinicians may occasionally accept AI-generated outputs without critically reviewing them, such as neglecting to verify the results independently or allowing the AI tool's output to unduly influence their clinical judgment, undermining confidence in their expertise, and increasing patient risk.

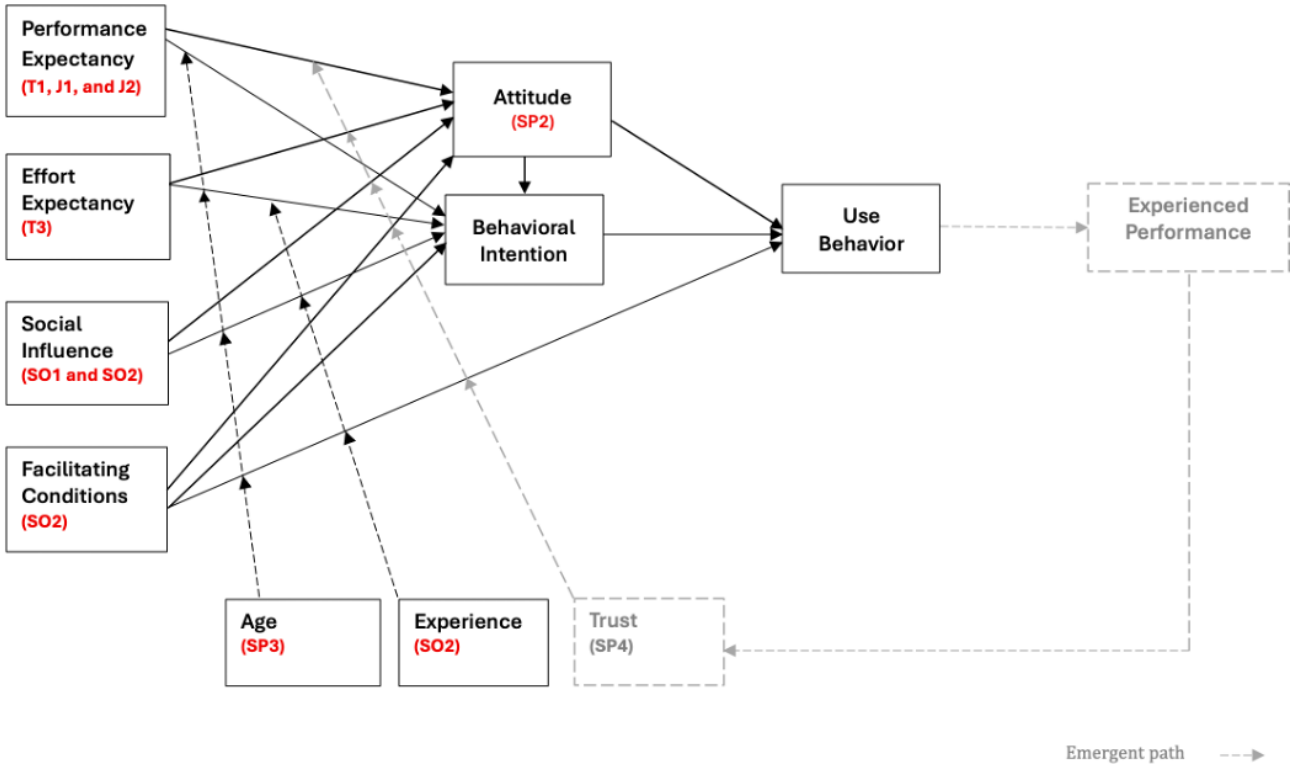
Regarding the actual technology, participants view AI tools as having great potential to help improve health care delivery. Achieving this requires alignment between the design and performance of the AI tool and the individual or organizational goal to accomplish a specific task. Explainability and interpretability are well-known challenges in medical AI, touted as posing a significant barrier to the adoption of AI tools in clinical workflows [49]. Explainable AI offers transparency regarding how AI models reach their outputs, enables error analysis, and increases clinician trust [49]. Although interpretability and explainability are clearly desirable, in contexts such as image diagnostics, their lack does not appear to be a significant impediment since doctors can themselves perform the same tasks manually. This allows them to verify, accept, or refute AI-generated results. In line with this, Aung et al [9] argue that since clinicians use technologies such as CT and MRI, whose internal mechanisms they may not fully comprehend, they may also somewhat accept AI tools that lack transparency if their efficacy is proven. Nevertheless, AI tools can identify anomalies that are invisible or inexplicable to human experts, resulting in a lack of consensus between the clinicians and the AI tools. Lack of consensus is not new and can happen between clinicians. In the same way, there are protocols in place to address human-AI disparities. Still, AI as a technical subsystem presents a challenge to the transparency of tool operations, negatively impacting users' understanding and trust in a tool's given outcomes. However, the social subsystem, like in the case of physicians in image diagnostics areas, fills in this gap using their expertise, illustrating how STS relies on the interplay between human insight and technical function. It is worth noting that explainability remains a critical requirement for AI-based clinical decision support systems in oncology [50]. In fact, explainable and interpretable tools would be advantageous in many contexts, but they may not always hinder tool use.

Although data-related challenges are coded under the technical subsystem in our results, this discussion elaborates on how these issues are embedded within broader sociotechnical dynamics. One key data-related concern highlighted by participants is privacy and security, a concern also explored by Momani [51] and Gawankar et al [52]. While compliance with regulations such as the General Data Protection Regulation (EU) and Health Insurance Portability and Accountability Act (US) may address data privacy and security concerns, the other risks associated with the dependence of AI models on data are inherently sociotechnical in nature. Issues of data generation, availability, and correctness cannot easily be disentangled from the social system. Failed AI implementations also do not necessarily imply technical flaws, as inaccurate outputs may stem from an AI tool itself, poor-quality data input, or misalignment with clinical routines, contributing to suboptimal system performance. Another significant concern that arises from the AI models' reliance on data is the propagation of bias, a phenomenon also documented in literature [53,54]. The issue of model bias warrants further scrutiny. Kotter and Ranschaert [43] argue that addressing this challenge requires standardized and regulated monitoring of outcomes.

Beyond the technical and social factors influencing AI adoption are broader external environmental factors. Participants expressed concerns about current regulatory frameworks for medical AI. They emphasize that regulations fail to account for the adaptive nature of AI algorithms, challenging the reproducibility of AI results. This is underscored by Chua et al [50], who also highlighted the need for a regulatory framework that acknowledges AI's self-learning characteristic. The ambiguity and complexity of regulatory requirements, as well as inconsistent enforcement, create loopholes that may be detrimental to clinical practice. There is a need for clear guidelines that offer sufficient detail and are easy to interpret and implement in real-world health care settings. Additionally, the stability of AI vendors may significantly influence their

XSL•FO
RenderX

sustained use. Participants express concern about the longevity of AI vendors, a concern that causes uncertainty since institutions show a preference for long-term partnerships with their suppliers. Continued use of AI tools requires adaptation and technical support, which depend on reliable vendor engagement. It is essential that vendors remain operational and maintain strong relationships with the institutions using their products. Failure to do so would lead to reduced user confidence and eventual tool abandonment. Although developing in-house solutions may be an alternative, health care institutions must be cognizant of the distinct challenges associated with such an approach [37,43].



Based on the shared perspectives, it can be inferred that the discussed social aspects are shaped by the views and performance of the technical system. Clinician behaviors evolve over time in response to using AI tools, while the tools themselves adapt through feedback to better meet the needs of clinicians, illustrating a mutual shaping of the social and technical systems. The main principle of the STS theory is that systems are most effective when the social and technical subsystems are jointly optimized to support a system's objectives, such as improving the efficiency of clinical processes. To achieve this outcome, there must be a good fit between the subsystems, which facilitates seamless integration of AI tools into clinical practice. A well-optimized system requires a careful balance between tools that provide value while preserving enough clinician involvement to mitigate concerns of loss of control, which could hinder AI acceptance. Viewing AI through the lens of STS theory emphasizes the need to maintain the human-in-the-loop approach. This is particularly relevant given that our results suggest that participants perceive an optimal state of working when both an AI tool and a health care expert function together in a complementary manner.

Acceptance of AI Tools by Clinicians

Overview

To answer the question of acceptance, we turn to the UTAUT model designed for understanding user acceptance. While themes aligned with the STS lens, some of our results reflect the constructs of UTAUT. UTAUT explains factors influencing BI, which in turn influence the use of technology [27]. The STS view of adoption, covering technical capabilities, user perceptions, and social factors, aligns well with the UTAUT constructs. Our results, on the other hand, also include actual use, as some participants have already begun using AI tools, and the use of technology is a strong signal of acceptance and successful integration. Figure 1 presents the UTAUT model, depicting the supporting factors according to our results, with relevant subthemes from the TA in parentheses, for example, T3 below.

Figure 1. UTAUT diagram, with relevant subthemes between the parentheses in red (adapted from Dwivedi et al [55], which is published under Creative Commons Attribution 4.0 International License [56]). The moderators (age and experience) are as per the original UTAUT model by Venkatesh et al [27].

Effort Expectancy (T3)

Our findings show that participants perceive AI tools to be easy to use. As a result, individuals are likely to accept them [14,27]. These findings are in line with several studies identified in a recent literature review by Madan et al [8]. Indeed, some views suggest that some level of difficulty exists. Still, these views are accompanied by expectations that such challenges only happen at the initial stages after the AI tools are introduced, but tend to diminish in the long run. Results also indicate that understanding the tools does not require intense training.

XSL•FO
RenderX

Performance Expectancy (T1, J1, and J2)

The results show that AI tools are perceived to be useful. Perceived usefulness [14], also known as PE [27], is a strong predictor of BI to use a technology [27,57]. PE can be drawn from our results covering the potential for AI tools and the benefits of their use. The results show that participants expect and even experience increased performance with AI tools integrated into clinical practice. AI tools have the potential to streamline care and alleviate pressure on strained resources, provide informational support for patients, and support knowledge development. Participants report that AI tools align well with the tasks they need to perform and contribute to increased accuracy, reduced workload, reduced inter-reader variation, reduced perception errors, time savings, and efficient work processes.

Additionally, using AI tools is seen as a safeguard, likely to increase their awareness of potential human errors. These tools support clinicians' performance and benefit patients through early tumor detection, better treatment, and reduced recall. Given the overarching goal to provide high-quality care while optimizing resource use, these perceptions underscore the importance of EE in shaping positive attitudes and BI to use AI. These participants' perceptions are critical as successful adoption of technologies often depends on how individuals perceive their relevance and utility [58]. While our results indicate BI to use AI tools, the realization of the outcomes mentioned above also confirms actual usage.

Social Influence (SO1 and SO2)

Our results on social influence highlight that information exchange occurs through informal professional interactions. These discussions are positive in nature as they revolve around best-performing tools for specific use cases, as well as the visible benefits derived from the AI tools that are introduced, which are likely to influence or even reinforce their intention to use them. Since many clinicians face time constraints and huge workloads, AI tool benefits such as time-saving and workload reduction can encourage their acceptance [13]. Social influence is expected to have a more substantial effect on BI where tool use is mandated rather than voluntary [27]. Apart from facilitating formal communications, AI champions can also be great influencers.

Facilitating Conditions (SO2)

Several facilitating conditions have also been mentioned by the participants, such as validation of tools, organizational communication, and integration with other technical infrastructure. Facilitating conditions extend to ensuring access to the necessary knowledge [59]. Availability of training and support facilitates the use of AI tools and has been highlighted by participants. Proper training on how to use AI tools increases confidence and encourages acceptance of AI tools [13]. However, we also find that, in some contexts, AI tools are seen as intuitive enough to integrate and use without prior training. This may be particularly true in technically inclined specialties where the introduction of AI tools can be easily integrated into existing routines. In other contexts, however, concerns are raised regarding how well tools integrate with other existing platforms, which deters from the willingness to continue using them.

Moderators (SP3, SO2, and SP4)

Age is expected to play a role in the willingness of health care professionals to accept and use AI tools. While this is not reported in first-person terms, discussions suggest that there is a difference between how younger professionals perceive AI compared with older professionals. Age has already been proven to have a moderating effect between the first 3 constructs and BI [27] regarding technology acceptance. However, its impact in relation to AI tools should be further investigated. Exposure and experience with AI tools, even prior to joining health care institutions, are expected to positively influence the willingness to use AI tools in clinical practice. Participants expect younger professionals to have had more exposure and experience with AI tools, both in educational and personal settings. Apart from this, our study suggests that clinicians who work in tech-heavy specialties, while critical towards how AI tools perform, display less resistance towards AI use. Future research can elucidate whether the experience of technology use in general plays a role in individuals' BI to use AI tools.

Attitude (SP2)

Attitude, which had been included initially as a construct in the TAM, was not included in UTAUT after being found to be redundant as a predictor of BI. Dwivedi et al [55] reintroduced attitude to their UTAUT adaptation, finding that attitude plays an important role in acceptance and use of technology. In turn, attitude is influenced by EE, PE, social influence, and facilitating conditions. The latter is especially true in nonvoluntary settings. Our results reflect a more positive attitude than negative ones, as well as a keenness to use AI tools. According to Dwivedi et al [55], users with a positive attitude are more likely to use the technology; thus, attitude influences both BI and usage behavior. As earlier established, trust (SP4), or lack thereof, can impact whether individuals accept technology. The issue of trust is more pronounced in the context of AI tools, where functionality demands more autonomy and offers less transparency. Trust is likely to have a moderating effect between PE, EE, SI, and FC and an individual's attitude towards AI tools. We have also learned that experienced positive performance reduces skepticism and increases an individual's level of trust. Further research can elucidate the hypothesized effect of trust. A recent study [60] finds that age and experience do not significantly influence attitude.

The alignment of the data, as shared by participants, with UTAUT constructs suggests a strong foundation of acceptance of AI tools in cancer care, while also highlighting potential hindrances. The already established use of AI tools, accompanied by a broadly positive attitude, reflects acceptance and supports UTAUT's outcome of use behavior. However, continued use is contingent on consistent performance of AI tools, adaptability, and addressing unmet needs. While UTAUT helps us understand individual acceptance, its constructs clearly show the interplay between the social and the technical aspects of an STS.

XSL•FO
RenderX

PE, while seemingly technical, is not only about AI's capabilities and its usefulness, but it is also shaped by social perceptions and experiences. Performance of AI tools shapes how individuals perceive them, and perceptions of usefulness, in turn, influence the social aspect, human BI. EE may also appear to be a social aspect since it pertains to how people feel about using the technology and the effort required from them; however, it is influenced by the tool design, interface, and technical support. When AI tools are effectively integrated into clinical workflows, they are more likely to reinforce the perceptions of their usefulness. Social influence is more obviously tied to the social subsystem: people, relationships between them, and social norms. Facilitating conditions entwine the social and technical systems in that they encompass training and other factors relating to organizational preparedness, as well as technical infrastructure, interoperability, technical capability, and fit. These constructs influence sociotechnical outcomes: BI and use. This overlay between UTAUT and STS signifies how AI acceptance is shaped by the interplay between AI tools and the social system that they are intended to support. From an STS perspective, the relationship between user acceptance and the successful integration of AI tools in clinical workflows is bidirectional. Well-integrated AI tools that align with clinical tasks, provide utility, and minimize disruption can foster clinician acceptance [13,50]. However, clinician acceptance can also facilitate a smooth integration of AI tools into the clinical workflow. Openness and willingness to engage with AI tools enable learning, engagement in feedback and adaptation, and meaningful use.

Limitations

Recruiting participants with the specific profile required in this study was challenging due to their limited availability and demanding schedules. Using purposive sampling, we attempted to recruit 135 potential participants. Although efforts were made to recruit participants from a range of medical specialties within the set criteria, and without emphasis on proficiency levels, there remains a possibility of selection bias, as researchers cannot guarantee reaching all relevant individuals. Additionally, the voluntary nature of participation may have also introduced self-selection bias, whereby those with a stronger interest in AI were more likely to take part. We do not claim generalizability of these results to all oncology clinicians. However, the participants' time constraints and scarcity in research participation make the contribution of the participants especially valuable, lending it a unique strength.

Our sample included 18 health care professionals involved in cancer care, encompassing both practicing clinicians and nonclinical roles such as biomedical technicians and medical physicists, as well as one participant from AI research and development, to capture a broader range of insights related to AI adoption and use in cancer care. Although not all participants were patient-facing clinicians, those in nonclinical roles play a critical role in implementing and managing AI tools, particularly in diagnostic imaging, radiation therapy, and treatment planning.

While the sample size is adequate for qualitative analysis, it remains relatively small and is drawn from specific health care institutions, primarily located in the Nordic region. This may limit the transferability of the findings to other contexts or countries. The majority of participants are based in Sweden, a technology-forward country. Such a positive view may bias the results towards more positive perceptions of AI tools. Additionally, the study focused on contexts where image-based AI tools are used. For this reason, issues that may be unique to cancer care contexts that use different data modalities could have been missed. However, this is not expected to invalidate the results, as literature shows that the most approved AI tools in cancer care are AI-based image diagnostic tools.

We acknowledge that the term "AI tool" may be perceived as too general. However, we maintain its use as an umbrella term because participants describe a variety of AI tools and even similar tools used differently within similar clinical domains. This diversity reflects real-world variation in AI implementation and related experiences across health care settings. As with all qualitative studies, the findings are intended to offer rich, contextual insights into the phenomena of AI acceptance and adoption and not statistical generalizability. Despite these limitations, this study offers a valuable perspective into the real-world application of AI tools in cancer care from a sociotechnical viewpoint.

Conclusions, Recommendations, and Future Research Directions

Participants (primarily users/evaluators in settings where AI tools are present) generally perceive AI tools to deliver tangible benefits for both clinicians and patients. However, successful implementation requires careful integration into workflows, alignment with clinician needs, and continued validation. Applying STS theory, we offer a holistic view of how AI tools shape and are shaped by health institutions, people, and their work processes. Understanding this sociotechnical interplay is critical for AI tools that support clinicians in delivering quality care while preserving clinical expertise. Using UTAUT, we identify the determinants influencing the clinicians' intention to adopt or continue using AI tools. Our findings suggest that acceptance is not only a precursor to use but can also result from how well AI tools integrate into and support established work routines and clinical needs. Although a general positivity towards using AI tools is seen, we highlight the need for health care institutions to pay attention to the concerns that negatively impact clinicians' acceptance of AI tools, such as the need for communication early on in the project, performing an impact analysis to ascertain tool impact on people and workflows early on, increasing knowledge of AI and potential negative consequences, and carrying out continual validation.

More importantly, the newly arising negative effects of AI use, such as automation bias and potential skill erosion, must be addressed. Mitigation strategies, such as periodic non-AI proficiency runs where work should periodically be done independently and without the support of AI tools, have been suggested by participants to preserve skills. Another way is AI implementation that enforces double reading for edge cases to ensure that 2 clinicians attend complex or ambiguous cases and continue to apply and sharpen their skills.

External factors such as regulations, vendor stability, and broader infrastructure and governance at the national level can

XSL•FO
RenderX

also facilitate or hinder adoption and sustained use. Current approaches to validation are perceived as onerous. The cost, time, data, and data preparation tasks, and effort to perform local validation for every trial AI product are not sustainable and delay AI adoption. As suggested by participants, shared regional validation consortia may be a solution. This may be a reasonable approach for regions within a single country or group of countries where a similar patient population is served. Within such a consortium, validation strategies, resources, and experiences can be shared, which may reduce costs and uncertainty and result in more robust, long-term implementations.

Future research should address training needs and how to implement safeguards against unintended consequences, such as overreliance and skill erosion, as well as prioritize co-design with clinicians to ensure better tool-task alignment.

Acknowledgments

We want to thank Neshe Tuna, who assisted during the data collection process. We would also like to thank our participants for sharing their time and valuable contributions.

Funding

The authors declare no financial support was received for this work.

Data Availability

All data generated or analyzed during this study are included (in aggregated form) in this published article (and its supplementary information files).

Authors' Contributions

ACK and ASA contributed to the conceptualization, data collection, analysis, and writing of the manuscript.

Conflicts of Interest

Abstract

Background: Digital health services (DHS) are an increasingly integral part of health care services. Understanding users' abilities to engage with DHS is crucial to ensuring that health technology meets their needs. Assessing digital health literacy (DHL) and health technology readiness can help identify the strengths and weaknesses of DHL in different subgroups.

Objective: This study aimed to assess DHL and health technology readiness among people with epilepsy or multiple sclerosis (MS) and, accordingly, identify and categorize them into distinct subgroups or profiles. In addition, we aimed to investigate respondents' use of DHS in managing their chronic condition and differences in DHL and health technology readiness between DHS users and nonusers.

Methods: An electronic survey was distributed to people with epilepsy or MS with the help of patient organizations. The questionnaire included the Finnish version of the Readiness and Enablement Index for Health Technology. The subgroups of respondents were identified using k-means cluster analysis. Nonparametric tests were used to compare health technology readiness among identified subgroups.

Results: Respondents (N=289) had mid- to high-level scores in all the dimensions describing DHL and health technology readiness. A total of 4 distinct profiles emerged with different strengths and weaknesses in their DHL and health technology readiness. There was a significantly higher proportion of DHS users among the 2 profiles with the highest DHL, profile 1 (62/81, 76.5%) and profile 2 (59/80, 74.7%), compared with the profile with the lowest DHL, profile 4 (20/50, 40%; $P<.001$). In contrast, those with the lowest confidence in their DHL had higher emotional distress, reported lower confidence in the support from their health care providers, and had a smaller proportion of DHS users. In addition, the DHS users had significantly higher DHL levels in 6 of the 7 dimensions, as well as higher confidence in the support they received from their health care providers (mean 2.71, SD 0.72; $P=.01$) compared with nonusers (mean 2.42, SD 0.90) and in social support for health (mean 2.81, SD 0.71; $P=.02$), compared with nonusers (mean 2.54, SD 0.85).

Conclusions: Identifying subgroups with distinct profiles, characterized by different strengths and weaknesses in their DHL and health technology readiness, is crucial in ensuring the development of responsive and inclusive DHS to meet the needs of all users, particularly those requiring support in using DHS. In addition, the nonusers had lower confidence in the support they received from their health care provider than the users. Further research is needed to understand this difference.

KEYWORDS

digital health; digital health literacy; health technology readiness; epilepsy; multiple sclerosis

Introduction

Digital health interventions have proven to be clinically effective [1-9], cost-effective [2,3], and beneficial in the self-management of chronic diseases [4,10]. These interventions are closely associated with digital health literacy (DHL) [11-14], which refers to the ability to search for, understand, and evaluate health-related information from electronic sources and then use it to solve health-related problems [15]. Therefore, assessing DHL is crucial for elucidating the success of digital health interventions [16].

A high DHL level has been associated with higher education [17,18], increased use of digital health [17,19,20], and digital competence [21]. However, the relationship between DHL and chronic diseases remains complex. Some studies have noted low or inadequate DHL among patients with chronic diseases

XSL•FO
RenderX

[17,22,23], whereas others have found good levels of DHL [18,19]. Chronic diseases, including neurological disorders [24], are a growing cause of increased disability-adjusted life years and a burden on health care systems [25]. Epilepsy and multiple sclerosis (MS) are chronic preference-sensitive neurologic conditions [26] with multiple treatment options [27,28]. Treatment success depends on a combination of evidence-based medicine and patient-provided information [29] alongside individualized care plans and regular monitoring [30,31].

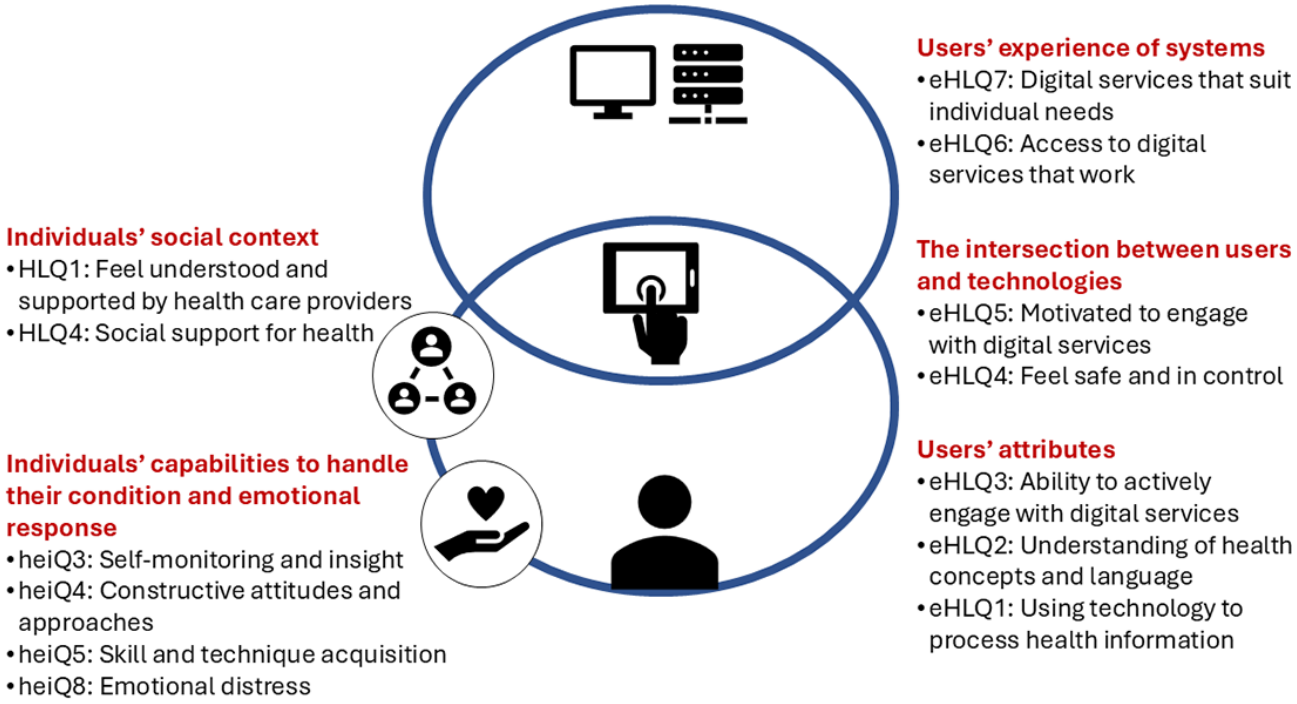
Both patients and health care providers have found digital health applications useful in the care and self-management of chronic conditions [32]. This trend is reflected in the increasing use of digital health technology for neurological care [33]. For example, the Finnish Neuro Registry is integrated into electronic patient records and includes a patient interface for people with MS and a digital seizure diary for those with epilepsy [34]. Similarly, electronic patient interfaces for epilepsy [35] and MS [36], as well as disease-specific digital care pathways for MS [37,38], have demonstrated promising results in improving care [35-37].

To ensure the effectiveness of digital health services (DHS), it is essential to elucidate the DHL of individuals with chronic diseases. In addition to disease-related background and sociodemographic characteristics, individuals' health technology readiness and emotional and mental well-being should be assessed to identify vulnerable subgroups [39]. It is also essential to understand more about individuals' strengths and weaknesses in terms of DHL and health technology use. Therefore, in this study, we assessed DHL and health technology readiness among people with epilepsy or MS and identified profiles of DHL and health technology readiness in this population. In addition, we investigated respondents' use of DHS in the management of their chronic condition and compared DHL and health technology readiness between the users and nonusers of DHS.

Methods

Recruitment

A cross-sectional survey was conducted between April 2022 and April 2023 to investigate DHL and health technology readiness among people with epilepsy or MS. The questionnaire was available in both Finnish and Swedish, the official languages of Finland. The survey targeted people diagnosed with epilepsy or MS, with no other eligibility criteria.



The first round of data collection began in April 2022 with an invitation to an online survey distributed by the Finnish Neuro Society to its members. The survey was closed in August 2022, when no further responses were received despite reminders. The second round involved paper questionnaires and the online survey. The latter was distributed by the Finnish Epilepsy Association to its members in November 2022 and by the Finnish Pensioners' Federation in January 2023, with the aim of reaching members diagnosed with epilepsy. The second round of data collection was closed in March 2023. The paper questionnaires were distributed to all eligible patients at the Department of Neurology of a university hospital in Finland. Additionally, they were distributed at events organized by the Finnish Epilepsy Association. The final paper questionnaires were distributed at the end of March, with a final response deadline in April 2023.

Instruments

The questionnaire was based on the Finnish version of the Readiness and Enablement Index for Health Technology (READHY-FIN) [40]. Readiness and Enablement Index for Health Technology (READHY) is an internationally validated instrument that measures levels of DHL and health technology readiness [41]. It consists of questions from 3 widely used instruments: the Health Education Impact Questionnaire [42], the Health Literacy Questionnaire [43], and the eHealth Literacy Questionnaire [44]. READHY-FIN comprises 65 items across 13 dimensions assessing 5 aspects of DHL and health technology readiness (Figure 1 [41]). These items are rated on a 4-point Likert scale ranging from 1="strongly disagree" to 4="strongly agree." The dimension of *emotional distress* was reverse-coded such that a higher score depicted less emotional distress. The score for each dimension and domain was calculated as the mean of the scores for the included items. If at least 50% of the items within a dimension were answered, the score for the dimension was manually calculated as an average of the items that were answered [41]. The READHY-FIN instrument was translated and culturally tested according to the protocol of the University of Swinburne [45] and validated in the Finnish population [40]. For the Swedish questionnaire, we used the Swedish version of READHY (READHY-SWE), which was translated by the developers of the original instrument [41].

RenderX

Figure 1. Finnish version of the Readiness and Enablement Index for Health Technology [40] (adapted from Kayser et al [41], which is published under Creative Commons Attribution 4.0 International License [46]). eHLQ: eHealth Literacy Questionnaire; heiQ: Health Education Impact Questionnaire; HLQ: Health Literacy Questionnaire.

Additionally, the questionnaire included items describing the participants' sociodemographic and disease characteristics. The use of different service channels for managing their chronic condition included multiple choices. Of these, the use of DHS was defined as the use of any digital health service channel (patient interfaces or digital care pathways for MS or epilepsy) to manage their chronic condition; nonusers were defined as those who never used DHS to manage their chronic condition.

Statistical Analysis

The data analysis was performed with SPSS (version 29.0; IBM Corp). The data are presented as percentages and means. K-means clustering was used to identify profiles of respondents based on the dimensions of the READHY instrument. Cluster analysis can be used to identify subgroups or profiles of technology users based on the similarity of response patterns [47]. In previous studies using the READHY instrument, the number of clusters was 4 [41,48], 5 [39], or 6 [49]. Therefore, we tested our data using models ranging from 3 to 6 clusters. We assessed the appropriateness of the number of clusters by evaluating SDs and ANOVA for between-group differences, as well as pairwise comparisons between profiles on each READHY dimension. We chose the 4-cluster model because it produced the best between-profile variability and minimal within-profile variability.

To increase understanding of the dimensions and domains of READHY in different groups of respondents, we conducted comparisons based on respondents' characteristics, use of DHS, and the profiles identified in cluster analysis. We conducted further analyses using nonparametric Kruskal-Wallis and Mann-Whitney tests to compare different profiles and respondent characteristics, as well as to compare the characteristics of users and nonusers of DHS. The significance level was set at $P<.05$ [50]. Pairwise comparisons were performed when significant differences ($P<.05$) were indicated. Significance values were adjusted by the Bonferroni method for multiple tests to control for type I error.

Ethical Considerations

Ethics approval for the research was obtained from the Ethics Committee of Tampere University Hospital (R21057). The research complied with the World Medical Association's Declaration of Helsinki and was conducted in accordance with the principles of good research practice [51,52], the Finnish National Medical Research Act [53], and guidelines governing nonmedical research [54].

The respondents were informed that participation was voluntary and they had the opportunity to opt out at any time. Their anonymity was guaranteed, and no identifiable information was collected. Written informed consent was obtained from the respondents after they read the information sheet and privacy notice and before they started to fill out the anonymous questionnaire. Responding on behalf of a person was possible when the respondent was unable to do so themselves [54]. No compensation was provided to participants.

Results

Respondent Characteristics

The total number of participants was 289; their characteristics are summarized in Table 1. Their average age was 49.3 (SD 13.3) years, with most respondents (228/287, 79.4%) identifying as women. Two-thirds (188/289, 65.1%) of participants were diagnosed with MS, and two-thirds (188/288, 65.3%) were identified as users of DHS in managing their chronic condition.

Educational level (n=286)					
Primary and lower secondary education	22 (7.7)	6 (7.9)	5 (6.3)	5 (6.4)	6 (12.2)
Upper secondary or vocational education	88 (30.8)	16 (20.0)	21 (26.6)	26 (33.3)	25 (51.0)
Bachelor's-level degree	89 (31.1)	24 (30.0)	28 (35.4)	26 (33.3)	11 (22.4)
Master's-level or doctoral degree	87 (30.4)	34 (42.5)	25 (31.6)	21 (26.9)	7 (14.3)
Use of DHS[a] for the care of chronic disease (n=288)					
Active users (monthly or more often)	58 (20.1)	20 (24.7)	18 (22.5)	15 (19.5)	5 (10.0)
Occasional users (once or few times a year)	130 (45.1)	42 (51.9)	41 (51.3)	32 (41.6)	15 (30.0)
Nonusers	100 (34.7)	19 (23.5)	21 (26.3)	30 (40.0)	30 (60.0)

[a]DHS: digital health services.

Most respondents were evenly distributed across 3 of the 4 educational levels (Table 1): upper secondary school or vocational education (88/288, 30.8%), lower-level university degree (89/288, 31.1%), and upper-level university degree or doctoral degree (87/288, 30.4%).

The Use of Health Care Services and Digital Health for Managing Chronic Conditions

The use of various health care channels for managing respondents' chronic conditions is reported in Table 2. Face-to-face visits were the most common channel used by the respondents (271/288, 94.1%). However, nearly two-thirds (172/271, 63.5%) of those with face-to-face visits contacted their health care provider only once a year or less often.

Nearly half (91/188, 48.4%) of the users of DHS for managing their chronic condition had used DHS a few times a year, and one-quarter (47/188, 25.0%) of the users had used it monthly. There were also very active users, as 5.9% (11/188) used DHS weekly.

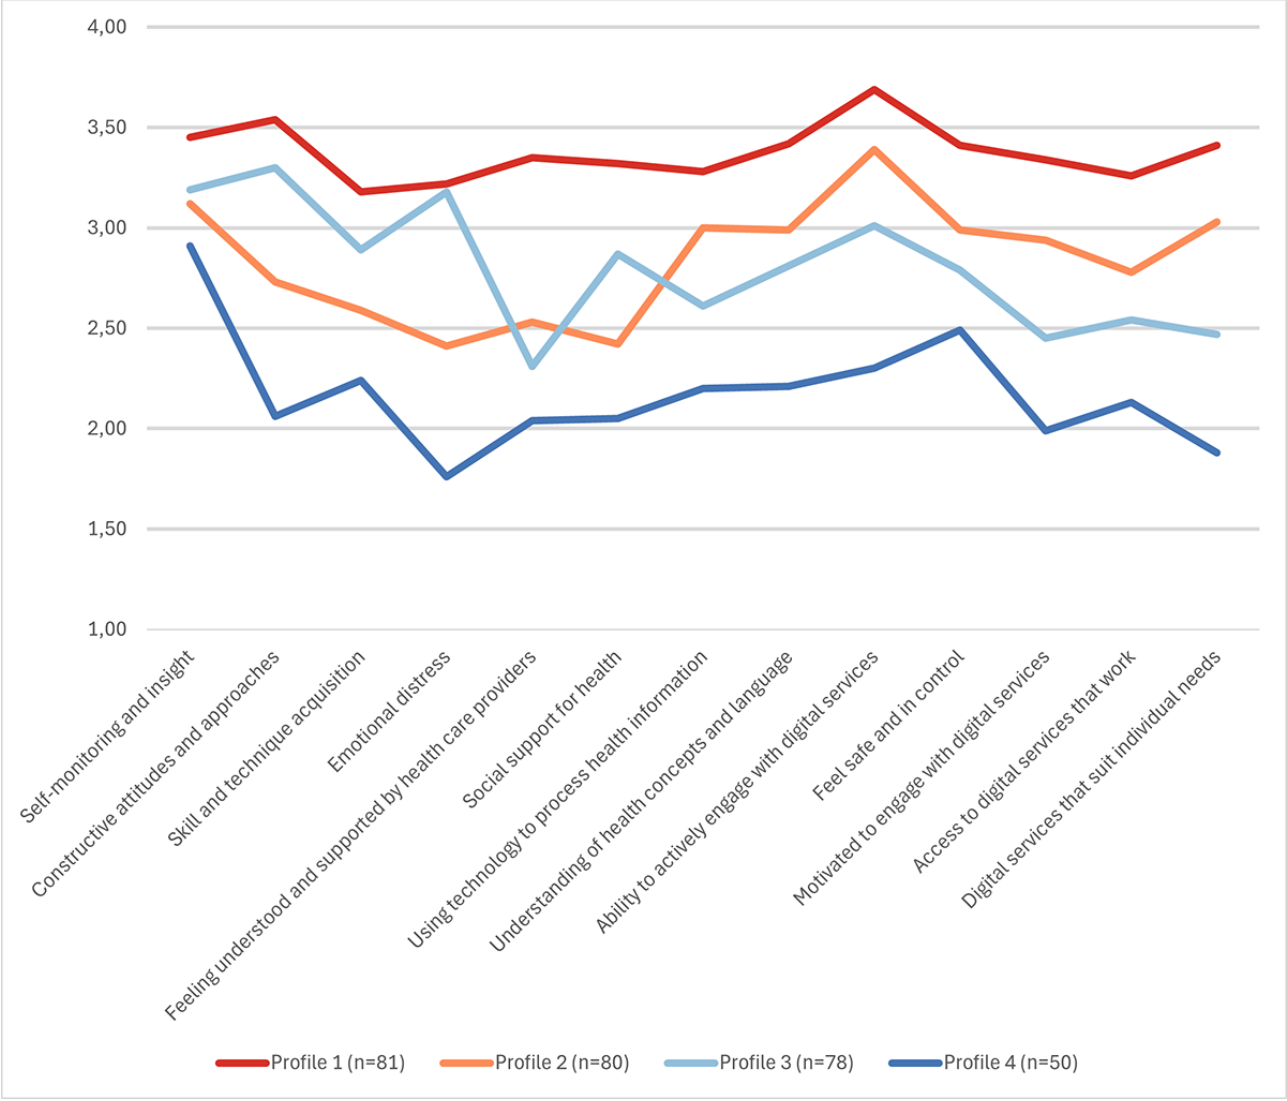
XSL•FO
RenderX

Table . Use of health care service channels.

	Face-to-face clinical visits (n=288), n (%)	Phone and video calls (n=289), n (%)	Digital health services (n=288), n (%)
Weekly or several times a week	3 (1.0)	1 (0.3)	11 (3.8)
Monthly	7 (2.4)	6 (2.1)	47 (16.3)
Few times a year	89 (30.9)	91 (31.5)	91 (31.6)
Once a year or less often	172 (59.7)	86 (29.8)	39 (13.5)
Not at all	17 (5.9)	105 (36.3)	100 (34.7)

DHL and Health Technology Readiness

The average level of respondents' DHL and health technology readiness, measured using the READHY dimensions, ranged from 2.61 to 3.19 (Multimedia Appendix 1). Respondents were highly confident in their *ability to actively engage with digital services* (mean 3.19, SD 0.70), *self-monitoring and insight* (mean 3.19, SD 0.42), and *constructive attitudes and approaches* (mean 3.00, SD 0.71). The dimensions in which respondents were least confident were *feeling understood and supported by health care providers* (mean 2.61, SD 0.82) and *social support for health* (mean 2.72, SD 0.76).



Respondents with higher educational levels had more confidence in their DHL and health technology readiness than those with lower educational levels. In pairwise comparisons, participants with master-level or doctoral degrees scored significantly higher than respondents with upper secondary school or vocational education in the domains of *users' attributes* ($P<.001$), *the intersection between users and technologies* ($P=.001$), *users' experience of systems* ($P<.001$), and *individuals' social context* ($P=.005$). Additionally, respondents with bachelor-level degrees had significantly higher scores than those with upper secondary or vocational education in the domains of *intersection between users and technologies* ($P=.02$) and *users' experience of systems* ($P=.02$).

Four READHY Profiles to Describe Subgroups of Individuals With Epilepsy or MS

We identified 4 profiles based on respondents' DHL and health technology readiness (Figure 2).

XSL•FO
RenderX

Figure 2. Four profiles of digital health literacy and health technology readiness.

Profile 1 (81/289, 28%) had a high level of DHL and health technology readiness. They scored high in all READHY dimensions, especially in the *ability to actively engage with digital services* (mean 3.69, SD 0.42) and *constructive attitudes and approaches* (mean 3.54, SD 0.44).

Profile 2 (80/289, 27.7%) had generally high and higher midlevel scores in DHL and health technology readiness. Their scores on DHL ranged between 3.39 (*ability to actively engage with digital services*) and 2.78 (*access to digital services that work*). They had high confidence in their *self-monitoring and insight* (mean 3.12, SD 0.33) but lower midlevel confidence in their abilities to handle *emotional distress* (mean 2.42, SD 0.54).

Profile 3 (78/289, 27%) had generally midlevel DHL and health technology readiness. They had midlevel scores in all DHL dimensions and in the social context. In addition, they had high-level scores in *constructive attitudes and approaches* (mean 3.30, SD 0.45) and in *self-monitoring and insight* (mean 3.19, SD 0.34).

Profile 4 (50/289, 17.3%) had low to lower midlevel DHL and health technology readiness. They did not score high on any READHY dimensions, with the lowest scores in their ability to handle *emotional distress* (mean 1.76, SD 0.51). They had lower midlevel confidence in both dimensions describing their confidence in their social context. However, they had higher midlevel scores on *self-monitoring and insight* (mean 2.91, SD 0.54).

Educational levels varied significantly among the 4 profiles (P<.001). Pairwise comparisons indicated that profile 4 had significantly lower educational levels than profiles 1 (P<.001) and 2 (P=.009).

DHL and Health Technology Readiness Among Users and Nonusers of DHS

Respondents who used DHS to manage their chronic condition reported higher levels of DHL and health technology readiness than nonusers (Table 3). The significant difference was evident in 6 of the 7 dimensions describing the respondents' DHL, as well as in both dimensions describing the respondents' social context. In addition, the difference was significant in *skill and technique acquisition*, one of the 4 dimensions describing individuals' capabilities to handle their condition and emotional response.

XSL•FO
RenderX

Table . Means of Readiness and Enablement Index for Health Technology domains among the users (n=188) and nonusers (n=100) of digital health services.

Dimensions	Users, mean (SD)	Nonusers, mean (SD)	*P* value[a]
Self-monitoring and insight	3.23 (0.36)	3.12 (0.50)	.20
Constructive attitudes and approaches	3.06 (0.66)	2.88 (0.79)	.08
Skill and technique acquisition	2.85 (0.50)	2.62 (0.66)	.002
Emotional distress	2.79 (0.72)	2.64 (0.82)	.18
Feeling understood and supported by health care providers	2.71 (0.72)	2.42 (0.90)	.01
Social support for health	2.81 (0.71)	2.54 (0.85)	.02
Using technology to process health information	2.94 (0.50)	2.62 (0.62)	<.001
Understanding of health concepts and language	3.03 (0.50)	2.73 (0.61)	<.001
Ability to actively engage with digital services	3.32 (0.61)	2.93 (0.79)	<.001
Feel safe and in control	3.04 (0.55)	2.84 (0.71)	.06
Motivated to engage with digital services	2.91 (0.58)	2.46 (0.68)	<.001
Access to digital services that work	2.84 (0.55)	2.54 (0.55)	<.001
Digital services that suit individual needs	2.95 (0.30)	2.48 (0.77)	<.001

[a]*P*<.05 is considered statistically significant.

Users of DHS were significantly younger (*P*=.03) than nonusers. This was the only statistically significant difference identified between the 2 groups in terms of their characteristics. However, we identified significant differences (*P*<.001) in the proportion of DHS users among different profiles. In pairwise comparisons, there were significantly fewer users of DHS among profile 4 compared with profile 1 (*P*<.001) and profile 2 (*P*=.001).

Discussion

Principal Findings and Comparison With Prior Research

The key finding of our study was that, although the respondents were fairly to highly confident in their overall DHL and health technology readiness, we identified 4 subgroups with distinct READHY profiles. Each profile had different strengths and weaknesses in their confidence in the 13 READHY dimensions.

Our findings align with those of previous research with the READHY instrument [48,49] and with research using other DHL instruments [17,21]. More specifically, our results indicate that among people with chronic conditions, there are differences in their DHL, suggesting that, in addition to their disease background, other factors are also associated with their DHL, which is consistent with earlier findings [21,55]. However, despite being highly confident in their ability and motivation to manage their condition and emotional response, the respondents reported lower confidence in receiving social support compared with previous research [48,49,56]. Consistent with this, Kuusisto et al [57] reported that people with MS felt that the information obtained from their health care professional was insufficient to facilitate their participation in shared decision-making regarding their care. This potential gap in patient-health care provider communication needs to be addressed to ensure that individuals with chronic conditions receive the support necessary to manage their condition. Further research is needed to determine whether this is a cultural phenomenon or a result of the health care system.

The 4 READHY profiles had different strengths and weaknesses. Profiles 1 and 2, with the highest confidence in their DHL, also had a significantly higher proportion of DHS users compared with profile 4 with the lowest level of DHL, indicating an association between DHL and the use of DHS for managing their chronic condition. However, although profile 1 had high confidence across all dimensions, profile 2 had higher *emotional distress* and lower confidence in their *skill and technique acquisition* to manage their condition and in the social support they received compared with profile 1. This implies that profile 2 could benefit from additional support for managing their health and emotional well-being. Profile 3, with midlevel scores, and profile 4, with low to lower midlevel scores on DHL dimensions and fewer users of DHS, indicated that they could represent individuals who need more support in using DHS. Additionally, profile 4—characterized by the highest emotional distress and the lowest confidence in the social support received compared with the other profiles—may represent individuals who require more support when using DHS to manage their chronic condition and who may therefore be more likely to prefer traditional face-to-face visits.

XSL•FO
RenderX

Our results also indicated that respondents with higher educational levels had significantly higher DHL, supporting the conclusion by Thorsen et al [39] that factors other than general sociodemographic characteristics and having a chronic disease are significant for the level of DHL and health technology readiness. The 4 profiles we identified increase this understanding of the factors related to DHL and health technology readiness. Identifying the various factors that support and hinder each profile's readiness to use health technology [53] is crucial for developing targeted health technology solutions [57]. Thus, although all 4 profiles reported good confidence in their ability to self-monitor their condition, promoting DHL remains necessary.

Our finding of two-thirds of the respondents having used DHS aligns with research on other chronic conditions [13,37,58]. In addition, DHS could be seen as a channel for frequent contact, as it was used several times a year, even monthly. In comparison, although most participants had face-to-face visits with their health care providers, these visits typically occurred only once or a few times per year. This finding indicates a need to identify the use cases that could be directed to DHS. Furthermore, user-centered development of DHS and the promotion of DHL may support the effective use of DHS.

Users of DHS had higher DHL and health technology readiness than nonusers. In addition, users also had significantly higher confidence in their *social support for health, feeling understood and supported by health care providers*, and *skill and technique acquisition* related to their capabilities to handle their condition. On the basis of these results, more research is required to investigate these relationships. Notably, despite the significant differences between users and nonusers of DHS, the nonusers also had reasonably good DHL and health technology readiness. This could be a result of variation in the level of digitalization among public health care providers, potentially resulting in inequality in access to and opportunities to use DHS.

Limitations and Recommendations for Future Research

This study has several limitations. First, despite the questionnaires being distributed via patient organizations and a neurology outpatient clinic, the sample size remained limited. Because the total number of individuals who received the questionnaire was unknown, it was not possible to calculate sample estimates. This may affect the generalizability of the findings. Second, because participation was voluntary, our sample may be subject to selection bias, potentially leading to an overrepresentation of DHS users. However, the questionnaires were also distributed in paper format through a neurology outpatient clinic, aiming to reach individuals who might not engage with online platforms. Third, prior computer use was not included as a background variable; thus, the association between DHS use and prior computer use could not be investigated.

In addition, this study was conducted in a single geographical area, reflecting the Finnish health care context, and caution must be exercised when generalizing the findings to other health care systems. Finally, the cross-sectional nature of the study precluded the determination of the evolution of DHL level, health technology readiness, and DHS use, necessitating additional longitudinal research. Further research is also required to elucidate whether the participants' perceptions of receiving inadequate social support regarding their health are a cultural phenomenon or a result of the health care system. Furthermore, additional research is needed on using the READHY instrument in the Finnish population and other health care systems.

Conclusions

Our key finding was the identification of 4 subgroups with distinct READHY profiles and different strengths and weaknesses in their DHL and health technology readiness. Understanding these strengths and weaknesses can help in the development of targeted interventions to encourage specific patient groups to take full advantage of DHS. However, this requires the development of processes to facilitate the identification of profiles. Additionally, adequate resourcing of different care channels is needed to meet users' needs.

We identified 2 profiles with high confidence in their DHL, both of which had a high proportion of DHS users and may possibly represent active users of various DHS. In contrast, the profiles with lower DHL could be more likely to use traditional face-to-face health care services and therefore benefit from the support in using DHS in the management of their chronic conditions. Notably, although all 4 profiles expressed generally high confidence in *self-monitoring and insight*, 3 reported low or medium confidence in *being understood and supported by health care providers*. This underlines the importance of ensuring that all individuals feel understood and supported by their health care providers, regardless of the health care channel they use. Future studies should further explore the phenomenon of not feeling supported by health care providers.

Acknowledgments

The authors would like to thank the Finnish Neuro Society, Finnish Epilepsy Association, and Finnish Pensioners' Federation, as well as the Department of Neurology of Tampere University Hospital, for their help in the dissemination of the survey.

Abstract

Background: Young people increasingly experience mental health challenges and often turn to the internet for support. Self-guided digital mental health promotion services have become widely used resources for youth seeking help and guidance. These platforms offer accessible, anonymous support, yet little is known about the concerns young people articulate when engaging with them.

Objective: This study aims to examine inquiries submitted to the digital letter box of Mindhelper.dk, Denmark's most widely used digital mental health promotion service. Using qualitative analysis, the study aims to identify recurring themes in young people's mental health concerns, explore gender differences in engagement, and generate insights to inform the development of more relevant and targeted digital self-help interventions.

Methods: Using an inductive thematic approach informed by a constructivist-grounded theory coding framework, this study analyzes 2523 inquiries submitted to the Mindhelper digital letter box between March 2016 and August 2023. The dataset provides unsolicited first-person accounts from young people in moments of emotional vulnerability, offering insights into how mental health concerns are articulated in naturalistic settings.

Results: The analysis identifies 17 recurring themes reflecting the mental health challenges young people seek help for. These were grouped into 3 overarching analytical categories: Social Relationships and Social Contexts, Emotional Life, and Body and Illness, with the first 2 dominating the material. Prominent themes included Sociality, Love Life, Unease, Self-doubt and Insecurity, and Seeking Support. Across genders, inquiries frequently focused on social relationships, particularly Sociality and Love Life. However, girls were markedly overrepresented among users, while only minor gender differences were observed in the distribution of themes.

Conclusions: The findings suggest that young people's mental health concerns are closely tied to everyday developmental and relational challenges rather than severe psychopathology alone. Digital letter box services may capture early expressions of distress that might not otherwise reach formal support systems. This highlights the preventive potential of such services and the value of using self-initiated digital data to inform the development of relevant digital mental health support and better understand how young people articulate and act on emerging mental health concerns.

Introduction

A substantial proportion of young people in Denmark report poor mental health. This is particularly pronounced among young women, with 34.8% of women aged 16 - 24 years reporting poor mental health in the 2023 Danish National Health Survey, compared with 16.0% among men in the same age group [1]. A recent assessment of well-being in Denmark further indicates that more than 50% of young women aged 16 - 24 years report high levels of stress, compared with 31,6% among young men in the same age group [2]. This challenge is not unique to Denmark; globally, youth mental health trends indicate a substantial increase in issues such as anxiety, psychological distress, self-harm, suicide, and depressive symptoms [3,4]. According to the Lancet Psychiatry Commission, mental ill health now accounts for at least 45% of the overall burden of disease among individuals aged 10 - 24 years, and suicide remains the fourth leading cause of death among those aged 15 - 29 years worldwide [5]. These figures highlight the

XSL•FO
RenderX

significant global impact of mental health problems among young people.

Adolescence and emerging adulthood (the latter typically defined as ages 18 - 25 years) represent particularly vulnerable periods due to rapid physical, cognitive, emotional, and social development [6]. Poor mental health during these formative years can have severe long-term consequences [7,8]. For example, one study found that adolescents with poor mental well-being had significantly higher risks of mental illness, self-harm and suicide attempts, alcohol and substance abuse, interpersonal violence, and all-cause mortality than those with better mental well-being [9]. Emerging adulthood is also a critical window for the onset of mental disorders, with 63% - 75% of mental illnesses first appearing before the age of 25 years [5]. This emphasizes the need for preventive strategies during this developmental stage.

In response to these challenges, digital mental health interventions have emerged as a promising approach [5,10,11]. Digital mental health interventions refer to mental health care delivered via digital technologies, and they can take a variety of forms depending on the target population, purpose, and content of the intervention, the technology used, and the degree of human interaction involved [12]. Research indicates that such interventions have considerable potential to promote mental health, prevent distress, and support the treatment of mental illness. As young people are among the highest users of the internet and digital technologies, these interventions offer advantages such as accessibility, flexibility, and broad reach, making them well suited to address some of the limitations observed in traditional youth mental health services [5]. However, the potential of digital mental health services to promote well-being among young people is not without challenges. Evidence suggests that the level of engagement with digital interventions is critical for achieving positive mental health outcomes [13]. Yet, engagement is influenced by a range of facilitators and barriers that determine whether young people adopt and continue using these services [14].

To ensure that digital mental health support services are effective, it is essential that they are designed with content perceived as relevant and useful by young people. A systematic review by Ho et al [15] identified perceived fit and perceived usefulness as key facilitators of engagement with web-based mental health interventions for young people. Perceived usefulness was enhanced when interventions provided informative and actionable content, while content that was repetitive, overly simple, unspecific, or already known acted as barriers. Similarly, perceived fit was strengthened when interventions were age-appropriate, relevant, and culturally sensitive. Personalization—such as individualized interaction and feedback—further improved perceived fit, whereas lack of personalization and irrelevance (eg, cultural mismatch) reduced engagement. Findings from Borghouts et al [16] reinforce these conclusions, emphasizing that participants were more likely to engage when they perceived the intervention to be useful and a good fit for them. Furthermore, a review has shown that research on youth digital mental health interventions is primarily based on young women, leaving a significant gap in knowledge about how young men engage with and experience these interventions [17]. Understanding these gendered aspects is essential to ensure that digital mental health services are inclusive and meet the needs of all young people.

Building on this, this study seeks to contribute to the field by providing insight into the issues young people seek help for when experiencing mental distress. This is achieved by examining inquiries submitted to a digital letter box in Denmark's most widely used digital mental health promotion services, Mindhelper.dk. Specifically, the study aims to (1) identify recurring themes in young people's inquiries about mental health and well-being, (2) examine how gender may shape these experiences in the context of engaging with a self-guided digital platform, and (3) generate insights to inform the design of more relevant and targeted digital self-help interventions for young people. Through qualitative analysis of letter box inquiries, this study offers valuable knowledge about the mental health challenges faced by Danish youth and their engagement with digital support services.

Methods

This section presents the methodological framework of the study. To situate the analysis, we first describe the empirical context, followed by a detailed account of the data and ethical considerations. Finally, we outline the analytical strategy applied in the study.

Empirical Context

Mindhelper.dk was launched in 2016 and is now the largest public digital youth mental health–promoting service in Denmark with approximately 1 million visitors a year. Mindhelper is a self-guided service that aims to provide young people in Denmark with knowledge, advice, and tools on a wide range of mental health and well-being topics, including anxiety, depression, dating, and friendship problems, self-harm, and suicidal thoughts. The platform offers online courses, papers, videos, and guidance on where to seek help offline, as well as a digital letter box for personalized advice. In addition to its website, Mindhelper also provides support through an app with a focus on reducing stress, pressure, or anxiety.

Mindhelper primarily targets young people aged 13 - 25 years, but usage data show that the platform is also widely accessed by children younger than 13 years, young adults older than 25 years, and adults such as parents and professionals (eg, schoolteachers and student counselors). All services at Mindhelper are free, self-guided, and fully anonymous, requiring no user account.

Mindhelper was developed through a collaboration between the Centre for Digital Psychiatry (CEDIP) and 4 Danish municipalities. CEDIP oversees ongoing operations and content development, which is cocreated with young people through a youth network and a panel of 12 members who contribute to testing, feedback, and idea development. Since 2019, Mindhelper has been permanently funded by Denmark's 5 regions, and in 2025, national government funding was added.

RenderX

The Data Material

This study explores young people's inquiries to the Mindhelper letter box over a period of nearly 8 years, covering inquiries submitted between 2016 and 2023. Since 2016, young people have been able to write anonymously to the digital letter box and receive a response within 10 days from psychology students employed at CEDIP. All inquiries and responses are published on Mindhelper.dk, allowing users to read and benefit from each other's experiences. The only editing occurs when personally identifiable information is included, in which case the inquiry is anonymized. There is no censorship of content. Inquiries can be accessed via free-text search using subject-specific keywords or browsed through thematic categories available on the website.

Over time, a few changes have been made to the letter box. When the letter box was launched, young people were required to state their gender (male or female) and age (13 - 20 years) when submitting inquiries based on set categories. In 2021, the gender requirement was removed, and, in summer 2024, the age category was expanded to 13 - 25 years. When submitting inquiries, young people can write up to 1200 characters, and the date and time are automatically entered.

The letter box archive represents a unique empirical dataset, offering rare access to anonymous, first-person accounts from young people written in moments of emotional vulnerability. Unlike retrospective interviews or researcher-generated data, these inquiries are unsolicited and self-initiated, providing immediate and authentic expressions of mental health concerns. This makes the material particularly valuable for understanding youth experiences of distress and well-being as they unfold. At the same time, it is important to note that, as a digitally mediated dataset, the material is influenced by the platform's affordances and constraints, including its written format, character limits, and the characteristics of its user base.

The dataset analyzed includes all inquiries submitted to the letter box between March 4, 2016, and August 7, 2023, comprising a total of 2523 inquiries. The data extraction was conducted by CEDIP and included only the inquiries from the young people–not the associated responses–to ensure that the analysis was not influenced by the content of the replies. Additionally, the analysis did not take into account Mindhelper's thematic categorization of the inquiries.

Ethical Considerations

This study is registered and approved by the University of Southern Denmark in accordance with the Data Protection Regulation and the General Data Protection Regulation (EU) 2016/679 and has additionally been approved by the University's Research Ethics Committee (approval ID 23/24293). The analyzed material consists of anonymous inquiries submitted to the letter box of a digital mental health promotion platform. No compensation was provided, as users submitted inquiries voluntarily as part of their use of the platform. All inquiries were anonymized before researcher access and were already publicly available. Although users consented to having their posts published, they were not informed that the content might later be used for research, which raises an ethical consideration about secondary use of data. We assess the risk of harm as minimal because the data were anonymized and originally shared in a public forum. Obtaining informed consent was not feasible, as submissions were anonymous.

Protection of Anonymity in Quotations

However, several measures were applied to balance the use of illustrative quotations with the protection of contributor anonymity. First, all quotations were translated from Danish to English using an interpretive, meaning-based translation process rather than a literal translation. This constituted an additional analytical transformation and reduced traceability. Second, the majority of quotations were shortened to retain analytical relevance while avoiding unnecessary detail that could increase identifiability. In addition, quotations were deliberately selected to illustrate broader themes, shared feelings, or general experiences reflected across multiple inquiries, rather than highly specific or personally identifying narratives that also appeared in the material. Third, although inquiries on the platform were publicly associated with unique identification numbers, these identifiers were deliberately omitted from all quotations and descriptions in the manuscript to prevent direct linkage to the original submissions. Overall, this approach was consistent with principles for the responsible use of publicly available, anonymized data.

Analysis Strategy

Coding Framework

The analysis followed an inductive thematic approach, informed by Charmaz's constructivist grounded theory as a pragmatic coding framework, to examine patterns of meaning across the 2523 inquiries [18-20]. While guided by constructivist grounded theory principles, the aim was not to generate a formal grounded theory or explanatory model but to use iterative coding strategies to develop analytically grounded themes and categories. Coding followed 2 main phases described by Charmaz: initial coding, involving close reading of each word, line, or segment of data to remain open to multiple possible interpretations, and focused coding, which uses the most significant or frequent initial codes to sort, synthesize, and organize larger segments of the dataset [19]. These phases were operationalized across 3 coding rounds: round 1 (initial coding), and rounds 2 and 3 (focused coding), as described in the following sections.

Given the size of the dataset, we used NVivo (Lumivero), a qualitative analysis software, to facilitate data storage, coding, and comparison [18]. To ensure feasibility, the first author (AOK) conducted a pilot coding on a small sample (n=49 inquiries), focusing on the technical aspects of accessing and organizing the material and enabling comparison across the dataset. This confirmed NVivo as a suitable tool for managing the data. The test coding did not involve engagement with the thematic content, ensuring consistency with the inductive and grounded approach applied in the study.

Coding Round 1: Initial Open Coding

All inquiries were read and coded by the first author (AOK). The aim of the initial open coding round was to identify topics, descriptions, and statements that contributed to a nuanced understanding of why the young person contacted the letter box.

XSL•FO
RenderX

Following the grounded theory principle of line-by-line coding, each relevant segment was assigned a code, and a single inquiry could contain multiple codes, as short statements or excerpts often addressed several points [19]. The coding process remained close to the data, using simple and precise codes, as outlined in the codebook (Multimedia Appendix 1). Importantly, coding was kept open, allowing new codes to be created as new perspectives emerged. In addition to assigning short code titles, a code description was developed for each code.

In the open coding round, gender, age, and the electronically registered submission time and date were specified for each inquiry. For inquiries where gender was not stated—since it was not a requirement—"unknown" was entered, unless the content of the inquiry explicitly indicated gender (eg, "I am a 16-year-old girl"), thus relying solely on explicit, self-reported statements of gender and avoiding interpretive attribution. This would have applied equally to all explicitly stated gender identities, whether binary or nonbinary.

Gender and age were also adjusted if the information explicitly provided in the inquiry differed from the predefined categories, in which case the text always took analytical precedence. Such adjustments were particularly common in relation to age, as some young people stated that they were younger than 13 years or older than 20 years. Similarly, gender categorizations were guided exclusively by how young people described themselves in the inquiry text. If a young person had explicitly stated a gender identity other than girl or boy, this would have been recorded accordingly; however, no inquiries included such explicit self-description.

Among the inquiries included in the analysis, it was not possible to identify the gender of the young person in 455 inquiries. It should be emphasized that the unspecified gender category should not be interpreted as reflecting a particular gender identity or group. Rather, it solely indicates that the young person did not disclose their gender, regardless of whether their gender identity is binary, nonbinary, or otherwise.

Coding Round 2: Focused Coding and Refinement of Codes

In the second coding round, we moved toward focused coding, aiming to synthesize and explain larger segments of data [19]. At this stage, we sought to ensure consistency in the content of the codes and comparability between the inquiries assigned to each code, as the goal was to determine the adequacy of the codes. The first author (AOK) reread all coded data within each of the 115 codes, and any inquiry that did not align with the overall content of its assigned code was recoded. Similarly, code titles and descriptions were revised when necessary to better reflect their content and maintain proximity to the data. Codes were deleted if they became irrelevant due to recoding or merged when they overlapped with other codes. Code descriptions were actively used as analytical reference points during this process to assess whether the inquiries grouped under each code consistently reflected the defined content of the code. Where discrepancies were identified, codes and their descriptions were iteratively revised to maintain conceptual coherence and proximity to the data. After reviewing each code, frequently used words were searched across the remaining material to identify any potentially overlooked inquiries. This process involved comparing data with data and data with codes, which helped refine and strengthen the coding structure. Following this focused coding round, the number of codes was reduced to 101 (for a complete overview of the codes, see Multimedia Appendix 1).

Coding Round 3: Analytical Theme Formation

In the third and final round of coding, the 101 empirically generated codes were grouped into 17 distinct analytical themes. This step marks another move away from initial coding, which fractured the data into discrete segments, toward reassembling the material into a coherent whole. The focus is on constructing an analytical narrative that brings the emerging categories together in a meaningful and connected way [19]. The first author (AOK) drafted the initial themes, which were then discussed jointly with all the study's authors. Through this iterative process, the final themes and their labeling were iteratively refined and defined. To provide an additional overview of the thematic directions in the material, the 17 themes were further grouped into 3 overarching analytical categories: Social Relationships and Social Contexts, Emotional Life, and Body and Illness (Multimedia Appendix 1).

Following the coding rounds and the identification of themes, exploratory cross-tabulations were conducted between themes, as well as between themes and gender, age, and time of submission (month and year) using NVivo; only patterns deemed analytically meaningful are reported in the results. The unit of analysis was the individual inquiry; accordingly, the reported counts represent the number of inquiries associated with each theme, rather than population-level distributions of concerns.

In the presentation of the 17 identified themes in the Results section, selected quotes are included to support the thematic analysis. These quotes were chosen based on their capacity to vividly exemplify the thematic patterns identified. The aim was to foreground excerpts that best articulate the meaning and scope of each theme, thereby supporting the analytical claims made and providing insight into how each theme is grounded in the data.

Exclusion of Inquiries

During the 3 rounds of coding, inquiries were continuously excluded. Of the 2523 inquiries, 93 were excluded, primarily because they fell outside the scope of the letter box service—for instance, inquiries from young people seeking assistance with school assignments. Inquiries submitted by parents concerning their children's well-being were also excluded, as the study focuses exclusively on inquiries submitted by young people themselves. Inquiries that were incomprehensible were likewise excluded. Additionally, 19 inquiries could not be categorized under broader themes due to their highly individual content and are therefore not included in the thematic analysis. The final thematic structure is based on 2411 inquiries.

Results

This section presents the main findings, including identified themes, intersections between themes, and gendered patterns.

XSL•FO
RenderX

Thematic Analysis

Textbox 1 presents the 17 identified themes, organized across 3 analytical categories: Social Relationships and Social Context, Emotional Life, and Body and Illness. Each theme includes an integrated analytic description that captures recurring patterns in the data. For ease of presentation, the themes will hereafter be referred to using their short title shown in italics.

As illustrated in Figure 1, young people predominantly write about themes within the overarching category Social Relationships and Social Contexts when reaching out to the letter box service. However, a notable number of inquiries also touch upon topics related to complex emotions, as reflected in the themes grouped under the category Emotional Life. Themes within the overarching category Body and Illness appear less frequently in the inquiries, with the notable exception of the theme Psychiatric Diagnoses, which stands out as more prominent.

Textbox 1. Identified themes with integrated analytic descriptions.

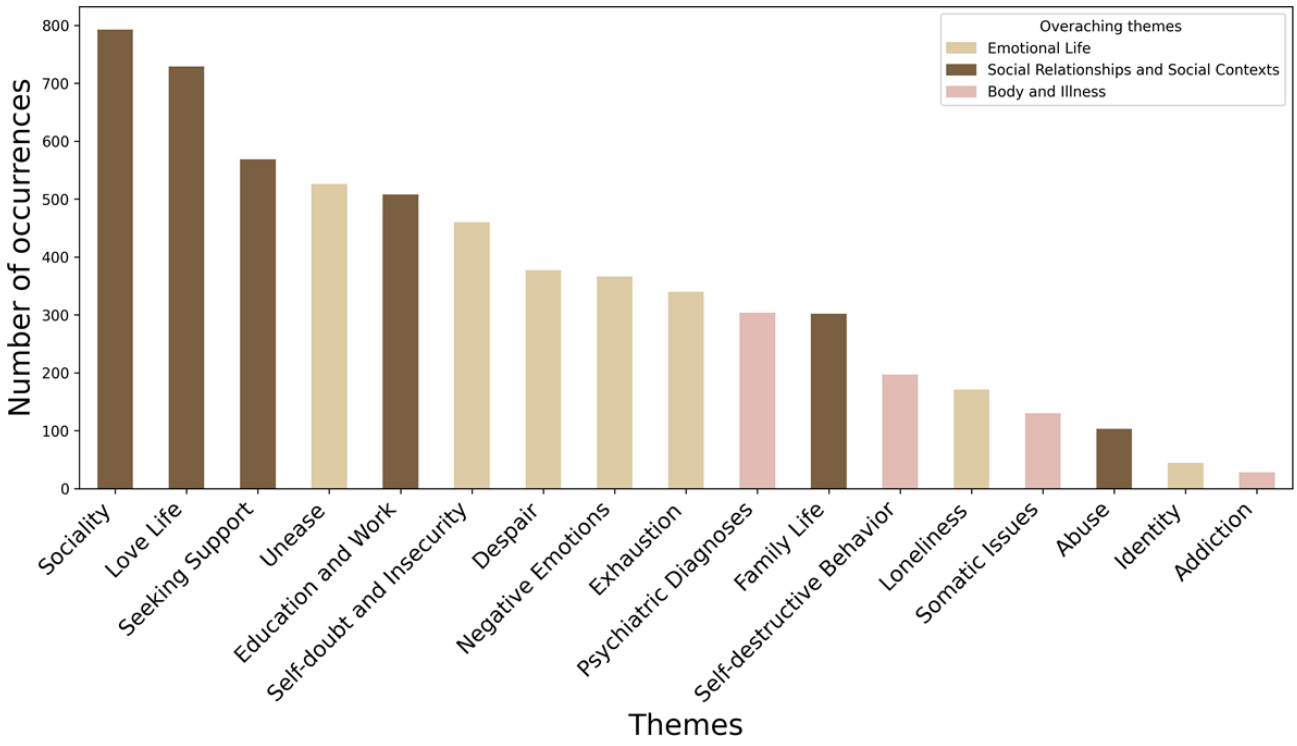
Social Relationships and Social Contexts

- Sociality: navigating social relationships
- Love Life: navigating romantic relationships and feelings
- Seeking Support (represents a crosscutting theme related to help-seeking behavior rather than a distinct concern or emotional issue): attempts to seek support that are often unmet
- Education and Work: experiencing educational distress and uncertainty
- Family Life: experiencing strained family relationships
- Abuse: experiences of violence and harm in relationships

Emotional Life

- Unease: experiencing persistent anxiety and worry
- Self-Doubt and Insecurity: negative self-evaluation
- Despair: experiences of hopelessness, emptiness, and loss of meaning
- Negative Emotions: low and fluctuating mood
- Exhaustion: persistent tiredness and feeling overwhelmed
- Loneliness: feeling alone and excluded from others
- Identity: struggling to form identity

Body and Illness



- Psychiatric Diagnoses: experiences of and seeking clarification about psychiatric diagnoses
- Self-Destructive Behavior: engaging in harmful practices
- Somatic Issues: bodily symptoms, experiences, and concerns
- Addiction: experiences and concerns related to addictive behaviors

Figure 1 shows the distribution of the 2411 inquiries across the identified themes and 3 analytical categories.

The analyses indicate that inquiries to the letter box come from children and young people aged between 8 and 28 years, with the median age across themes ranging from 15 to 17.5 years. Those writing about topics such as *Love Life*, *Psychiatric Diagnoses*, and *Somatic Issues* tended to be slightly older than individuals addressing other themes. In contrast, inquiries related to *Self-Destructive Behavior* were generally submitted by younger individuals compared with the remaining themes. Furthermore, cross-tabulations between themes and time of submission did not reveal any notable patterns.

XSL•FO
RenderX

Figure 1. The distribution of inquiries across 17 identified themes.

Social Relationships and Social Contexts

Social relationships and the social contexts that young people navigate throughout adolescence play a significant role in their inquiries to the digital letter box. Under this analytical category, we present 6 themes that represent some of the most frequently addressed topics in young people's inquiries.

With 793 inquiries, *Sociality* emerges as the most addressed theme, reflecting how young people navigate social relationships. Nearly half of the inquiries within this theme involve friendships, for example, fears of losing friends, broken friendships, conflicts, or feeling misunderstood or unwanted, as the following quote illustrates:

> *[...] I don't really talk to many people my own age, and I haven't spent time with anyone outside of school or work in the past year, except for my partner. Honestly, I don't know what to do and just feel like crying. When I do try to take the initiative to arrange something with friends or acquaintances, it never ends up happening. I generally just feel rejected and unaccepted. It's like I'm stuck in a bubble all by myself.* [Boy, aged 17 years]

Some describe dilemmas such as romantic feelings for friends, worries about friends, or comparing themselves to others. Other submissions reflect more broadly on social life—how they act in social settings, expectations to be social, or doubts about their social skills, for example:

> *I am 20 years old and do not feel that I am doing enough "typical youth things." I often feel more mature than my peers. I therefore feel that I have too few friends and do not know what to spend my time on after work... [...].* [Gender unspecified, aged 20 years]

Some young people seek advice on becoming more social, while others express a desire to withdraw. Many describe insecurity in social situations, such as fear of judgment, saying the wrong thing, or feeling awkward. Others mention shyness, introversion, or being withdrawn. A number of young people also write about concerns of close relationships—family, partners, or friends—where young people seek advice on how to support someone or cope with being close to someone with, for example, mental illness, as expressed by a 13-year-old girl: "My friend has been going through a difficult time lately, and I would like to help him with it. [...]." Finally, some write about social relationships or contexts that have had a particularly negative impact, such as encounters with bullying, experiences of betrayal and mistrust, facing cultural practices within the family, and dealing with difficulties forming close connections.

Love Life is also a central theme with 729 inquiries, highlighting how young people navigate romantic relationships and feelings. These include experiences of being in love, having a crush, or flirting with someone. One submission reads:

> *I'm a 13-year-old boy. I've met a girl—she's really sweet, but I don't know her very well. I think I might have a crush on her, but I'm not sure what that feels like since I've never had a girlfriend before. I don't know if we're a good match, because she goes to a different school than I do, and she's 12. I don't know if she likes me back, and I'm afraid of embarrassing myself. How can I tell if she likes me—can I sense it from the way she talks or looks at me? Thanks in advance for your help.* [Boy, aged 13 years]

While such experiences can be positive, they can also involve dilemmas, such as falling for a friend, someone with a different sexual orientation, or someone who does not reciprocate the feelings. Additionally, young people write about heartbreak and

XSL•FO
RenderX

ex-partners, as one shares: "I desperately need help. My boyfriend broke up with me very suddenly, which now makes me feel like my life has come to a standstill [...]" [Girl, aged 17 years]. Numerous inquiries concern challenges or dilemmas related to romantic relationships with partners including insecurity, jealousy, being apart from their partner, doubts about the relationship's future, and conflicts between romantic partners and friends or family. Few young people write about broader worries in love life, such as how to handle specific romantic situations, worries about finding love, or meeting expectations around love: "[...] I have realized that I am probably afraid of love. I am afraid of being let down. I am afraid of being hurt [...]" [Girl, aged 16 years]. Intimate experiences and sexuality are rarely mentioned, but the few inquiries that do address these topics describe issues such as sex in relationships, sexual expectations, reflections on sexual debut, and coming out or exploring one's sexual identity.

Represented by 569 inquiries, the theme *Seeking Support* points to how young people attempt to seek support but are often not met with the help they need. Rather than reflecting a specific domain of concern, this theme captures how young people navigate help-seeking processes across different types of issues. In the inquiries, young people reflect on or describe experiences, attempts, or actual interactions of seeking help or support related to worries or mental health struggles, most often involving reaching out to partners, friends, or parents. While some young people report positive experiences when reaching out to others, many instead receive limited or insufficient support. Others describe explicitly negative experiences, such as being rejected or dismissed by those they turned to, as the quote demonstrates:

> *I feel like I can't turn to anyone, and I've been feeling really bad lately. Everywhere I read, it says you should talk to someone about it, but what if you don't have anyone to talk to at all? When I try to talk to my mom, we end up arguing because she doesn't understand me and places really high expectations on me. My dad and I don't have a close relationship. [...]* [Gender unspecified, aged 15 years]

Several express reservation about seeking help due to fear of mental health stigma and the shame it generates, and a few mention lacking a support network entirely—prompting them to turn to the letter box instead. Experiences of seeking professional help, such as from general practitioners, psychologists, or services such as Headspace and BørneTelefonen (The Children's Helpline), are also shared in the inquiries:

> *[...] I have been going to a psychologist. She didn't help me, and she seemed indifferent to me and my problems just like everyone else is, indifferent...So what can I do now? [...]* [Girl, aged 15 years]

These encounters are often described as inadequate or disappointing, leading them to seek support through the Mindhelper letter box. Others ask for advice on whether or how to approach professional support. Additionally, several inquiries mention interactions with teachers—ranging from helpful conversations to unsuccessful attempts to get support. Finally, a few young people express a general difficulty in talking about emotions or opening up to others.

A total of 508 inquiries is included under the theme *Education and Work* capturing experiences of educational distress and uncertainty. Nearly half describe educational distress—often due to feelings of insecurity, loneliness, or experiences of exclusion from their class, as expressed by the 17-year-old girl: "I am terrified that I will be left out again in group work. […]." A few young people mention both supportive and difficult teacher relations. Many inquiries concern academic performance, including descriptions of pressure to achieve good grades or difficulties keeping up academically, for example: "My grades are dropping, and it really stresses me out a lot. [...]" [Girl, aged 14 years]. Challenges such as giving presentations, participating in group work, or engaging in classroom activities are also mentioned. Additionally, a few young people write about difficulties with concentration in school. Several young people express thoughts about dropping out, changing their educational path, or switching schools, indicating that youth is a time marked by transitions that often lead to worry and reflection. This is illustrated by a young person who states:

> *I need your help. I'm in a situation where I'm unsure whether I've chosen the right education or the right place for my apprenticeship. My motivation isn't what it used to be when I first started, and I no longer look forward to going to work. I don't feel safe or comfortable at my workplace the way I think I should. [...] I'm training to become a baker, but the way people speak there doesn't really match the kind of person I am. I'm quiet, shy, and introverted, and the industry is much tougher and harsher than I expected. What should I do?* [Girl, aged 19 years]

These concerns are also reflected in inquiries about choosing an education, taking a gap year, or starting at a new educational institution. A few inquiries concern work or part-time jobs, describing pressure, poor conditions, low energy, or workplace well-being. Some also seek advice on job opportunities.

Family Life is addressed in 302 inquiries, illustrating experiences of strained family relationships. Young people describe their relationship with parents or family dynamics, shaped by events such as divorce. Some describe specific conflicts or disagreements with parents, while others express general distress at home, saying that they find it difficult to be there:

> *I can't be around my parents for more than a couple of hours without us starting to argue. Not a day goes by without them making me cry. Normally, I'm a strong person, but I can't handle being torn down every day, and I no longer want to live at home. [...]* [Boy, aged 15 years]

A few mention problematic parental behavior, including dynamics marked by violence or growing up with alcohol abuse by 1 or both parents. Some inquiries also include descriptions of sibling relationships, which can be either positive or negative—for example, concerns about siblings or reflections on how sibling dynamics affect the family as a whole.

XSL•FO
RenderX

The least frequent theme within the category of Social Relationships and Social Contexts, *Abuse*, appears in 103 inquiries, pointing to experiences of violence and harm in relationships. Young people report experiences of physical, psychological, or sexual violence, as illustrated by the account of a young person:

> *[...] At home, I'm having some problems...My dad...I'm afraid of him...But I'm also very stubborn and often talk back. But he becomes very violent when things don't go his way...He yells loudly, grabs us (me and my little brother), and sometimes pushes us. [...]* [Girl, aged 16 years]

Over half concern physical abuse, including violence in romantic relationships or violence observed between parents. The inquiries also include descriptions of sexual abuse, rape, or incest. Others describe psychological or verbal abuse, and a few reflect on having inflicted psychological harm on others.

Emotional Life

A large proportion of young people's inquiries to the letter box concern their emotional life, reflected in 7 distinct themes. *Unease* emerges as the most prominent theme within the emotional category, represented by 528 inquiries, reflecting experiences of persistent anxiety and worry. Young people describe unease in various ways, often explicitly referring to anxiety or panic attacks, for example: "I have struggled with anxiety since I was 6 years old, but it has never been diagnosed. [...]" [Girl, aged 15 years]. Others report uncontrollable racing thoughts, overwhelming worries, or a tendency to overthink everything, for example, worries about the future, or intrusive fears related to death or illness, as expressed in the following excerpt from an enquiry:

> *I can't be in myself anymore, I have far too many thoughts that I can't manage. I overthink EVERYTHING, to the point where it hurts. All kinds of thoughts are spinning around in my head. It's so exhausting, and it affects my everyday life. I can't even feel happy anymore, because I'm constantly thinking about everything. [...]* [Girl, aged 16 years]

In some cases, unease is expressed through physical symptoms resembling panic attacks, such as heart palpitations, shortness of breath, sweating, or dizziness. In a limited number of inquiries, young people describe a sense of unreality, such as feeling detached from their body or being unable to distinguish between dream and reality.

With 460 inquiries, the theme of *Self-doubt and Insecurity* emerges as a central concern revealing patterns of negative self-evaluation among the young people writing to the letter box. The young people express this by thoughts of not feeling good enough, feeling worthless, or being generally unsure of oneself. For some, this is aimed at their body and appearance, with statements such as feeling ugly or fat, as expressed in the following quote:

> *I'm a 15-year-old girl writing here because I'm really unhappy with my body and appearance. Lately, I've become truly dependent on food and have been eating large amounts outside of meals—often in secret because it feels so shameful. I just feel ugly and stupid. My family sees me in a very negative light, which I guess is understandable, but it's also exhausting.* [Girl, aged 15 years]

A small number of inquiries also describe a pervasive perfectionism, rooted in high expectations of oneself and a fear of failure. In other cases, young people explicitly state that they struggle with low self-esteem or lack of confidence. Among 377 inquiries, young people express profound *Despair*, reflected in experiences of hopelessness, emptiness, and loss of meaning. Over half of the inquiries within this theme mention suicidal thoughts, while others describe a sense of detachment—likened to, for example, carrying a black hole inside.

> *I've been feeling empty for a while. Especially in the evenings, I feel like I have nothing to live for. I find it hard to concentrate at school. Sometimes I feel okay, but other times I feel absolutely terrible. Sometimes I just wish I could disappear. Of course I want to live, but I also want to feel good. I'm afraid to tell my parents, even though I know it's one of the best things I could do. I'm also scared to say it out loud, mostly because I don't have a reason to be sad. But still, I feel really awful. Is it normal to cry without having a reason?* [Gender unspecified, aged 13 years]

A recurring statement is the loss of motivation and desire, whether for everyday tasks, former interests, or pursuing education or work. Some express a wish to escape—physically by leaving everything behind or mentally by becoming invisible or disappearing. For others, it takes the form of hopelessness and the belief that nothing will ever improve.

Negative Emotions such as feeling sad, depressed, or downcast are reflected in 366 inquiries, where low and fluctuating mood frequently emerges. Many young people describe a persistent sense of emotional distress, often articulated as a lack of joy, a constant urge to cry, or crying frequently, which is exemplified by a 20-year-old young woman, who opens her inquiry by writing: "I have been feeling sad and down for quite some time. Without being able to say for sure, I'm afraid I might be developing depression. [...]."

While sadness dominates this theme, a few inquiries express anger or frustration, sometimes through descriptions of shouting or screaming, as a 17-year-old girl writes in her inquiry: "[...] I also get angry and irritated with people more quickly, and that makes me even more angry. [...]." Some young people seek advice on managing overwhelming emotions or mood swings. This theme also includes experiences of grief and anticipatory grief.

Exhaustion is a recurring theme in 340 inquiries, described as constant fatigue or feeling drained of energy. Sleep problems are also common, including difficulty falling asleep or poor sleep quality, for example: "[...] I have trouble sleeping. I often lie for several hours with my eyes closed. [...]" [Boy, aged 13 years]. Additionally, some report feeling stressed, pressured, or overwhelmed in their daily lives. These experiences are clearly illustrated in the following inquiry:

XSL•FO
RenderX

> *I feel constantly down, sad, and incredibly tired all the time. I usually bike 14 km on weekdays, but I can't cope with it, and I'm just really sad. I get stressed and angry quickly, and I find it hard to tolerate many things, which makes me easily irritated with people. What could be wrong with me? Or what can I do to feel better?* [Girl, aged 16 years]

The theme of *Loneliness* is based on 171 inquiries, with loneliness expressed both directly and indirectly in young people's accounts of feeling lonely, alone, or experiencing life as lonely. While several young people explicitly mention loneliness, others express it through statements about often being alone, as seen in the words of a 15-year-old who begins their inquiry with: "I feel very left out, wrong, and alone. [...]."

The final theme within Emotional Life concerns *Identity* and appears in 44 inquiries, where young people struggle to form a sense of identity. Most involve young people reflecting on their interests and hobbies as part of shaping their identity. One young person describes her struggle with finding purpose:

> *I just have this problem that I don't have any interests or hobbies to spend my time on. I have a boyfriend and a job, and when I'm not working or with my boyfriend, I simply don't know what to do. As a child, I tried a whole range of extracurricular activities—everything from handball to cooking and crocheting—but nothing ever caught my interest. I have no talents, and I'm neither creative, musical, nor anything like that. TV series and movies don't really appeal to me, and books can't hold my attention either. Because I don't have anything I'm passionate about or spend my time on, I feel empty inside.* [Girl, aged 19 years]

A few describe compulsive lying to close relations—sometimes, for example, about sexual experiences—which have spiraled out of control. Others express a sense of identity crisis, feeling disconnected from who they once were.

Body and Illness

While 4 themes concerning Body and Illness have been identified, their significance appears limited within the overall narrative of young people's inquiries to the letter box. However, several young people write about *Psychiatric Diagnoses*, constituting the largest theme within this category, with 304 inquiries. Thus, although the category Body and Illness itself is relatively small, the theme *Psychiatric Diagnoses* ranks as the tenth most prevalent across the 17 identified themes, as previously shown in Figure 1. This theme includes both young people's experiences with psychiatric diagnoses and their desire to clarify whether they might have one. Depression is the most frequently described condition, with young people sharing current or past experiences of living with depression, and many seeking advice and information about whether they might be experiencing symptoms. This is illustrated in the words of a young person who writes:

> *I'm unsure whether I'm just going through a rough patch or if I'm starting to develop depression. I feel really down, drained of energy, and I don't find joy in the things that usually make me happy. [...]* [Girl, aged 20 years]

In addition to depression, 13 other psychiatric diagnoses are mentioned in the inquiries, with some of the most frequently cited being eating disorders, autism, obsessive-compulsive disorder, and attention-deficit/hyperactivity disorder.

The theme of *Self-Destructive Behavior* is identified in 197 inquiries, where young people engage in harmful practices, primarily covering accounts of current or past self-harming behavior such as cutting, scratching the skin, or hitting themselves. One young person shares: "I really can't take it anymore...Self-harm and suicidal thoughts are taking up so much space, and I just feel completely awful about myself. [...]" [Girl, aged 15 years]. Additionally, several young people express having a disturbed relationship with food, which may manifest in both their thoughts and behaviors.

A total of 132 inquiries to the letter box concern *Somatic Issues* encompassing bodily symptoms, experiences, and concerns. About half describe recurring physical symptoms linked to psychological distress, such as stomach pain, headaches, physical discomfort, tension, dizziness, nausea, and heart palpitations.

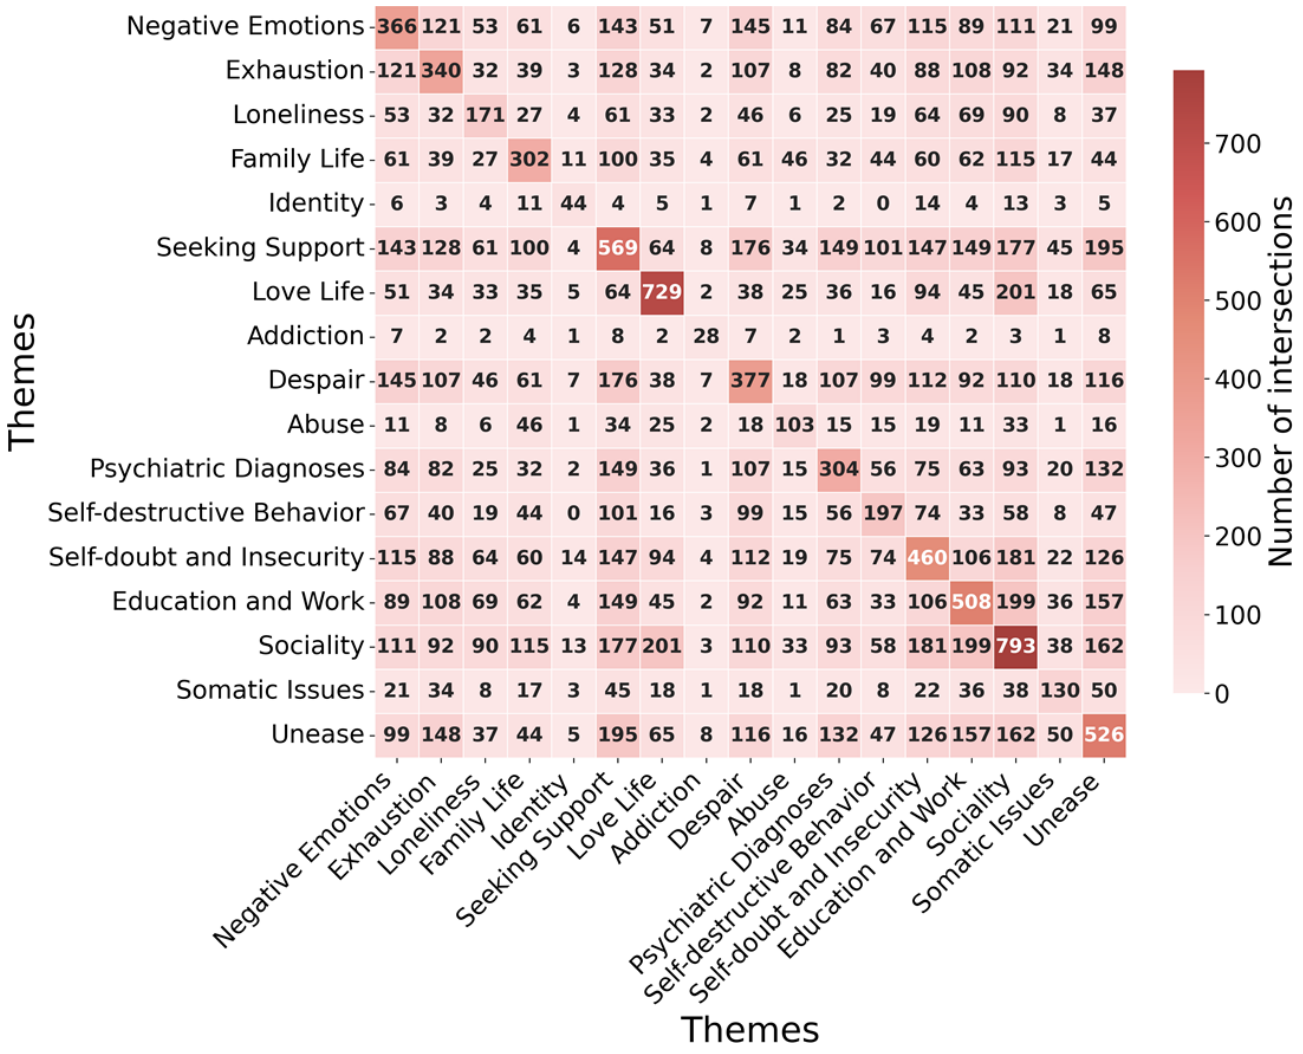
> *[...] I have so many thoughts that just keep going around in circles. Thoughts like: Why do I always do everything wrong, why didn't I say anything, I'm fat, I should lose weight, etc. These thoughts also often make me feel nauseous, and I feel like I'm about to throw up just from the thought of having to eat something. [...]* [Girl, aged 15 years]

Other inquiries reflect the impact of living with physical illness or injury on mental health and well-being. Additionally, several young people ask questions about the body, including reactions to various conditions, menstruation, pregnancy, contraception, sexually transmitted infections, diet, and exercise.

The final theme related to Body and Illness is the smallest in the letter box analysis, with 28 identified inquiries concerning *Addiction* focusing on young people's experiences and concerns related to addictive behaviors. Over half involve the use of alcohol, cannabis, or harder drugs as the young person writes about in his inquiry:

> *I've lost my entire circle of friends from childhood and school to hash or because I got kicked out of school. [...] Now I mostly sit alone from morning to evening and smoke myself numb. [...] I feel alone with everything and can't really see a way out...Help plz.* [Boy, aged 19 years]

While young people do not always describe their use as addiction, the extent of substance use is central to the problems they seek help for. Others write about addiction-related issues such as dependency on gaming, exercise, or shopping.



Intersection of Themes

This section explores the intersections between the 17 identified themes. The heatmap (Figure 2) shows how the themes are connected, with darker areas indicating stronger overlaps between themes. By presenting the data as a heatmap, we gain

XSL•FO
RenderX

a clearer understanding of the complexity and interrelated nature of young people's concerns.

Figure 2. Intersection of themes.

The central role of social relationships in young people's well-being is confirmed by examining the 3 most frequent combinations of 2 themes. A total of 201 inquiries from young people address both the themes *Love Life* and *Sociality*. These entries often revolve around dilemmas related to romantic feelings and friendships, as the 14-year-old girl expresses it in the title of her inquiry: "I'm in love with my friend, but she's not into girls," or issues involving partners and friends, as expressed by a 13-year-old girl who writes: "I have a friend who can't keep her hands off my boyfriend."

The combination of the themes *Sociality* and *Education and Work* is also frequently represented in young people's inquiries (n=199). These inquiries often include descriptions of social challenges within the school context and how such difficulties negatively impact their overall school well-being, as one young person puts it:

> *I'm a 14-year-old girl in 8th grade. I don't really fit in with my class, and I really want to. I feel left out during events and I'm not really part of the conversations. [...] And I really want to have more friends in my class and maybe be part of the community. But I don't know how.* [Girl, aged 14 years]

The third most common thematic combination is found in the pairing *Seeking Support* and *Unease* (n=195). A significant proportion of the inquiries within this theme combination reflect young people's experiences with anxiety, while also expressing efforts to seek professional help or posing questions about how to access such support. This is exemplified in the following inquiry:

> *I think I'm struggling with social anxiety. I've never been formally diagnosed, but I've had a few panic attacks. I generally feel very uncomfortable in large groups of people, and I break out all over my body when I'm at parties, in my school's cafeteria, or even just walking down the street. I'm fairly aware of my situation and I know what to do when I experience these "attacks" and the spots on my skin. Still, I'm tired of how much it affects my everyday life, and that's why I wanted to ask what you think I should do about it. Should I start seeing a psychologist and talk about it, even though I'm quite self-aware? Or should*

XSL•FO
RenderX

I just accept that this is how my daily life is going to be? [Girl, aged 18 years]

Furthermore, Figure 2 highlights that most inquiries to the digital letter box involve multiple themes within a single inquiry, with intersections appearing across nearly all 17 themes. Notably, the heatmap reveals that the theme *Seeking Support* is frequently addressed in conjunction with other themes, indicating that it rarely stands alone. This theme captures young people's experiences of navigating help-seeking processes in response to distress, functioning as a crosscutting dimension rather than expressing a specific concern or emotional issue, as is the case with the other 16 themes. Accordingly, it underscores the potential of a digital letter box as a space for outreach when traditional support networks feel inaccessible. The only theme combination not represented is between *Identity* and *Self-Destructive Behavior*, marked with a zero in the corresponding square to indicate that no inquiries addressed both themes.

Gender Patterns Across Themes

Table 1 presents the gender distribution across themes, highlighting a notable gender imbalance in young people's use of the letter box, with girls being overrepresented. Although this overall trend is clear, only slight variations appear when comparing gender distribution across individual themes. For instance, *Love Life* was the most frequently addressed theme among boys (105/286, 36.7%) compared with girls (499/1670, 29.9%) and those with unspecified gender (125/455, 27.5%). Conversely, *Sociality* was most prevalent among girls (567/1670, 34.0%) and the unspecified gender category (130/455, 28.6%), although it was also common among boys (96/455, 33.6%). Girls (416/1670, 24.9%) and individuals with unspecified gender (105/455, 23.1%) wrote more often about *Seeking Support* than boys (48/286, 16.8%). Similarly, for *Education and Work*, girls (366/1670, 21.9%) and those with unspecified gender (96/455, 21.1%) addressed these themes more frequently than boys (46/286, 16.1%).

Table . Gender patterns across themes.

Themes	Inquiries[a]		
	Girls, n (%)	Boys, n (%)	Unspecified gender, n (%)
Sociality	567 (34.0)	96 (33.6)	130 (28.6)
Love Life	499 (29.9)	105 (36.7)	125 (27.5)
Seeking Support	416 (24.9)	48 (16.8)	105 (23.1)
Education and Work	366 (21.9)	46 (16.1)	96 (21.1)
Family Life	205 (12.3)	30 (10.5)	67 (14.7)
Abuse	68 (4.1)	14 (4.9)	21 (4.6)
Unease	377 (22.6)	43 (15.0)	108 (23.7)
Self-Doubt and Insecurity	315 (18.9)	50 (17.5)	95 (20.9)
Despair	254 (15.2)	43 (15.0)	80 (17.6)
Negative Emotions	289 (17.3)	22 (7.7)	55 (12.1)
Exhaustion	253 (15.1)	26 (9.1)	61 (13.4)
Loneliness	119 (7.1)	18 (6.3)	34 (7.5)
Identity	28 (1.7)	9 (3.1)	7 (1.5)
Psychiatric Diagnoses	229 (13.7)	25 (8.7)	50 (11.0)
Self-Destructive Behavior	154 (9.2)	12 (4.2)	31 (6.8)
Somatic Issues	88 (5.3)	14 (4.9)	30 (6.6)
Addiction	9 (0.5)	12 (4.2)	7 (1.5)
Total	1670 (100)	286 (100)	455 (100)

[a]A single inquiry may appear under multiple themes.

Small variations were also observed across gender categories within themes related to emotional life. Young people with unspecified gender (108/455, 23.7%) and girls (377/1670, 22.6%) were more likely to address topics related to *Unease* than boys (43/286, 15.0%). Similarly, experiences with *Negative Emotions* were more frequently described by girls (289/1670, 17.3%) and those with unspecified gender (55/455, 12.1%) than by boys (22/286, 7.7%). Mentions of *Exhaustion* were also more common among girls (253/1670, 15.1%) and the unspecified gender category (61/455, 13.4%) than among boys (26/286, 9.1%).

XSL•FO
RenderX

For themes related to body and illness, the greatest variation was observed between boys and girls. Girls were considerably more likely to write about *Self-Destructive Behavior* (154/1670, 9.1%) than boys (12/286, 4.2%), while individuals with unspecified gender fell in between (31/455, 6.8%). Likewise, boys addressed subjects related to the theme *Addiction* more frequently (12/286, 4.2%) than girls (9/1670, 0.5%), with the unspecified gender category again positioned between the two (7/455, 1.5%).

Discussion

Principal Findings

This study analyzed inquiries submitted to the digital letter box of Mindhelper, Denmark's most widely used digital mental health promotion service, to identify key mental health themes and gender differences in engagement. A thematic analysis revealed 17 themes across 3 overarching categories— Social Relationships and Social Contexts, Emotional Life, and Body and Illness.

With some of the most salient themes centering on *Sociality* and *Love Life*, our findings confirm adolescence as a socially sensitive stage [6,21] and extend existing knowledge by showing that distress rarely occurs in isolation. Instead, it is deeply entangled with relational contexts such as friendships, romantic relationships, and family life [22,23]. These patterns may help inform how digital support services are structured to better reflect and respond to interconnected user needs.

A central insight emerging from this study is that digital help-seeking often occurs at the intersection between unmet needs in informal support networks and barriers to formal care. While previous research has emphasized the importance of social networks for youth help-seeking and conceptualized it as a socially embedded process [24-28], our findings suggest that some young people turn to digital platforms precisely when these networks are experienced as insufficient, inaccessible, or unresponsive. This shift carries both potential and limitations. On the one hand, digital letter boxes provide a low-threshold, anonymous entry point to support, enabling young people to articulate concerns that might otherwise remain unexpressed [29,30]. On the other hand, help-seeking outside established social relationships may risk reinforcing isolation or limiting opportunities for sustained support, particularly given the one-off and text-based nature of such services. The findings suggest that digital mental health services should be designed not only as stand-alone support but also as bridges to existing social and professional resources, with particular attention to users who lack supportive networks.

Second, our analysis highlights gendered engagement patterns without sharp divides. While social relationships are important for both boys and girls, boys more frequently address *Love Life*, whereas girls more often write about friendships, broadly social life, and themes related to Emotional Life. While girls dominate overall volume, boys' inquiries often cluster around behavioral expressions such as addiction and abuse, suggesting that they may be more likely to externalize distress through behaviors such as substance use, a pattern noted in previous research on gendered expressions of distress [31].

These patterns prompt a closer look at help-seeking behavior. Girls turning to the digital letter box for advice far more often than boys may reflect a higher prevalence of distress among Danish girls, as documented in national health surveys [5], but it may also indicate that boys are less inclined to seek help. Previous research has identified gendered barriers to help-seeking among young men [32-35]. For instance, a review of 31 studies found that 27 identified masculine attitudes—such as the need to appear strong, preference for self-management, and viewing help-seeking as weakness—as barriers to seeking support [32]. While the review covered youth help-seeking and health care access broadly, most studies focused on mental health (n=17) and sexual health (n=10). Although evidence suggests that understandings of masculinity and related behaviors influence perceptions of mental health and help-seeking [31], several scholars stress the importance of incorporating broader contextual factors when examining gender differences in help-seeking behavior. For instance, studies have shown that ethnicity, education, and age also influence help-seeking tendencies [36-38]. McKenzie et al [39] also underline the importance of adopting an intersectional perspective to better understand men's experiences of mental illness stigma, noting that factors such as homophobia and racism can shape these experiences. Moreover, gender differences in help-seeking appear to diminish at higher levels of psychological distress, which may suggest that men are less likely than women to recognize mild symptoms of mental distress [40-42]. Furthermore, research has highlighted the role of social network quality in shaping help-seeking behavior [43,44].

Building on this, the role of the digital context should be further considered in studies of gender differences in help-seeking and engagement within mental health services. Digital features such as anonymity and accessibility may shape some of the patterns observed between genders. Importantly, a review study highlights that attitudes and preferences—such as trust and distrust in health care providers, beliefs about the necessity or effectiveness of care, perceived dissimilarity with providers, preferences for self-reliance, and concerns about anonymity or other potential negative consequences—are strong predictors of help-seeking among young people [45]. This suggests that research on gendered barriers to help-seeking should consider not only the individual factors but also the broader context of service provision, including whether services are delivered digitally. In line with other scholars, we therefore point to the need for models of help-seeking and engagement that incorporate these contextual factors to gain a more comprehensive understanding of gendered digital mental health behavior and to inform the development of designs that more effectively appeal to boys [41,46,47].

Analyses such as the present one are important because they enable the systematic identification of emerging help-seeking needs among young people. These needs might otherwise go unnoticed and yet are essential for developing relevant support content. At the same time, it is necessary to consider the rapidly evolving landscape of digital mental health services driven by

XSL•FO
RenderX

technological developments. Over the course of this study, major changes occurred that may influence young people's help-seeking behavior and use of digital services such as letter boxes. In late 2022, ChatGPT was launched, and by 2025, artificial intelligence–generated content became a dominant feature of Google's search results, potentially introducing new sources for youth seeking mental health advice. Previous studies, conducted before these developments, show that text-based queries via search engines remain the most common online help-seeking approach among young people [30,48]. This reliance on search engines underscores how artificial intelligence integration may reshape the information young people encounter, creating new challenges for developers to ensure access to professional, evidence-based resources. These developments underscore the need for future research to examine their implications for youth help-seeking behavior and engagement with digital mental health platforms.

Strengths and Limitations

While this study offers valuable insight, it is important to acknowledge both its methodological strengths and limitations. A key strength lies in its unique data foundation, providing rare access to young people's real-time expressions of mental health challenges, rather than retrospective accounts. The anonymous digital context enables open engagement with sensitive and stigmatized topics, supporting more candid insights into youth experiences. Additionally, the large and temporally broad dataset allows for a comprehensive view of evolving challenges young people face.

Despite the study's strengths, several limitations should be acknowledged. Each submission to the Mindhelper letter box provides a one-time snapshot of a young person's mental health concerns, without the possibility of follow-up or contextual elaboration beyond what the individual chooses to express. Moreover, the material reflects a specific context: young people who choose to engage with this type of digital service. Consequently, the sample may be biased toward those who are willing and able to seek help through digital platforms. In addition, written communication is central on a digital platform, which means the format requires users to be able to read and write, potentially excluding youth with limited literacy skills. However, no formal writing standards are imposed, which is reflected in the data, occasionally marked by linguistic ambiguity.

Finally, attention should be drawn to the analytical process. The coding was conducted by a single researcher, which may have introduced some bias. However, the systematic and transparent approach, combined with reflexive engagement and author group involvement, supports the credibility of the analysis. In addition, changes in gender categories on Mindhelper introduced limitations for the gender-related analyses. Initially, binary categories allowed some insight into differences between boys' and girls' mental health struggles, although this approach excluded nonbinary youth and may have discouraged nonbinary self-identification. Removing gender categories entirely improved inclusivity but restricted the ability to examine how gender may shape mental health. Future research should seek methods that capture gender diversity while enabling meaningful analysis.

Conclusions

Seventeen themes emerged, reflecting the diverse concerns young people seek advice for, with social relationships and emotional experiences constituting central domains. Gender differences were observed in the extent of engagement, with girls more frequently using the digital letter box than boys, while only minor variations appeared in the distribution of themes across genders. Taken together, the findings suggest that many of the concerns young people raise are closely tied to everyday developmental and relational challenges rather than severe psychopathology alone. The digital letter box thus captures a broader spectrum of lived experience, including early signs of distress that may not otherwise reach formal systems. This highlights both the preventive potential of such services and the value of using self-initiated digital data to better understand how young people articulate and act on emerging mental health concerns.

Acknowledgments

The authors are grateful to the Mindhelper team at the Centre for Digital Psychiatry for their assistance in extracting the data. Furthermore, they would like to express their gratitude to Teresa Beata Bundgård for her assistance in refining the figures. The authors used Microsoft Copilot (GPT-5), an artificial intelligence–based language model, to assist with language editing and refinement of this manuscript, in accordance with journal guidelines. CHD was affiliated with the National Institute of Public Health at the University of Southern Denmark at the time the study was conducted and is currently affiliated with the company Capgemini.

Funding

This research was supported by an institutional grant from the University of Southern Denmark, funds from the Jascha Foundation, Danish Regions, and TrygFonden.

Data Availability

The datasets analyzed during this study are available from the corresponding author upon reasonable request. While the original inquiries are publicly accessible via the Mindhelper.dk platform, anonymized analytical materials (eg, coded data and NVivo project files) may also be shared in accordance with ethical and data protection considerations.

Abstract

Background: With Türkiye's aging population and widespread internet usage, the excessive seeking of health information through online platforms, formally identified as cyberchondria, has emerged as a concern affecting older individuals' health perception and psychological well-being.

Objective: This study aimed to evaluate the association of cyberchondria with health perceptions and psychological well-being among older participants in a third-age university program.

Methods: This cross-sectional study included 352 participants aged ≥60 (mean 67.4, SD 4.7) years from Tazelenme University, Antalya, Türkiye, and was conducted between November and December 2024. Data were collected using the Cyberchondria Severity Scale Short Form (CSS-12), Individual Health Perception Scale, and Psychological Well-Being Scale for Older People (PWBS-OP). Statistical analyses included correlation and multiple regression analyses.

Results: The mean age of the 352 participants was 67.4 (SD 4.7, range 60-87) years, 38.6% (n=136) were first-year students, 69.6% (n=245) were men, 58.8% (n=207) were married, 48.9% (n=172) were university graduates or above, and 65.1% (n=229) had chronic diseases. Significant negative correlations were found between CSS-12 distress, compulsion, and total scores with both Individual Health Perception Scale and PWBS-OP scores (P<.05). According to the multiple linear regression analysis, the presence of chronic disease was the only significant positive predictor of higher health perception levels (B=2.16, 95% CI 1.721-3.593; P=.003), whereas factors such as age, gender, education level, and CSS-12 total scores did not demonstrate a statistically significant impact (P>.05). Psychological well-being (PWBS-OP) was significantly and positively predicted by age (B=0.22, 95% CI 0.037-0.399; P=.02), marital status (B=1.67, 95% CI 1.064-2.716; P=.002), economic status (B=2.10, 95% CI 1.729-3.464; P=.003), and the thought of having an undiagnosed disease (B=3.38, 95% CI 1.038-5.830; P=.007), whereas it was significantly and negatively predicted by medical examinations in the past year (B=−1.29, 95% CI −2.093 to 0.485; P=.002), undergoing examinations without a physician's recommendation (B=−2.04, 95% CI −3.794 to −0.290; P=.02), searching for health-related topics on the internet (B=−1.26, 95% CI −2.152 to −0.360; P=.006), and CSS-12 total scores (B=−0.13, 95% CI −0.261 to −0.060; P=.04).

Conclusions: High cyberchondria levels significantly impair older adults' psychological well-being and health perception. While demographic factors positively influence health perception, excessive internet-based health seeking deteriorates psychological well-being. Digital health literacy programs, professional online health counseling, and psychological support should be recommended to target cyberchondria risks in older populations.

KEYWORDS

cyberchondria; third-age university; health perception; psychological well-being; older adults

Introduction

In alignment with global demographic shifts, Türkiye is experiencing a significant increase in its older population. In 2024, the older population was 10.6% of Türkiye's total population and is expected to increase to 13.5% by 2030 [1]. Parallel to this demographic transition, technology has become an indispensable component of daily activities, education, and health care [2]. Modern society necessitates that older adults

XSL•FO
RenderX

engage with new information and communication technologies to maintain independence, safety, and social connectivity. Research shows that the percentage of individuals aged ≥65 years who search for health information online rose from 14.5% in 2011 to 43.6% in 2020 [3]. Consequently, internet usage among older adults in Türkiye reached 46.9% in 2024, with health-related information seeking emerging as one of the most frequent online activities [1]. While these digital tools empower older adults in health management and decision-making, the unregulated nature of online information has introduced a distinct challenge: the phenomenon of cyberchondria.

Cyberchondria is defined as the excessive and compulsive seeking of medical information online, a behavior typically driven by and resulting in heightened health anxiety [4-6].

The dissemination of misleading or incomplete information, combined with the internet's capacity to reinforce preexisting fears, creates a reinforcing cycle in which search attempts intended to provide relief instead exacerbate distress [7]. This information pollution directly undermines efforts to achieve "complete well-being," which the World Health Organization (WHO) defines not merely as the absence of disease, but as a state of total physical, mental, and social wellness [8]. Within this holistic framework, cyberchondria poses a significant threat to an individual's subjective evaluation of their own health and their overall mental equilibrium.

The subjective assessment of an individual's physical and mental state is conceptualized as "health perception." Health perception involves a complex blend of feelings and thoughts that may not always align with objective, clinically determined health status [9].

In the context of cyberchondria, intensive exposure to disease symptoms online can lead individuals to select and adapt these symptoms to their own self-image, potentially deteriorating their health perception even in the absence of clinical illness.

Beyond perception, this behavior also impacts "psychological well-being," a multidimensional construct encompassing self-acceptance, environmental mastery, and autonomy. When older adults encounter inconsistent or frightening health information, it can diminish their sense of environmental mastery and autonomy, thereby reducing their overall quality of life [7].

To mitigate these risks and promote active aging, "lifelong learning" programs have become vital interventions. In Türkiye, the 60+ Tazelenme University model provides a platform for education and social engagement that has been shown to improve life satisfaction and self-health evaluations among participants. However, while these students are encouraged to use technology for healthy aging, their vulnerability to cyberchondria and its subsequent impact on their psychological and perceptual health remains an area requiring closer investigation.

A study also showed that older participants from third-age universities improved life satisfaction, subjective well-being, and health habits [10]. Third-age university students showed improved self-care behaviors in comparison to their nonparticipant peers and reported better self-health evaluations [11]. This reveals that education and social engagement help senior citizens with their health perception and psychological wellness. However, the amount and quality of online health information, to some extent, is disruptive, especially the cyberchondria phenomenon, which manifests as excessive and anxiety-driven searches. It is likely to exacerbate the perception and mental health of older adults.

Third-age university students are an illustrative example of the so-called "active agers," and this group has a higher degree of motivation for self-care and social involvement than the average older adult. Nevertheless, the paradox of this greater digital involvement stems from the fact that, although this group, being engaged in education, ought to be the most psychologically protected, the existence of an "at-risk" phenomenon, in health-related internet searching, may, for multiple reasons, increase their exposure to the internet and, as a consequence, increase health-related misinformation, health-related anxiety, and cyberchondria. As of now, the literature has completely overlooked the question of whether the environment of lifelong education has the potential to counteract the negative psychological effects of cyberchondria. For this reason, this study aimed to provide answers to the following hypotheses:

- Hypothesis 1: Higher levels of cyberchondria are correlated to lower health perceptions of older adults participating in lifelong learning programs.
- Hypothesis 2: Higher levels of cyberchondria are correlated to lower psychological well-being of those individuals.
- Hypothesis 3: Specific sociodemographic and digital usage patterns are significant predictors of health perception and well-being within this educational context.

Given this context, understanding the relationship between internet-based health seeking and the holistic well-being of older adults is essential for developing effective digital health literacy and psychological support programs. Therefore, this study aimed to evaluate the association of cyberchondria with health perceptions and psychological well-being among older participants enrolled in a third-age university program.

Methods

Study Design

This study is a descriptive and cross-sectional study conducted at the Tazelenme University of Antalya Campus between November and December 2024. 60+ Tazelenme University is a third-age university established as a social responsibility project that has been providing 4 years of free education since 2016 with the principle of lifelong learning for individuals aged ≥60 years.

Study Sample

The research population comprised 643 Tazelenme University students enrolled in the program conducted within the scope of Akdeniz University Center for Applied Research on Aging Studies (1st grade: n=215, 33.4%; 2nd grade: n=184, 28.6%; 3rd grade: n=124, 19.3%; and 4th grade: n=120, 18.7% students) [12]. The sample size was calculated using the "Sample Size for % Frequency in a Population" module in the OpenEpi program [13] for a cross-sectional study. The population size

XSL•FO
RenderX

was taken as 643, the expected frequency or proportion was determined as 50% because no prior estimate was available, the confidence level was set at 99%, the absolute margin of error was set at 5%, and the design effect was set at 1.0 under the assumption of simple random sampling. Under these assumptions, the minimum sample size required was calculated as 327. Inclusion criteria for the research were being aged ≥60 years, being a Tazelenme University student, and volunteering to participate in the research. Noninclusion criteria for the study included being aged <60 years, not being officially enrolled in the specified university campus, and not having internet access or a valid email address, as an online survey platform was used for data collection. Exclusion criteria included surveys containing incomplete or inaccurate data and withdrawal of consent at any point during the survey process.

Data Collection Tools

Data were collected using a "Personal Information Form," "Cyberchondria Severity Scale Short Form (CSS-12)" [14], Individual Health Perception Scale (IHPS) [15,16], and the Psychological Well-Being Scale for the Older People (PWBS-OP) [17].

The data were collected between November and December 2024 using an online survey form created with Google Forms. The survey form was sent to the students' email addresses. The survey took approximately 15 minutes to complete. The research surveys were conducted in a single session.

Personal Information Form

Overview

This form was created by the researchers and included questions related to demographic information, such as age, class (1, 2, 3, or 4), gender (female or male), marital status (married or single), family type (nuclear or extended), and educational status (the educational status of the participants refers to the highest level of formal education completed before joining the third-age university program). As 60+ Tazelenme University is a social responsibility project based on the principle of lifelong learning, it accepts students from all educational backgrounds, provided they meet the age requirement (primary school, secondary school, high school, university, or higher), marital status (married, divorced, widowed, or single), socioeconomic status (income less than expenditure, income equals expenditure, and more income than expenditure), presence of health insurance (yes or no), smoking status (nonsmoker, ex-smoker, or current smoker), living arrangement (with spouse, alone, spouse and children, or children), number of physician visits in the past year (never, 1 - 3 times, 4 - 6 times, 7 - 9 times, or ≥10 times), daily internet use duration (1 - 2 h, 3-4 h, 5-6 h, or >6 h), the source for accessing health information (health care professionals, TV or radio, printed press, internet, family members, or friends).

CSS-12

The scale was developed by McElroy et al [14]. The Turkish validity and reliability study of the scale was conducted by Tuğtekin and Tuğtekin, reporting a Cronbach α coefficient of 0.92 for the overall scale [18]. In this study, the internal consistency coefficient (Cronbach α) for the total CSS-12 was calculated as an α of 0.75. The scale consists of 4 dimensions and 12 statements. The scale is a 5-point Likert-type scale (1=never, 2=rarely, 3=sometimes, 4=often, and 5=always).

A total score between 12 and 60 can be obtained from the scale. An increase in the score obtained from the scale is interpreted as an increase in the level of cyberchondria. The total cyberchondria score is calculated by summing the scores obtained from each question.

The CSS-12 consists of 4 dimensions: excessiveness (EXC), which assesses increasing or repeated health-information searching (items 1, 3, and 6); distress (DIST), which assesses anxiety or distress resulting from searching (items 4, 8, and 9); reassurance (REAS), which assesses searching attempts that lead individuals to seek medical support (items 5, 11, and 12); and compulsion (COMP), which assesses searching that may interfere with online or other aspects of daily life (items 2, 7, and 10) [18].

IHPS

The Health Perception Scale, used to assess health perception, was developed by Diamond et al [15]. The validity and reliability of the Turkish version were established by Kadıoğlu and Yıldız, who reported a Cronbach α coefficient of 0.77 for the total scale [16]. For this study sample, the internal consistency of the IHPS was found to be an α of 0.69. It is a 5-point Likert-type scale consisting of 15 items and 4 subfactors (control center, self-awareness, certainty, and importance of health). The scale consists of 6 items with positive statements (1, 5, 9, 10, 11, and 14) and 9 items with negative statements (2, 3, 4, 6, 7, 8, 12, 13, and 15). Each item is scored as follows: "1, strongly disagree"; "2, disagree"; "3, undecided"; "4, agree"; and "5, strongly agree." Negative statements are scored in reverse (5=strongly disagree, 4=disagree, 3=undecided, 2=agree, and 1=strongly agree). The scale ranges from a minimum score of 15 to a maximum score of 75. A high score indicates a high perception of health, while a low score indicates a low perception of health.

Control center (COM) subdimension aims to determine whether the individual attributes being healthy to factors outside themselves (luck, fate, or religious belief), that is, whether they gather the control center in themselves for being healthy and their confidence in themselves to change their health (items 2, 3, 4, 12, and 13).

Self-awareness (SAW) subdimension aims to determine the level of the individual's belief about whether being healthy is in their own hands regarding their self-awareness perception about exercise and proper nutrition for being healthy (items 5, 10, and 14).

Certainty (CER) subdimension aims to determine whether the individual has a definite idea about what they should do to stay healthy and be healthier (items 6, 7, 8, and 15).

Importance of health (IOH) subdimension aims to determine how much importance the individual gives to their health, to what extent they make financial sacrifices in this regard, and

XSL•FO
RenderX

whether the importance they give to health is one of the priorities in their life (items 1, 9, and 11) [16].

PWBS-OP

The scale was developed and validated for the Turkish older population by Gümüş Demir, with a reported Cronbach α of 0.89 [17]. In this study, the internal consistency coefficient for the PWBS-OP was determined to be an alpha of 0.92. PWBS-OP consists of 15 items and a 5-point Likert scale, ranging from 1 (strongly disagree) to 5 (strongly agree). No cutoff score has been determined for the scale. The minimum score that can be obtained from the scale is 15, and the maximum score is 75. Items 8 and 13 are scored in reverse. Higher scores indicate a higher level of well-being [17].

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki. The study was approved by the Akdeniz University Medical Scientific Research Ethics Committee (TBAEK-511, dated July 25, 2024). The necessary legal permissions were obtained from the Directorate of the Center for Applied Research on Aging to conduct the research. In addition, informed consent was obtained from all participants who volunteered to participate in this study.

Statistical Analysis

The study data were analyzed using SPSS 25.0 for Windows (SPSS Inc). For descriptive findings, categorical variables were presented as numbers and percentages, while continuous variables were presented as mean (SD) and minimum to maximum values. The Kolmogorov-Smirnov normality test was used to determine whether the data showed a normal distribution. It was determined that the data, except for the CSS-12 total score, did not conform to normal distribution. In the analysis of nonparametric data, the Mann-Whitney *U* test, Kruskal-Wallis test, and Spearman correlation were used. For variables where the difference was significant, pairwise comparisons between groups were evaluated using the post hoc Dunn test (with Bonferroni correction). Pearson correlation analysis was used in the analysis of parametric data. Factors playing a role in predicting participants' health perception and psychological well-being levels were evaluated using multiple linear regression analysis. Variables found to be statistically significant in the pairwise comparison were included in the regression model. Categorical variables were included in the regression analysis by defining one dummy variable (coded as 0 - 1) representing the number of categories in the variable. Multiple linear regression models were created using the forward selection method. The normality of the residuals obtained from the final regression model was checked using the Kolmogorov-Smirnov test. All the findings were tested at a significance level of 0.05.

Results

Characteristics of Participants

The mean age of the 352 participants was 67.4 (SD 4.7, range 60-87) years. Of the 352 participants, 136 (38.6%) were first-year students, 245 (69.6%) were men, 207 (58.8%) were married, and 172 (48.9%) were university graduates or above (Table 1). No statistically significant difference was found between the daily internet usage times of the 4 classes (*P*=.10).

In terms of health status, 229 (65.1%) participants reported living with at least one chronic disease, and 199 (56.5%) spent between 1 and 2 hours on the internet daily. Participants demonstrated a high level of engagement with online health information; 167 (47.4%) participants reported searching the internet before starting a treatment recommended by their physician. While 247 (70.2%) participants were unsure about the reliability of online health resources, official health care organization websites (n=189, 52.8%) and social networks (n=133, 37.8%) were the most preferred sources for health searches. Notably, a small but significant minority (n=15, 4.3%) reported discontinuing medical treatments based on information found online (Table 2).

[a]Based on a multiple-response question, participants could select more than one option.

[b]Percentages are calculated based on the total number of participants (N=352) and may exceed 100% due to multiple selections.

Score Averages of All Scales

Descriptive statistics for the assessment tools revealed a mean CSS-12 total score of 28.50 (SD 6.96), indicating the sample's general level of cyberchondria. The mean scores for health perception (IHPS) and psychological well-being (PWBS-OP) were 53.74 (SD 6.53) and 58.82 (SD 8.41), respectively. Within the subdimensions of the CSS-12, "excessiveness" (mean 8.31, SD 2.72) and "reassurance seeking" (mean 7.57, SD 2.45) were observed to have the highest mean values (Table 3).

Table . Subscale scores and total score averages of all scales.

Subscales and total scores	Mean (SD)	Minimum to maximum
CSS-12[a]-excessiveness	8.31 (2.72)	3 - 15
CSS-12-distress	7.40 (2.39)	3 - 15
CSS-12-reassurance	7.57 (2.45)	3 - 15
CSS-12-compulsion	5.21 (2.27)	3 - 15
CSS-12-total Score	28.50 (6.96)	12 - 53
IHPS[b]-COM[c]	18.01 (3.62)	8 - 25
IHPS-SAW[d]	11.05 (2.09)	5 - 15
IHPS-CER[e]	13.39 (3.11)	4 - 20
IHPS-IOH[f]	10.56 (1.94)	4 - 15
IHPS-total score	53.74 (6.53)	39 - 75
PWBS-OP-total score[g]	58.82 (8.41)	30 - 74

[a]CSS-12: Cyberchondria Severity Scale Short Form.

[b]IHPS: Individual Health Perception Scale.

[c]COM: control center.

[d]SAW: self-awareness.

[e]CER: certainty.

[f]IOH: importance of health.

[g]PWBS-OP: Psychological Well-Being Scale for the Older People.

The Relationship of Sociodemographic Characteristics, Medical Data, and Internet Usage With IHPS and PWBS-OP

Comparative analyses indicated that health perception levels were significantly higher among male participants (P=.02) and those with a high school education or above (P=.047; Table 4). Conversely, psychological well-being was found to be lower in participants who were married (P=.002), those with lower income levels (P<.001), and those who reported thinking they might have an undiagnosed illness (P<.001). The psychological well-being level of older people living with their spouse and children was found to be lower than that of those living alone (P=.02; Table 4). The analysis demonstrated no statistically significant differences in IHPS and PWBS-OP total scores across classes, smoking, and presence of health insurance, all failing to reach the formal significance threshold (P>.05).

According to the pairwise comparisons in the Dunn test with Bonferroni correction displayed, PWBS-OP total scores differed significantly only between married participants (mean rank 162.70, SD 100.96) and widowed or single participants (mean rank 210.20, SD 101.10; adjusted P=.002). No statistically significant differences were observed between married and divorced participants (adjusted P=.56) or between divorced and widowed or single participants (adjusted P=.26). Individuals who are widowed or single tend to have higher total PWBS-OP scores. The statistically significant variance in health perception based on education level identified in the overall Kruskal-Wallis analysis (P=.047) was not robust enough to be sustained during pairwise comparisons after applying the Dunn test with Bonferroni correction designed to mitigate type I error.

XSL•FO
RenderX

Nonetheless, an examination of the mean ranks indicates that older adults with a primary or middle school education level tended to exhibit lower health perception compared to those with high school (adjusted *P*=.06) and university (adjusted *P*=.06) degrees. Pairwise comparisons in the Dunn test with Bonferroni correction were performed to investigate the specific differences in PWBS-OP total scores across perceived economic status groups. The post hoc analysis revealed that participants who perceived their income as "greater than expenses" (mean rank 232.97, SD 86.05) exhibited statistically significant and substantially higher PWBS-OP total scores compared to both the "income equal to expenses" group (mean rank 170.95, SD 100.08; test statistic=−62.019; *P*<.001) and the "income less than expenses" group (mean rank 147.07, SD 101.72; test statistic=−85.892; *P*<.001). Conversely, the difference in PWBS-OP total scores between the "income equal to expenses" and "income less than expenses" groups was not statistically significant after applying the Dunn test with Bonferroni correction (test statistic=−23.873; *P*=.24). Following the significant overall Kruskal-Wallis test (*P*=.02), pairwise comparisons in the Dunn test with Bonferroni correction were performed to identify the source of variation across living arrangement groups. The post hoc analysis confirmed that participants living alone (mean rank 197.04, SD 98.23) exhibited statistically significant higher PWBS-OP total scores compared to those living with their spouse and children (mean rank 143.92, SD 97.82; test statistic=53.122; adjusted *P*=.009).

Table . Differences in IHPS[a] and PWBS-OP[b] scores according to the sociodemographic characteristics of participants.

Characteristics	IHPS total score		PWBS-OP total score	
	Mean (SD)	*P* value	Mean (SD)	*P* value
Gender		.02[c]		.15[c]
Male	55.0 (5.6)		57.9 (8.4)	
Female	53.2 (6.8)		59.2 (8.4)	
Marital status		.44[d]		.002[d]
Married	53.6 (6.3)		57.7 (8.4)	
Divorced	54.6 (6.6)		59.2 (7.9)	
Widowed or single	53.3 (7.1)		61.6 (8.5)	
Educational status		.047[d]		.05[d]
Primary or secondary school	51.2 (5.6)		60.8 (9.3)	
High school	54.2 (6.8)		58.7 (8.1)	
University or higher	54.0 (6.4)		58.5 (8.4)	
Economic status		.44[d]		<.001[d]

Children or relatives	53.3 (6.1)		57.7 (10.2)	

[a]IHPS: Individual Health Perception Scale.

[b]PWBS-OP: Psychological Well-Being Scale for the Older People.

[c]Mann-Whitney *U* test.

[d]Kruskal-Wallis test.

Participants without chronic illnesses had significantly higher levels of perceived health (*P*=.001). PWBS-OP total score of those with chronic disease was determined to be lower than that of those that of without chronic disease (*P*=.008). The IHPS score average of older people who do not think they have an undiagnosed disease is higher than that of those who have such thoughts (*P*=.02). PWBS-OP total score of those who never went to a physician examination in the past year was found to be higher than that of those who did (*P*<.001). In the Dunn test with Bonferroni correction, older individuals who had not had a physician's examination in the past year were found to have higher PWBS-OP total scores than other groups. The Dunn test

XSL•FO
RenderX

with Bonferroni correction revealed statistically significant differences between those who visited a physician 1 to 3 times and those who visited 7 to 9 times (P=.01), between those who visited 7 to 9 times and those who did not visit at all (P=.001), between those who visited 10 times and those who did not visit at all (P=.02), and between those who did not visit at all and those who visited 4 to 6 times (P=.03). PWBS-OP total score of those who had medical tests done without a physician's recommendation in the past year was determined to be higher than those who did not have tests done (P=.002). PWBS-OP total score of those who do not think they have an undiagnosed disease was found to be higher than those who have such thoughts (P<.001). PWBS-OP total score of those who stated that they "always" research health-related topics on the internet was found to be higher than the groups giving other answers (P=.02). The Dunn test with Bonferroni correction showed that those who always search for health information online had the highest total PWBS-OP score compared to other groups. In pairwise comparisons, statistically significant differences were found between those who frequently search for health information online and those who always do so (P=.08) and between those who always do so and those who sometimes do so (P=.03; Table 5). The analysis demonstrated no statistically significant differences in IHPS and PWBS-OP total scores across daily internet use duration, internet-based self-diagnosis and self-medication in the past year, internet research before starting prescribed treatment, internet-driven treatment discontinuation, and perceived reliability of online health resources, all failing to reach the formal significance threshold (P>.05).

Table . Comparison of IHPS[a] and PWBS-OP[b] scores based on participants' medical data and internet usage habits.

Characteristics	IHPS total score		PWBS-OP total score	
	Mean (SD)	*P* value	Mean (SD)	*P* value
Presence of chronic disease		.001[c]		.008[c]
Yes	52.9 (6.4)		57.0 (8.3)	
No	55.4 (6.6)		60.4 (8.4)	
Number of physician visits in the past year		.48[d]		<.001[d]
Never	55.3 (7.4)		63.4 (7.8)	
1 - 3	53.9 (6.4)		60.1 (7.8)	
4 - 6	53.8 (6.9)		57.9 (7.8)	
7 - 9	51.8 (5.2)		54.8 (7.7)	
≥10	53.4 (6.6)		55.9 (10.9)

[a]IHPS: Individual Health Perception Scale.

[b]PWBS-OP: Psychological Well-Being Scale for the Older People.

[c]Mann-Whitney *U* test.

[d]Kruskal-Wallis test.

To delineate specific differences across physician visit frequency groups following the general Kruskal-Wallis analysis, pairwise comparisons with Bonferroni correction were conducted. Significant variations were observed among groups. Specifically,

XSL•FO
RenderX

participants reporting no physician visits (mean rank 234.71, SD 100.06) exhibited significantly higher PWBS-OP scores compared to those visiting 7 to 9 times (mean rank 123.33, SD 92.66; test statistic=111.381; adjusted *P*=.001), 10 or more times (mean rank 153.40, SD 108.34; test statistic=81.306; adjusted *P*=.02), and 4 to 6 times (mean rank 165.12, SD 95.99; test statistic=69.588; adjusted *P*=.03). Furthermore, participants with 1 to 3 visits (mean rank 190.08, SD 99.74) also demonstrated significantly higher scores than those with 7 to 9 visits (mean rank 123.33, SD 92.66; test statistic=66.757; adjusted *P*=.01). No statistically significant differences were found between the "none" and "1 to 3 times" groups (adjusted *P*=.45) or among the groups with 4 or more visits. Participants reporting that they "always" search for health-related topics on the internet (mean rank 229.71, SD 87.80) exhibited significantly higher PWBS-OP scores compared to those searching "frequently" (mean rank 154.14, SD 101.58; test statistic=75.568; adjusted *P*=.008) and "sometimes" (mean rank 171.25, SD 99.94; test statistic=58.459; adjusted *P*=.03). No statistically significant differences were found among other pairwise comparisons after applying the stringent Bonferroni correction, notably between the "always" group and the "never" (adjusted *P*>.99) or "rarely" (adjusted *P*=.20) groups.

Correlations Between Participants' Characteristics and CSS-12, IHPS, and PWBS-OP Scores

In the research, a negative and low-level significant correlation was found between the CSS-12 compulsion subscale and the COM subscale score of IHPS and between participants' age and the SAW subscale score of IHPS (*P*<.001 and *P*<.05, respectively). A negative and low-level significant correlation was found between CSS-12-distress, CSS-12-compulsion, and CSS-12-total score and the CER subscale score of IHPS (*P*<.001). A positive and low-level significant correlation was found between CSS-12-reassurance and CSS-12-total Score and the IOH subscale score of IHPS (*P*<.05). A positive and low-level significant correlation was found between participants' age and IHPS total score and PWBS-OP total score (*P*<.05). A negative and low-level significant correlation was found between CSS-12-distress, CSS-12-compulsion, and CSS-12-total score and IHPS total score and PWBS-OP total score (*P*<.05; Table S1 in Multimedia Appendix 1).

Multiple Linear Regression Analysis of Factors Affecting Health Perception and Psychological Well-Being in Highly Educated Older Adults Engaged in Lifelong Learning

According to the multiple linear regression analysis, the presence of chronic disease was the only significant positive predictor of higher health perception levels (*B*=2.16, 95% CI 1.721-3.593; *P*=.003), whereas factors such as age, gender, education level, and CSS-12 total scores did not demonstrate a statistically significant impact (*P*>.05). Psychological well-being (PWBS-OP) was significantly and positively predicted by age (*B*=0.22, 95% CI 0.037-0.399; *P*=.02), marital status (*B*=1.67, 95% CI 1.064-2.716; *P*=.002), economic status (*B*=2.10, 95% CI 1.729-3.464; *P*=.003), and the thought of having an undiagnosed disease (*B*=3.38, 95% CI 1.038-5.830; *P*=.007), whereas it was significantly and negatively predicted by medical examinations in the past year (*B*=−1.29, 95% CI −2.093 to 0.485; *P*=.002), undergoing examinations without a physician's recommendation (*B*=−2.04, 95% CI −3.794 to −0.290; *P*=.02), searching for health-related topics on the internet (*B*=−1.26, 95% CI −2.152 to −0.360; *P*=.006), and CSS-12 total scores (*B*=−0.13, 95% CI −0.261 to −0.060; *P*=.04; Table S2 in Multimedia Appendix 1).

Discussion

Principal Findings

In this study, increased levels of cyberchondria were found to be associated with significant decreases in both health perception and psychological well-being. The findings demonstrated that age, marital status, economic status, and the absence of undiagnosed illness had significant positive effects on psychological well-being. Particularly, the absence of undiagnosed illness positively influenced the psychological well-being of highly educated older adults engaged in lifelong learning.

Interestingly, this study observed slight but significant increases in health perception and psychological well-being as age advanced. This phenomenon has been explained in the literature by factors such as increased life experience, acceptance, and meaning-seeking among older individuals [19]. However, this finding is not consistent across all studies. For instance, Vuorre and Przybylski [20] reported in their analysis across 168 countries that the association between internet and mobile technology use and well-being did not differ significantly by age and was generally minimal. This situation may vary according to cultural factors, individual coping styles, and levels of digital awareness among highly educated older adults engaged in lifelong learning.

The significantly lower psychological well-being levels found among women compared to men are also noteworthy. Chen et al [21] indicated that older women are psychologically more vulnerable due to higher loneliness, lack of social support, and caregiving responsibilities. Similarly, Li et al [22] revealed that women developed higher anxiety when facing uncertainty in the pandemic context. Older women often serve as primary "health managers" or informal caregivers within family networks. When navigating digital health ecosystems, familial responsibility can manifest as a heavy psychological burden. Unlike men, older women tend to be more meticulous and overly cautious in online symptom checking, driven by a sense of duty to protect both their own well-being and the well-being of those they are responsible for. As web-based health resources generate highly ambiguous medical information, this extensive data searching behavior without formal clinical filtering triggers a cycle of cognitive fatigue and cyberchondria. Consequently, the low psychological well-being in older women may not only be a reflection of structural vulnerability but also a direct result of the overly cautious, digitally driven overanalyzing loop that disproportionately affects highly educated older women engaged in lifelong learning.

The negative relationship observed between worsening economic conditions and psychological well-being reveals that

XSL•FO
RenderX

financial security serves as a fundamental buffering mechanism for mental health in older adults [23]. Economic vulnerability not only increases individual stress levels but also damages well-being by limiting social participation and sense of belonging [6]. For highly educated older adults engaged in lifelong learning, quality of life is not just about food and shelter; it is about attending courses, buying books, and participating in intellectual communities. The economic crisis directly undermines this lifestyle and identity. What they are experiencing is not just economic stress, but an identity disruption. The person wants to be educated, knowledgeable, and intellectually active, but their budget does not allow it. This gap (higher education vs lower economic status) creates deep psychological unease in their personality. As educated individuals can read macroeconomic trends, inflation curves, and the future more rationally, they are more susceptible to a wave of anticipatory anxiety about the future.

In individuals with thoughts of undiagnosed illness, lower levels of health perception and psychological well-being were identified. This finding demonstrates that difficulty coping with uncertainty and diagnostic ambiguity can trigger cyberchondria behaviors and anxiety [22,24]. Highly educated older adults engaged in lifelong learning have solved lifelong problems by "reading and researching." When faced with an undiagnosed symptom, they exhibit the same reflex and turn to the internet. Highly educated older adults without medical training, however, become overwhelmed by the manipulative information pool on the internet. Owing to their high digital literacy, they conduct far deeper searches than the average user. This, instead of reducing uncertainty, leads to cognitive overload. The greatest bulwark of psychological well-being in old age is "autonomy" and "cognitive control." Consequently, within this specific cohort, the erosion of psychological well-being is not merely a consequence of fearing a physical illness but rather a reflection of a deeper existential crisis: the collapse of their cognitive autonomy and self-efficacy, which are fundamental pillars of successful aging when confronted with an unresolvable digital information maze.

This study found that more frequent physician visits in the past year, undergoing medical tests without physician recommendation in the past year, internet-based health research behavior, and cyberchondria behavior were significantly and negatively associated with the psychological well-being levels of highly educated older adults engaged in lifelong learning. The literature also indicates that excessive and inappropriate searching for health information online was associated with an increased likelihood of health anxiety and decreased psychological well-being in individuals [25]. Particularly in highly educated older adults engaged in lifelong learning, despite increased access to technological information, health anxiety and stress symptoms are associated with cyberchondria [3,7].

Intensive and complex health information online, especially in older adults with high health anxiety, is associated with an increased likelihood of worry and fear, which may be linked to impaired psychological well-being. Additionally, using information obtained from the internet without seeking expert opinion can negatively associate with health perception by causing misdiagnosis and unnecessary tests. As web-based health information is inherently ambiguous and probabilistic, this intensive data consumption without formal clinical filtration intensifies latent health anxiety rather than mitigating it [9]. The unique pathway-based insight offered by this study is that this digitally driven anxiety directly translates into concrete, uncoordinated medical overconsumption. To resolve the cognitive dissonance generated by alarmist online information, these highly educated older adults engaged in lifelong learning bypass professional triage, leading to frequent physician visitations and self-directed, unrecommended diagnostic testing. Every ambiguous test result or clinical nuance, in turn, sparks further online cross-referencing, reinforcing the cyberchondria cycle and severely deteriorating both their psychological well-being and their trust in health care systems [26]. Consequently, our findings emphasize that in highly educated older cohorts, technology use is a double-edged sword; high digital literacy, when uncoupled from the ability to filter out cyberchondria-inducing medical noise, transforms a cognitive asset into a profound source of psychological and systemic vulnerability.

The impact of CSS-12's "distress" and "compulsion" subdimensions reveals a distinct process-oriented vulnerability in highly educated older adults. While cyberchondria is widely conceptualized as a compulsive, anxiety-driven pattern [24,27], in this specific cohort, it transforms an ingrained problem-solving orientation into a maladaptive loop. Driven to resolve somatic uncertainty, these digitally literate individuals engage in exhaustive online cross-referencing. However, because they possess the cognitive capacity to analyze complex data but lack formal clinical frameworks to filter it, this ambiguous web-based information precipitates severe cognitive overload. Ultimately, this pathway constitutes an active cognitive trap where an older individual's intellectual resources and drive for autonomy paradoxically undermine their mental resilience, thereby eroding subjective well-being.

The finding that 65% (n=229) of participants managed chronic conditions and underwent multiple examinations highlights a unique process-oriented mechanism within highly educated older adults engaged in lifelong learning. While clinical status traditionally shapes subjective health perception [21,28], a chronic diagnosis in this demographic threatens cognitive autonomy, driving individuals to deploy their digital literacy for intensive online research. However, navigating inherently ambiguous web-based health data creates an overanalysis trap that triggers a compulsive cascade of medical cross-checking and heightened anxiety. This pathway-based dynamic explains why the complete absence of chronic disease history emerged as the strongest positive predictor of health perception. Spared from the somatic triggers that launch them into the exhausting digital maze, these highly educated older adults engaged in lifelong learning avoid cyberchondria-induced cognitive overload, allowing their intellectual resources to function as stable psychological assets rather than anxiety amplifiers.

Particularly in older adults with multiple chronic diseases, deterioration in both physical and psychological functioning is common. Ryff developed the "Psychological Well-being" model, which divides well-being into 6 distinct dimensions: self-acceptance, positive relationships with others, autonomy,

XSL•FO
RenderX

environmental mastery, finding purpose and meaning in life, and personal growth [29]. When psychological well-being is evaluated according to the subdimensions of Ryff's model, cyberchondria behavior can be considered to have negative effects on autonomy and environmental mastery dimensions.

The findings that nearly half (n=167, 47.4%) of the participants engaged in preconsultation internet research and a critical minority (n=15, 4.3%) discontinued medical treatment based on online information expose the behavioral realities of digital health tracking in highly educated older adults engaged in lifelong learning [30]. Evaluating these findings through a process-oriented framework reveals how an older, highly educated demographic's pursuit of medical autonomy can paradoxically manifest as clinical nonadherence. For these intellectually engaged individuals, researching symptoms prior to a physician visit is an active effort to maintain agency over age-related somatic changes. However, when highly educated individuals cross-reference complex, unverified web data with professional clinical advice, it often generates profound cognitive dissonance. When this dissonance is left unresolved, the pathway-based trajectory shifts from proactive self-care to dangerous behavioral autonomy, driving individuals to independently terminate prescribed treatments. This maladaptive pattern clarifies why an increased frequency of digital health seeking correlates negatively with psychological well-being, as unguided online searches systematically deteriorate uncertainty-coping mechanisms and amplify somatic threat perceptions [6,31]. Furthermore, this distinct nuance reconciles the apparent contradiction with macro-level data, such as Vuorre and Przybylski's [20] finding that general broadband adoption does not consistently undermine global well-being. The critical insight here is that while general digital connectivity remains benign on a macro scale [20], a targeted, pathway-based exploration reveals that anxiety-driven medical overanalysis by highly educated older adults engaged in lifelong learning presents a direct, acute threat to their psychological resilience and subjective well-being.

Evaluating technology-induced well-being through a population-specific lens reveals a critical process-oriented nuance in our highly educated older cohort: the positive link between cyberchondria's "reassurance seeking" and health importance reflects an intellectual drive for autonomy rather than pure pathology. This intersection highlights a vital pathway-based pivot; while unguided searches induce anxiety, structured information gathering enhances health self-efficacy [32], converting anxious drives into proactive self-care agency. This adaptive trajectory is mirrored by the participants' sophisticated information seeking hierarchy, which uniquely included academic literature. However, as established by Cao and Chu [33], the perceived credibility of these mixed-reliability platforms fundamentally dictates subsequent psychological well-being. The resulting cognitive friction between official medical narratives and informal digital commentary ultimately determines whether this information pathway reinforces psychological resilience or precipitates cyberchondria.

This study determined that cyberchondria behavior in highly educated older adults engaged in lifelong learning was associated with an increased likelihood of deterioration in mental and physical health conditions and was negatively associated with psychological well-being. Schuster et al [3] similarly reported that older adults with high health anxiety experienced more stress when researching health information online. Additionally, encountering unreliable information sources provides grounds for older adults to discontinue treatment or self-diagnose [3,30,34]. Thus, for highly educated older adults engaged in lifelong learning, unguided digital health seeking serves as a critical vulnerability that undermines both subjective resilience and objective health safety.

The findings regarding participants' daily internet usage duration and source preferences in this study underscore the critical importance of enhancing digital health literacy among highly educated older adults engaged in lifelong learning. Recent evidence from Xu and Starcevic [7] highlights that in the modern digital era, health seeking behavior in older adults is intricately linked to mental well-being and health-related quality of life. Improving digital health literacy is now recognized as a vital protective mechanism that shields older individuals from the adverse effects of misinformation while empowering them to make informed and accurate health decisions. Therefore, initiatives aimed at reducing cyberchondria risk must prioritize the development of advanced digital literacy to align with the contemporary technological landscape.

It is emphasized that exposure to health information available online can create difficulties in accessing accurate information and cognitive fatigue, particularly in highly educated older adults engaged in lifelong learning, and therefore, cyberchondria can have negative effects on psychological well-being. Recent research underscores that this cognitive strain fuels cyberchondria, which in turn serves as a significant predictor of decline in various dimensions of Ryff's psychological well-being model [29], including psychological growth and psychosocial stability [7]. As highly educated older adults engaged in lifelong learning struggle to reconcile conflicting online reports, their "self-acceptance" regarding their health status and "autonomy" in health-related decision-making are compromised, as they become increasingly fused with anxiety-inducing information. Ultimately, this deterioration in eudaimonic well-being dimensions significantly reduces the overall quality of life in this population.

Limitations and Strengths of the Study

This study has several limitations. First, as the research has a cross-sectional design, establishing causal relationships between variables is limited. Second, the use of an online data collection method, while a methodological convenience that facilitated a larger sample size within the university network, inherently introduces concerns regarding data reliability and selection bias. As our sample consists of highly educated older adults engaged in lifelong learning who are already active internet users, individuals with lower digital access or literacy are not represented in the data. This limits the generalizability of our findings to the broader older population in Turkey. The majority of participants being men (approximately 70%) and having high education levels makes it difficult to generalize the findings to the general older population. Furthermore, the possibility that

XSL•FO
RenderX

health care service utilization may have changed following the COVID-19 pandemic was not considered.

The most important strength of the research is addressing the relationship between cyberchondria behavior and psychological well-being in the older population. Thus, digital health seeking behavior and psychological effects in highly educated older adults engaged in lifelong learning, which have not been sufficiently examined in the literature, were determined. By using validated tools such as the CSS-12, this study provides a foundational understanding of digital health seeking behaviors and their psychological impacts on an increasingly tech-savvy older population.

Conclusion and Recommendations

In conclusion, high levels of cyberchondria behavior in highly educated older adults engaged in lifelong learning negatively associate with psychological well-being levels. Furthermore, while sociodemographic factors may have positive effects on health perception, excessive and uncontrolled internet-based health information seeking can negatively impact the psychological well-being of highly educated older adults engaged in lifelong learning. Accordingly, to reduce the information confusion and misguidance that highly educated older adults engaged in lifelong learning encounter when seeking health information online, it is recommended to expand reliable digital health literacy education, increase internet-based health counseling services by health care professionals, and develop psychological support and awareness programs targeting cyberchondria risk. Additionally, conducting longitudinal research, including older adults from different socioeconomic and cultural levels in future studies, will provide stronger evidence regarding the association between cyberchondria and psychological well-being.

Abstract

Background: Digital health interventions (DHIs) are a potential tool to address communication challenges in primary care medicine by improving patient participation, treatment adherence, and self-management of chronic diseases. However, Germany's digital health infrastructure remains underdeveloped compared to other Organization for Economic Cooperation and Development (OECD) countries. Designing tailored, context-sensitive tools requires a deep understanding of patient needs, particularly for underserved populations navigating complex health care systems. Participatory approaches that actively involve end-users and stakeholders can help ensure that digital health tools are responsive to these needs. Behavioral science frameworks such as the Behavior Change Wheel (BCW), which incorporates the Capability, Opportunity, Motivation–Behavior (COM-B) model, can further support this process. Such technologies, developed using cocreation and behavior change frameworks, may improve health outcomes for underserved patient populations by addressing context-specific needs. This study explores how cocreation and behavioral science can inform the adaptation of a digital patient preparedness tool for international students accessing primary care in Germany.

Objective: This study aimed to gain insight into international students' experiences with primary care in Germany and explore whether adapting an existing digital patient preparedness intervention could address communication challenges and improve the standard of care. Using cocreation methods and the Behavior Change Wheel (BCW), we identified key design specifications and behavior change levers to inform tool development.

Methods: A mixed methods design was used to identify design specifications for a DHI across 4 cocreation workshops with 12 students at an international university in Germany. Quantitative data were used for descriptive insights, and qualitative data were analyzed using qualitative content analysis. Workshops were informed by the BCW and the Health CASCADE cocreation methods selector tool.

Results: Cocreators reported feeling misunderstood, anxious, and ill-informed during primary care interactions, with system-level barriers compounding communication difficulties. Despite this, many engaged in preparatory behaviors (eg, note-taking) to manage uncertainty and structure their consultations. Feedback on an existing digital intervention was mixed: while cocreators appreciated its intent, structured lesson formats were seen as too time-consuming. Cocreators preferred a concise, interactive design. Communication prompts, appointment scheduling, and personalized feedback were frequently requested features, though tool adoption was seen as contingent on addressing broader system-level frustrations.

Conclusions: International students' negative health care experiences, often stemming from unclear communication, perceived indifference, and difficulty navigating an unfamiliar medical system, may be mitigated through codesigned, personalized digital interventions. Frequently requested features, such as appointment scheduling, clinic directories, test result access, and interactive tools like chatbots, may help address barriers related to system navigation, communication, and access. This study demonstrates how cocreation methods can be integrated with the BCW to inform the development of context-sensitive digital health tools for specific target groups.

Introduction

Effective communication between patients and practitioners is pivotal to the quality and delivery of health care services [1]. This is especially true in primary care medicine where physicians serve as trusted advisors, functioning as the central hub for managing complex, chronic conditions and navigating care between multiple specialists. In these care spaces, effective patient-physician communication was found to improve understanding, trust, and engagement in health-related behaviors [2,3]. However, the burden on the primary care system in Germany, including physician shortages and resource constraints [4-6], has given rise to communication failures, which in turn have implications for the perceived quality of care [7,8]. These challenges are particularly pronounced for migrant populations in Germany, who are unfamiliar with the nation's health care system and clinical care methodology [9]. Communication challenges in German health care services, such as language and cultural barriers [10], have been linked to poor symptom management [11] and worsened patient outcomes [12].

Digital health interventions (DHIs) could be practical tools that address the communication challenges in primary care settings and improve overall standard of care. For example, in Norway, a digital symptom-reporting and communication intervention was shown to enhance patient-provider dialogue [11], and in Sweden, a digital portal for young diabetes patients was found to facilitate trust and dialogue between patients and health care workers [13]. Moreover, a recent systematic review found that, more broadly, digitalization in health care is generally beneficial for improving communication-related factors like patient participation, treatment adherence, and self-management in chronic care [14]. Based on the Bertelsmann Digital Health Index, Germany is far behind most European neighbors with respect to digitization in health care, being placed second to last in terms of digital readiness, policy, and data use [15]. These shortcomings stem not only from slow implementation, but also from tools that fail to address real-world needs [16]. In this context, cocreation offers a pragmatic approach to developing fit-for-purpose tools by involving patients and other end-users directly in the design of digital health tools.

Digital services can help individuals navigate health care systems [17], book appointments [18], increase access to care [19], improve patient engagement [20], and enhance disease monitoring and management [21]. DHIs may be especially useful for migrants who often face challenges in navigating the health care system, making appointments, preparing for consultations, and engaging effectively with health care providers, in addition to language and cultural barriers [22]. International students form a key subgroup within the migrant population are central to Germany's skilled migration strategy [23]. International students contribute to the economy through tuition fees, living expenses, and potential future participation in the skilled labor market if they remain in Germany after graduation [24]. Health care quality is a known factor influencing such decisions [25]. Therefore, understanding the needs of international students is not only critical to evaluating health care accessibility for future skilled migrants, but has broader economic implications for Germany [26].

The unique health care experiences and needs of the international student population in Germany have been largely unstudied, especially in primary care settings. However, some studies have been carried out exploring the health care experiences of young people in general. A cross-sectional study comparing university students in Germany and Belgium found that students in Germany were more likely to seek specialist and emergency care [27]. This pattern may indicate underusage of primary care services or difficulties navigating them. Moreover, there is evidence that individuals with a migrant background have higher odds of not having a general practitioner (GP), further suggesting that services may be underused [28]. These prior studies have highlighted communication barriers for broader migrant groups and refugees [29,30]. It is crucial to study international students as the intersection of these 2 populations to address the specific health priorities of this young, well-educated, and mobile population.

DHIs offer opportunities to personalize support and enhance communication before consultations. They also enable data capture on patient concerns, helping physicians develop more accurate patient profiles [31,32]. These tools are most effective when cocreated with end users to reflect their communication preferences, which often include clarity, empathy, and cultural sensitivity [33]. Behavioral science, particularly the Behavior Change Wheel (BCW) framework and the corresponding Capability, Opportunity, Motivation–Behavior (COM-B) model, offer a systematic way to map how digital tools can build patient capabilities, create opportunities, and motivate change [34]. The COM-B model conceptualizes behavior as arising from interactions between capability, opportunity, and motivation (COM), where capability refers to individuals' knowledge and skills, opportunity to external factors that enable or constrain behavior, and motivation to reflective and automatic processes that drive action. It is embedded within the BCW, which provides a structured process for identifying target behaviors and selecting appropriate behavior change techniques (BCT). Previous studies have demonstrated that the BCW provides a systematic approach to identifying design considerations for behavior change interventions [35]. Cocreation helps align the design of tools with real-world considerations [36] and, when combined with the BCW, can help create acceptable and context-sensitive interventions for specific target groups [37].

To address the above challenges and opportunities, this study aims to adapt an existing digital patient preparedness tool (DiPPT) using cocreation with students at an international university in Germany, guided by behavior change theory. The

XSL•FO
RenderX

cocreation workshops were structured using the PRODUCES framework [38], a cocreation framework for developing public health interventions that guides researchers through key stages of cocreation, including defining the Problem and Objective, planning the Design, identifying Users and Cocreators, and considering Evaluation and Scalability [38]. In the present study, the framework supported a systematic approach to end-user involvement, while the BCW [39] informed both the workshop topics and the derivation of intervention specifications from the workshop outputs. The workshops aimed to identify communication and preparation needs in primary care and to map behavior change levers for patient preparation using the COM-B model to inform the design of a digital intervention.

The study was guided by the following research questions which were investigated using different methods across a series of cocreation workshops:

1. How do international students prepare for conversations with physicians in German primary care settings?
2. What are the needs of international students with respect to receiving and relaying information in German primary care settings?
3. What are the waiting room experiences of international students prior to GP appointments?
4. What aspects of the preexisting DiPPT did international students see as suitable for a digital intervention to facilitate communication?
5. What aspects of the DiPPT did international students see as not suitable for a digital intervention to facilitate communication?
6. What are the needs of international students for a digital intervention to facilitate communication?

The methods used across the workshops demonstrate how cocreation can be used to identify end-user needs and translate these into design specifications for a behavior change intervention, which was a central objective of this Health CASCADE study.

Methods

Study Design

This study uses a convergent mixed methods design [40], with qualitative and quantitative data collected in parallel, to cocreate a digital health intervention for international students preparing for primary care consultations in Germany. The structure and methods of the cocreation workshops were specified in advance; building on a prior communication intervention (DiPPT) in obstetric care [41,42] and adapting it to the current target group.

Data integration occurred at the interpretation stage through narrative integration [43,44]. Quantitative survey data were used to descriptively characterize cocreators, summarize health care experiences, waiting room experiences, preparation behaviors, and evaluate ratings of existing DiPPT lessons. Qualitative data were used to explore and contextualize these experiences and behaviors in greater depth to identify needs and preferences for a redesigned digital intervention. See Table 1 for how qualitative and quantitative data were used to understand cocreators' experiences and behaviors, and inform the adaptation of DiPPT for international students accessing primary care in Germany.

XSL•FO
RenderX

Table . Overview of cocreation workshops conducted with international students accessing primary care in Germany, aligned with stages of the BCW[a] framework in a convergent mixed methods study.

BCW[a] stage	Aim	Methods
Understand the behavior	Explore the communication experiences of international students accessing primary care.	Qualitative data • Focus groups. Quantitative data • Survey on doctor-patient communication.
Identify intervention options	Evaluate the relevance of content from an existing intervention (DiPPT)[b].	Qualitative data • Empathy maps exploring patient emotions and behaviors in waiting rooms. Quantitative data • Survey on clinic waiting room experience. • Rating each communication training component from DiPPT based on brief descriptions of each lesson.
Identify intervention options	Explore needs for a digital intervention in general as well as refine and prioritize content and features from the existing DiPPT for a redesigned digital tool.	Qualitative data • Card sorting exercise of intervention ideas. Quantitative data • Rerating each communication training component from DiPPT after having used the web-app.
Identify intervention options	Co-design and discuss the structure and core features of a tailored preparedness intervention.	Qualitative data • Visioning exercises and cocreation of design charts. • Focus groups to evaluate proposed intervention. Quantitative data • Survey on demographics and health.

[a]BCW: Behavior change wheel.

[b]DiPPT: digital patient preparedness tool.

Ethical Considerations

Ethical approval for the study was granted by the Ethics Committee at Constructor University (application number: 2022_01_B). All cocreators provided informed consent prior to taking part in each workshop and were informed about the purpose of the study, the types of data collected, and their rights as cocreators. Eleven out of 12 cocreators were employed as paid contributors and compensated equally based on the number of hours they contributed to the project (US $14.36/h). One cocreator was unable to receive payment due to visa-related employment restrictions and participated voluntarily. To protect cocreator privacy and confidentiality, audio recordings and workshop materials were anonymized with disclosure controls applied to names, health conditions, institutions, countries, and locations.

Digital Patient Preparedness Tool

The original digital intervention (DiPPT) was developed to support communication between pregnant women and health care professionals in obstetric care [41,42,45,46]. The web-based tool delivered structured communication training through short lessons and exercises designed to help expectant mothers prepare for consultations and express concerns clearly. The intervention targeted safe communication behaviors during maternity care encounters and was informed by the Health Action Process Approach (HAPA) model, primarily using action planning (BCT 1.4) to encourage patients to plan for obstetric and midwife consultations ahead of time.

Recruitment and Data Collection

To ensure the intervention was grounded in real-world experiences, international students were engaged as cocreators. The following section outlines how they were selected and involved in a series of cocreation workshops designed to explore patient behaviors and collaboratively adapt a digital preparedness tool using the BCW [39]. Additional details are mentioned in Supplement 1 in Multimedia Appendix 1 that consists of a full list of tools used to collect data from cocreators.

Selecting Cocreators

Cocreators were purposively sampled from an international university in Germany, using criterion sampling [47]. Eligibility criteria included being at least 18 years old, English-speaking, and having received primary care in Germany. Recruitment took place via in-class presentations, posters, flyers, and digital listings. Interested individuals completed an eligibility screening form and participated in a brief interview to gauge motivation for taking part. Twelve cocreators were selected. Of these, 10 attended all 4 workshops and 2 attended 3. Cocreators were

XSL•FO
RenderX

relatively homogeneous with respect to demographic characteristics. All were between 19 and 22 years of age, and 9 of the 12 were female. Cocreators represented 6 academic disciplines, including psychology (n=5), chemistry and biotechnology (n=3), and computer science, economics, business administration, and medicinal chemistry (n=1 each). Eight cocreators were born in Asia or Africa, with the remaining cocreators originating from the Americas (ie, North, Central, South America) (n=2) and Europe (n=2) (Supplement 4 in Multimedia Appendix 2).

Cocreation Workshops

The aim of the cocreation workshops was to explore how international students in Germany prepare for health care consultations and to collaboratively adapt an existing digital communication intervention (DiPPT) into a preparedness tool tailored to this group's needs. To design the intervention, the BCW [39] was used to inform the structure of the workshops: to first understand patient behaviors and then identify and refine potential intervention options. Workshop methods were sourced from consultation with experts in qualitative research methods and from the cocreation methods selector tool [48], which was developed within the Health CASCADE research network to support evidence-based cocreation in public health. To structure the cocreation workshops so that they could be evaluated in scientific terms, the PRODUCES framework was used [38]. The PRODUCES framework guides cocreation of public health interventions by structuring the planning, conduct, evaluation, and reporting of participatory processes, enabling a systematic and reproducible approach to intervention development [38]. Table 1 details how relevant stages of the BCW were operationalized in terms of workshop aims and methods used.

Quantitative Data Collection

A combination of nominal, Likert-scale, and free-text items was used in the survey instruments. All survey measures were developed specifically to explore patient needs and experiences in primary care, with a particular focus on communication and waiting room experiences. As there were no instruments with established psychometric properties that aligned precisely with the research focus, the bespoke tools were deemed fit for purpose. Furthermore, the need to capture target group–specific variables, minimize respondent burden, and reduce disclosure risk further supported the use of a short, tailored instrument rather than adapting existing scales designed for different contexts. Supplement 1 in Multimedia Appendix 1 consists of the full list of survey items.

Qualitative Data Collection

A variety of qualitative methods for data collection was used in the workshops to capture cocreators' thoughts, opinions, experiences, and emotions both in primary care and concerning the requirements of a DHI designed to support international students in seeking health care. Focus groups were employed to elicit a broad range of experiences in primary care and to facilitate discussion of proposed interventions. These were supplemented by methods such as empathy maps to collect data on emotions and visioning exercises designed to stimulate creative thinking about adapting the original DHI to the primary care context.

Data Processing and Analysis

Quantitative Analysis

Survey responses were processed using R (v4.5.1; R Foundation for Statistical Computing) [49] and RStudio (Posit PBC) [50], with health conditions categorized according to *International Statistical Classification of Diseases and Related Health Problems, Tenth Revision* (*ICD-10*) codes and countries of origin generalized to regions. Descriptive statistics and visualizations (bar charts, histograms, heatmaps) were used to summarize patterns in health status, waiting room experiences, and communication challenges; no inferential statistical analyses were conducted, as the quantitative data were solely intended to provide descriptive workshop-level insights alongside the qualitative findings. All code used to derive descriptives can be found in the Open Science Framework (OSF; Center for Open Science) repository, with the OSF Identifier: JBEAP [51].

Qualitative Analysis

Audio recordings from the focus groups were transcribed verbatim by a transcription agency. Transcripts were checked for accuracy by trained student assistants and anonymized using QualiAnon (v1.3.1; Qualiservice) [52]. Empathy maps, card sorting grids, and visioning charts were digitized using photographic records and recreated in JamBoard (Google LLC) for analysis.

Data was analyzed using structured qualitative content analysis (QCA) [53]. A coding frame was developed iteratively through deductive and inductive approaches. Initial categories were defined deductively based on the research questions and communication constructs from the original DiPPT, then expanded inductively through review of transcripts and workshop outputs. The final frame consisted of 12 parent categories, some with secondary layers, resulting in 52 unique codes. Supplement 2 in Multimedia Appendix 3 details the full coding frame.

Coding was carried out by 2 independent researchers (VAK and MS) across three iterative rounds using QualCoder (v3.5; Colin Curtain) [54]. Thematic segmentation was first applied to identify units of meaning. In each round, the 2 coders independently assigned codes to a shared subset of data (initial round: 45.95% of all segments), blinded to each other's coding decisions during the initial coding stage. After each round, discrepancies were discussed and resolved either through consensus or by refining the coding frame. This two-pronged approach ensured both coder agreement and alignment with the data. As a result, the coding frame evolved in close collaboration between VAK and MS and was refined to improve consistency, clarity, and coverage. All frame iterations were documented to create an audit trail. Reliability and validity assessments were conducted after each round, yielding a final interrater agreement of 74.55% and a "miscellaneous" coding rate of 4.2%, indicating improved frame specificity and low residual ambiguity. Regarding the reliability assessment, code-specific metrics such as Cohen κ were not used due to the large coding frame relative to the sample set, which can distort agreement estimates when

XSL•FO
RenderX

codes were infrequently used or unused [49]. Reliability and validity measures for each category are presented in Supplement 3 in Multimedia Appendix 4. Final coding was then completed by the lead researcher (VAK) using the validated frame. Outputs were extracted using custom SQL queries (accessed through OSF with the identifier: JBEAP) [51].

Results

Cocreators

Twelve international students participated in the cocreation workshops. Half reported living with a long-standing illness, including conditions related to mental health, musculoskeletal issues, and respiratory disorders. Despite this, most cocreators had visited a GP fewer than 5 times in the past year. Supplement 4 in Multimedia Appendix 2 provides detailed information about all data visualizations describing cocreators.

Understanding Experiences and Behaviors of Cocreators

Cocreators described health care as an environment in which emotional uncertainty, system-level barriers, and communication breakdowns were common. Despite these challenges, many took active steps to prepare for appointments, suggesting that patient preparedness may be a promising target behavior. Insights from the workshops are presented below and summarized in Table 2. See Supplement 5 in Multimedia Appendix 5 for all data visualizations relating to cocreator experiences and behavior when receiving care.

Table . Topics, qualitative categories, example quotations, and most frequently used codes relating to health care experiences, waiting room experiences, and patient preparedness behaviors among international students in Germany.

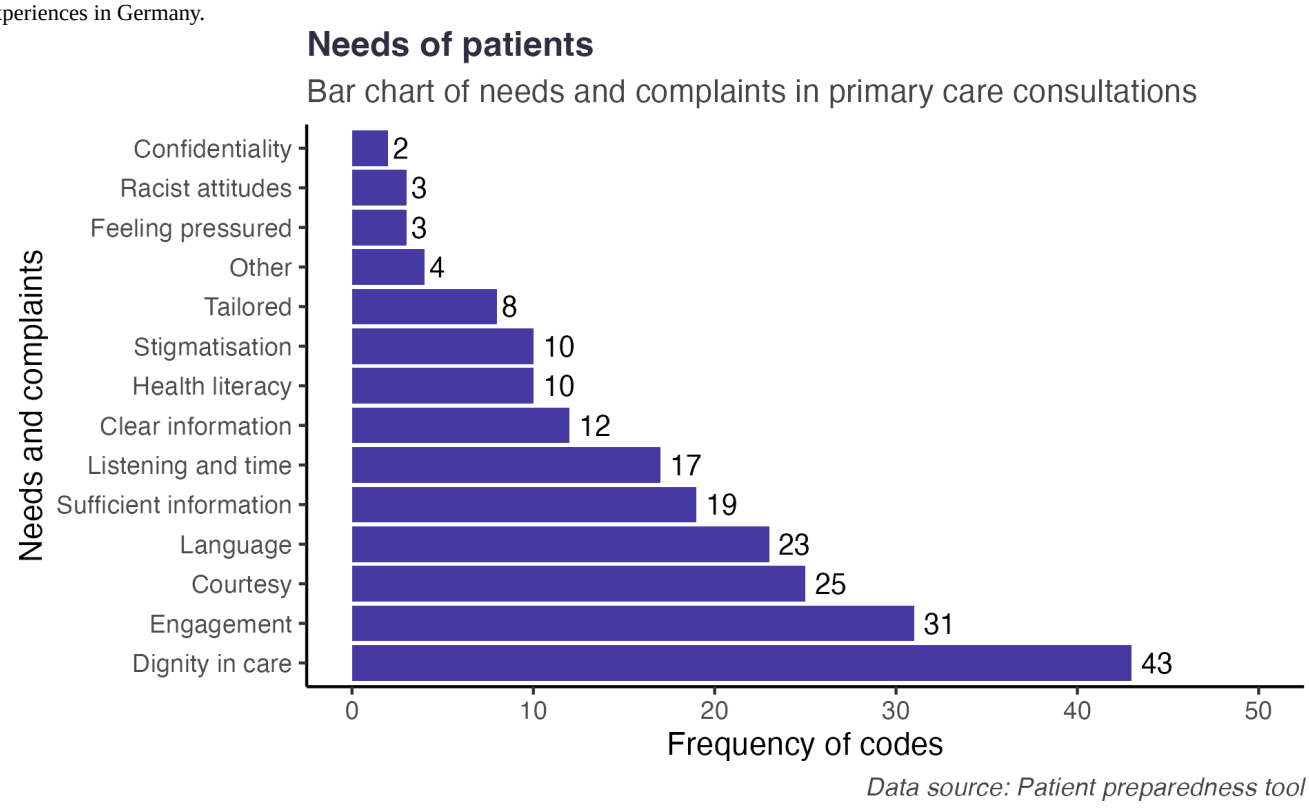
Topic and category	Code	Example
Experiences of cocreators		
Assigning responsibility	Primarily doctor	"I agree in the sense that it's both of their responsibilities, but I think it's mostly the health care workers" [Cocreator 2, February 6, 2024]
Needs and complaints in primary care	Dignity in care	"The doctor is feeling maybe that I'm wasting his time, and it's really not a nice feeling, like I'm being neglected" [Cocreator 5, February 6, 2024]
System challenges in Germany	Insufficient care	"Then, I feel like, okay, go on [REDACTED]'s page, look at the doctors that speak those languages, and then you look up their appointments and then they don't have more appointments." [Cocreator 4, February 6, 2024]
Emotions whilst waiting to see the doctor	Fear and anxiety	"The doctor came by and was like 'Let me have a look at your hand." He did some tests and then it was like 'Okay, we're going to get you to take an image.' Then again, I was just waiting and I didn't know whether I was supposed to tell somebody to take me to get the image or not. But then, after an hour and a half of waiting, someone came. However, there's this creepy aura" [Cocreator 2, February 6, 2024]
Thoughts while waiting to see the doctor	Anticipation or expectation	"Am I having a heart attack?" [Empathy map – Chest pain, February 9, 2024]
Behavior of cocreators		
Preparation method	Taking notes	"Usually, I write down everything I have to say to the doctor" [Cocreator 3, February 6, 2024]
Preparation location	On the way	"Then maybe you revise it like when you're on the train to refresh your mind" [Cocreator 11, February 6, 2024]
Preparation timing	Day before	"I think mostly like the day before" [Cocreator 11, February 6, 2024]
Reasons to prepare	Prompt the doctor	"I want to sometimes discuss with the doctor if this is a possible thing if this is a possible disease, or possible answer for whatever my symptoms are" [Cocreator 2, February 6, 2024]

Quantitative findings further showed that most cocreators viewed communication as a shared responsibility between physician and patient, although few felt that patients should take the lead role (Table 2 and Supplement 5 in Multimedia Appendix 5). Qualitative findings expanded on this pattern by demonstrating that cocreators generally expected physicians to

XSL•FO
RenderX

assume primary responsibility for facilitating effective communication because of their duty of care or professional obligation.

Waiting Room Experiences



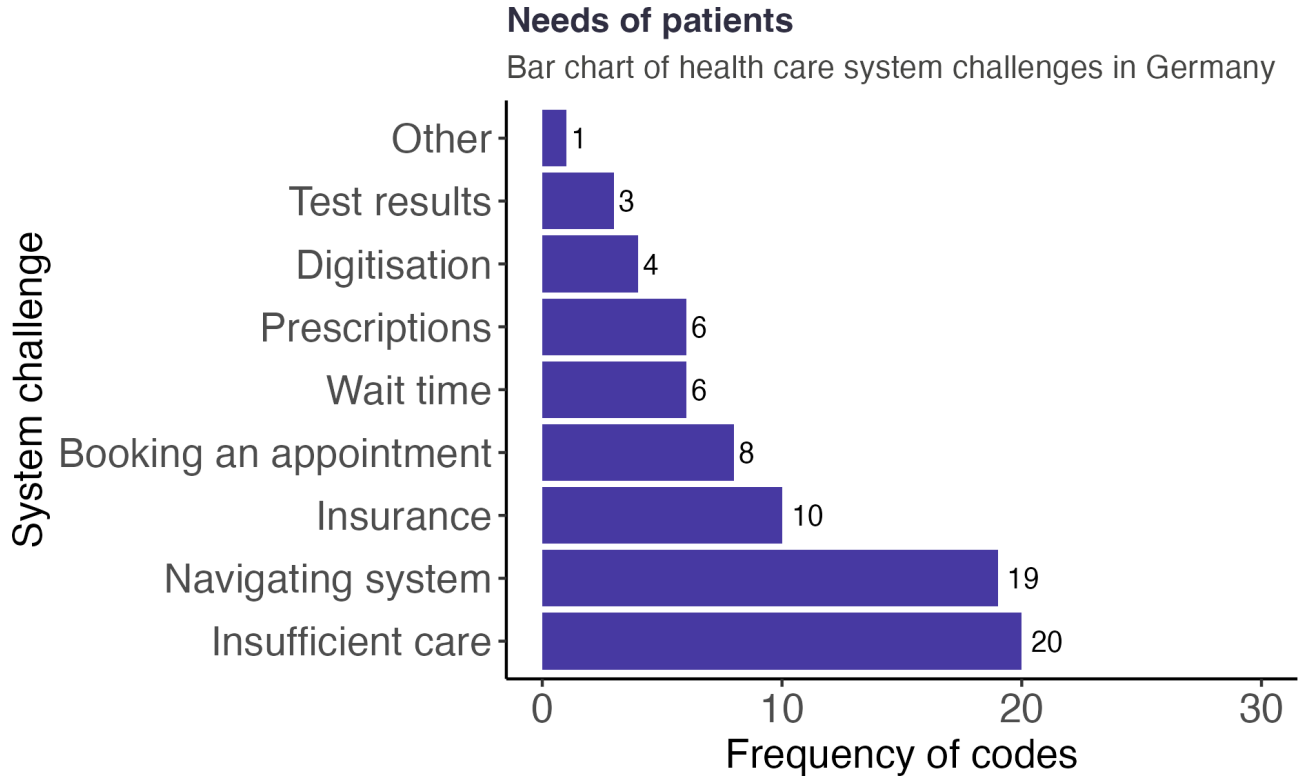
Quantitative and qualitative findings addressed different aspects of the waiting room experience. While survey data characterized where, with whom, and how long cocreators waited, qualitative findings highlighted the emotional experience of waiting. Survey data showed that the majority of cocreators arrived alone to appointments, had access to a waiting room, and waited inside the clinic. Waiting times varied considerably across cocreators; 6 waited less than 30 minutes on average, while 5 waited more than 30 minutes on average. The qualitative data showed that cocreators frequently experienced anxiety and uncertainty while waiting, often linked to anticipated diagnoses, unclear consultation expectations, or past experiences. This psychological vulnerability was one of the most frequently cited themes during empathy mapping activities.

Needs of Patients

Communication Needs and Challenges

With respect to communication challenges that patients face, qualitative and quantitative data converge. Eight cocreators reported feeling misunderstood by health care workers in the quantitative data, and 4 reported not being listened to. Qualitative data expanded upon this by specifying the perceived causes of communication difficulties. Language barriers, lack of empathy and engagement, insufficient explanations, and dismissive behavior were frequently reported communication challenges across the focus groups. Figure 1 details the frequency of all codes used for the category “needs and complaints” in health care settings. Cocreators articulated a range of communication needs, including clearer explanations, culturally sensitive interactions, emotionally validating exchanges, and information delivered in plain language. Time constraints during consultations were also identified as a barrier to effective communication.

Figure 1. Frequencies of communication-related needs and complaints reported by international students during cocreation workshops on primary care experiences in Germany.



System Level Needs and Challenges

In addition to interpersonal issues, cocreators highlighted system-level needs in the focus groups such as improved access to appointments, better navigation support, and more user-friendly digital infrastructure, particularly for tasks like receiving test results. Complaints about difficulty navigating the system and inadequate digital services were among the most frequently cited challenges across the dataset. Figure 2 contains the frequency of all codes used for the category “system level challenges” in the German health care system.

XSL•FO
RenderX

Figure 2. Frequencies of system-level challenges reported by international students when navigating the German health care system during cocreation workshops.

Patient Preparedness behavior

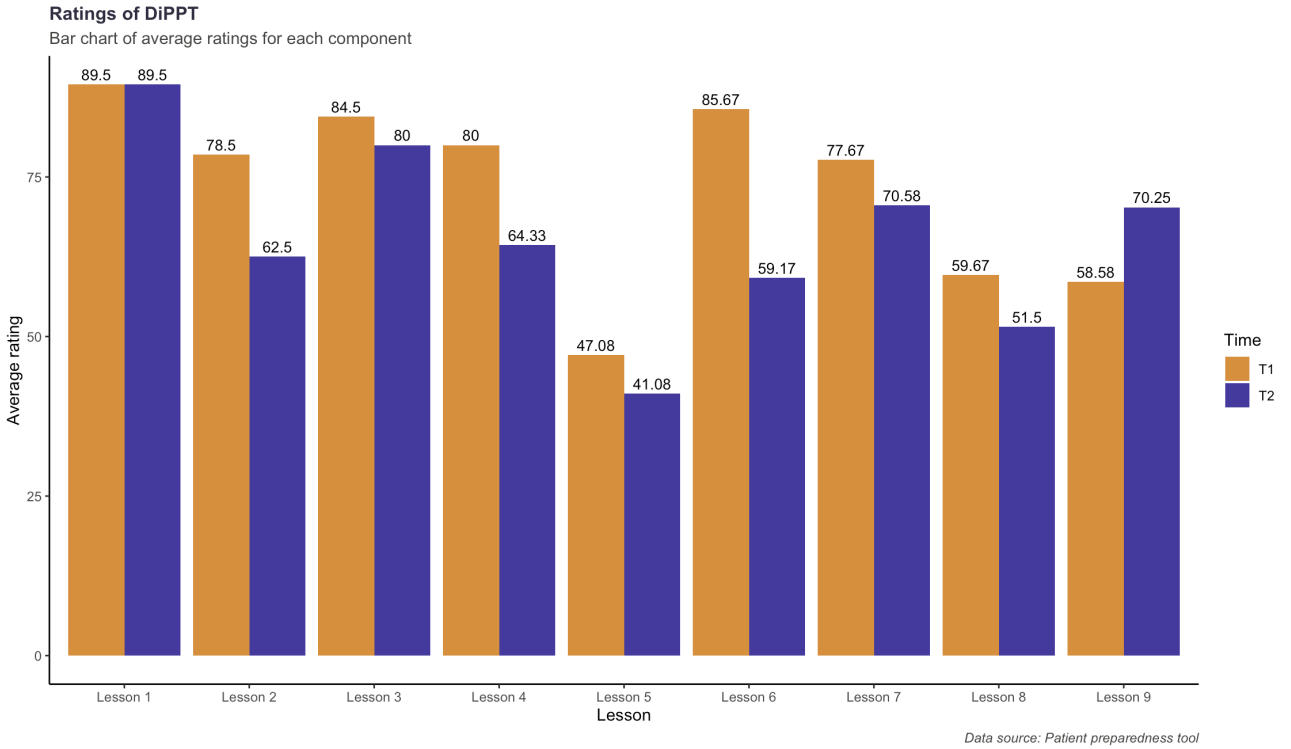
Focus groups revealed differences in how patients prepared for their appointments. Cocreators frequently described taking notes, listing symptoms, or researching conditions the day before or on the way to the clinic. These actions were intended to structure the consultation, ensure efficiency, and psychologically prepare for the encounter. “Taking notes” was one of the most frequently coded behaviors in the dataset. Some cocreators used preparation as a way to prompt the physician, express concerns clearly, or guide the direction of the conversation.

Intervention Options

Qualitative data revealed that while the concept of a DiPPT was welcomed, the design must prioritize usability and relevance. Rather than structured training, cocreators sought lightweight, responsive features that could flexibly support them before and during primary care consults. These insights are detailed below and summarized in Table 3. Supplement 6 in Multimedia Appendix 6 outlines all data visualizations relating to cocreator needs for the digital health intervention.

XSL•FO
RenderX

Table . Qualitative categories, example quotations, and most frequently used codes relating to perceptions of the DiPPT[a] and desired features for a redesigned digital preparedness intervention.



Category	Code	Example
Elements of DiPPT[a] to retain	Retain content	“Maybe some lessons could be especially useful to a lot of people.” [Cocreator 5, February 20, 2024]
Elements of DiPPT to modify	Modify content	“Lesson 3 was frustrating, get to the point.” [Visioning flip chart – Lesson 3, February 20, 2024]
Features to include in the digital health tool	Communication training	"We had problems going to the Hausarzt explaining our state, like giving an explanation to the Hausarzt about our state, our symptoms. That was the main problem. If this app kind of helps in all of this, the communication between us and the doctors, then we can be better. " [Cocreator 10, February 20, 2024]
Features to exclude in the digital health tool	Open-ended responses	“When you’re typing a long answer... you expect something back.” [Cocreator 6, February 20, 2024]
Utility of tool	Limited use	“I don’t think I would use it multiple times...maybe just once if I have a really serious appointment.” [Cocreator 7, February 20, 2024]

[a]DiPPT: Digital Patient Preparedness Tool.

Suitability of the Existing DiPPT

Quantitative data identified the lessons that cocreators rated most and least favorably, while qualitative findings help explain both the content and delivery characteristics that may have contributed to these ratings. Figure 3 presents the average ratings cocreators assigned to each lesson before using the web-app (ie, with only a description of what was covered in the lesson) and after using the web-app.

Figure 3. Average ratings of lessons from the digital patient preparedness tool (DiPPT) by international student cocreators before and after using the intervention during cocreation workshops in Germany.

With respect to intervention design, the data converge in suggesting a preference for concise, low-burden content. The highest-rated lessons were among the shortest in the intervention and contained relatively few open-ended or closed-ended exercises, while lesson 5, which had the lowest rating, contained the most open-ended activities of all lessons in the intervention. Qualitative data support this interpretation, with cocreators

XSL•FO
RenderX

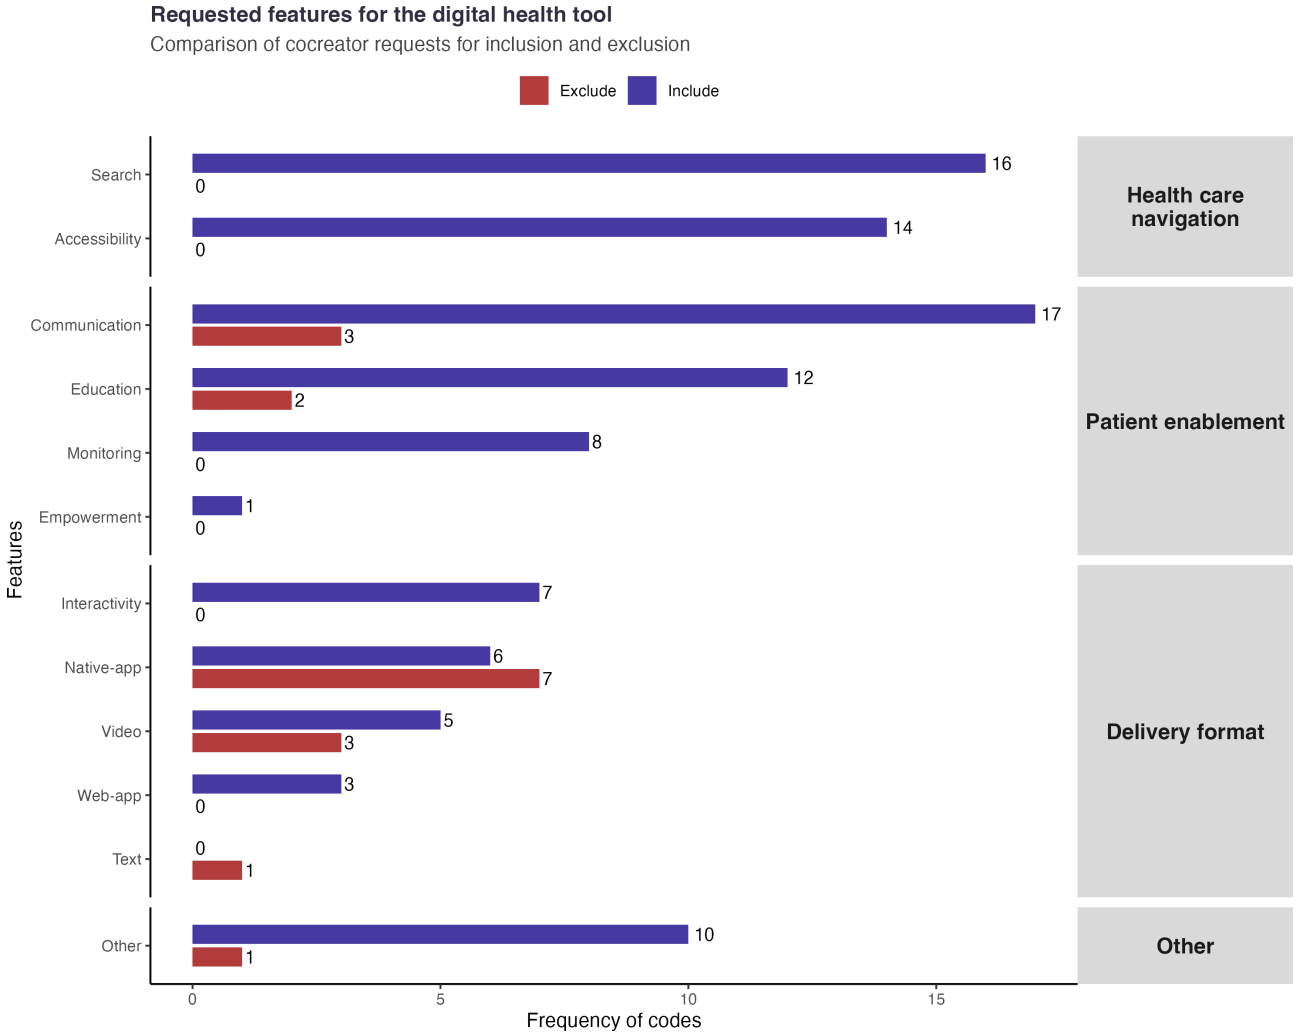
expressing dissatisfaction with lengthy lessons, quizzes, open-ended activities, and the existing lesson-based format.

With respect to communication support, the data converge in suggesting that cocreators valued content that helped them overcome barriers encountered during health care interactions, whereas lower-rated lessons asked patients to assume additional responsibility beyond overcoming those barriers. The highest-rated lessons focused on communicating information clearly (Lesson 1), speaking up about concerns (Lesson 3), and preparing for consultations (Lesson 7). Qualitative findings help explain this pattern, as cocreators frequently reported difficulties obtaining sufficient and clear information, having their concerns taken seriously, being listened to, and communicating effectively with health care workers. Lesson 3 directly addressed complaints relating to dignity in care, engagement, courtesy, and feeling heard by encouraging patients to express concerns and advocate for their needs. Lessons 1 and 7 addressed needs for sufficient and clear information by supporting patients in structuring information, asking questions, and seeking clarification. Lesson 1 additionally provided strategies for communicating clearly, which may be particularly relevant for cocreators who reported language-related communication difficulties.

The data also converge in suggesting that content perceived as shifting responsibility towards patients was viewed less favorably. Two of the lowest-rated lessons focused on empathizing with the doctor (Lesson 5) and structuring information for the doctor (Lesson 6), both of which emphasized adapting patient behavior to facilitate communication with health care workers. Qualitative findings support this interpretation, as most cocreators expected physicians to take primary responsibility for communication because of their professional role and expertise.

The data further suggest that alignment with cocreators' existing behaviors and perceived needs influenced lesson ratings. Lesson 7, which received a relatively high rating, aligned closely with preparedness behaviors identified in the workshops, including taking notes, prioritizing concerns, and preparing questions before consultations. In contrast, Lesson 8, which received a relatively low rating, did not directly address the communication difficulties or health care navigation challenges raised by cocreators. Instead, it focused primarily on stress management and may therefore have been perceived as less relevant to their immediate needs.

Together, the data suggest that cocreators valued practical communication support that directly addressed challenges encountered during primary care consultations, while content perceived as burdensome, less relevant, or shifting responsibility towards patients was viewed less favorably.



Needs for a Digital Tool

Quantitative lesson ratings indicated general acceptance of communication-related content, while qualitative data identified communication support as the most frequently requested feature. Together, the data suggest that communication support may be a useful component of a digital preparedness intervention for international students.

Qualitative data from focus groups, card sorting activities, and visioning exercises identified several additional functional needs. These included support for appointment scheduling, clinic search functions, access to patient rights and symptom information, health monitoring tools, personalized feedback, and interactive features such as chatbots. The most frequently requested features were communication prompts, scheduling functions, and interactive components. Figure 4 includes the features cocreators requested to be included and excluded from the design specifications for a digital health intervention.

XSL•FO
RenderX

Figure 4. Frequencies of features requested for inclusion and exclusion in a redesigned digital health intervention (DHI) for international students accessing primary care in Germany.

Qualitative data also highlighted reservations regarding adoption of the intervention. Many cocreators indicated that they would use such a tool only under certain conditions or not at all, particularly if it addressed only doctor-patient communication. Several cocreators suggested that the perceived value of the intervention would increase if it also supported broader health care needs, such as appointment scheduling, clinic navigation, or access to health care information.

Quantitative and qualitative data provided complementary insights into the suitability of delivering the intervention through a digital medium. While survey data indicated that most cocreators could use mobile devices while waiting for appointments, limited Wi-Fi availability and variable mobile data quality may restrict digital engagement in practice. Qualitative findings further highlighted concerns regarding the usefulness of a standalone communication app. Together, these findings suggest that successful implementation may depend on both the digital environment in which the intervention is used and the extent to which it addresses needs beyond communication support.

Discussion

Principal Findings

This study adopted a convergent mixed methods design to cocreate a DiPPT with students from an international university in Germany. To our knowledge, this study is the first to explore the health care needs and experiences of international students accessing primary care in Germany and to use these insights to cocreate a DiPPT. Quantitative and qualitative data together captured international students' health care experiences, preparation behaviors, and perceptions of a digital preparedness intervention. Integrating quantitative and qualitative findings enabled interpretation of both the prevalence and context of cocreators' experiences. Survey findings provided descriptive insight into communication perceptions, health care experiences, and waiting room conditions, while qualitative findings contextualized these patterns by exploring emotional vulnerability, preparation behaviors, and intervention preferences in greater depth. Cocreators' needs explored in the qualitative data included both interpersonal communication needs and challenges as well as broader system-level barriers related to navigating the health care system and accessing services. Importantly, these findings suggest that the health care experiences of international students may reflect the more

XSL•FO
RenderX

general experience of young adults navigating an unfamiliar health care system independently for the first time. Collectively, the data informed a design specification for a digital intervention tailored to international students in Germany while demonstrating a replicable approach for integrating cocreation methods and the BCW in digital health intervention development.

In the survey data, most cocreators agreed that communication should be a shared responsibility between physician and patient, and the majority disagreed that patients should carry the lead role. Qualitative findings indicated that despite the shared responsibility, physicians were expected to take the lead due to professional responsibility. The expectation that both parties should contribute to communication is consistent with evidence that younger people increasingly wish to participate actively in health care decisions rather than adopt a purely passive role [55,56]. Similarly, recent work on Generation Z has found that young adults value collaborative relationships with health care providers, leveraging digital fluency to become more health literate and actively taking part in decision-making [57]. However, expectations regarding who should lead the consultation may also reflect previous health care experiences in cocreators' countries of origin. Most cocreators in the present study originated from Asia and Africa, where shared decision-making often differs from the Western European and North American model. Across many South Asian settings, patients commonly value involvement while expecting physicians to provide recommendations and assume greater responsibility for directing consultations [58-60]. Evidence from African settings is more heterogeneous, but similarly suggests that clinician authority remains influential in many contexts, while patients continue to value involvement in decisions [61,62]. Taken together, these findings suggest that the pattern observed in this study may reflect the combined influence of being a young adult seeking active involvement in health care while drawing on previous experiences of health care systems in which physicians are expected to take greater responsibility for guiding clinical discussions.

Findings from the survey data further showed how many cocreators felt misunderstood or not listened to, while qualitative findings provided insight into the perceived causes of these experiences, including language barriers, insufficient explanations, lack of empathy, and dismissive behavior. Across the focus groups, cocreators reported feeling emotionally vulnerable during primary care interactions. For international students, these experiences may be compounded by the transition to a new health care environment.

Cocreators described not only communication difficulties during consultations but also uncertainty about how health care services operate in Germany. This suggests that experiences of care are influenced by both being recent migrants and navigating an unfamiliar health care system independently for the first time. Emerging adulthood is characterized by increasing responsibility for managing one's own health care, including recognizing when to seek care, arranging appointments, selecting providers, communicating symptoms, and making health care decisions without parental support [63]. Previous research has shown that young adults commonly experience uncertainty about how health care systems operate, question whether their symptoms warrant seeking care, worry about whether their concerns will be taken seriously, and often lack the health care knowledge and confidence developed through prior experience [64,65]. These challenges may be further amplified when young adults are simultaneously adapting to a new health care system with unfamiliar organizational structures, administrative processes, and communication norms. Previous studies in Hungary, Turkey, and the United States have reported similar findings: international students experienced language barriers, difficulties with appointment and insurance processes, perceived lack of dignity or insufficient care, and challenges navigating health care services [66-68]. These findings echo broader research documenting negative health care experiences among migrant groups in Germany, particularly concerning unclear communication, perceived indifference, cultural barriers and lack of dignity in care [69-72]. Complaints of dismissiveness and language barriers were among the most frequently coded responses, aligning with broader literature on migrant health care experiences in Germany [73,74].

This study confirms that in addition to provider demeanor, system-level needs and challenges also shape health care experiences of international students. While the surveys primarily characterized communication experiences and waiting room conditions, qualitative findings additionally identified broader system-level challenges, including difficulties arranging appointments, identifying suitable providers, and accessing digital infrastructure. These findings align with recent research showing that migrant groups in Germany often face structural barriers when navigating health care systems, including limited information about available services and administrative complexity [22]. While these challenges are common among migrant populations, they may have particular implications for international students, who must navigate unfamiliar health care processes independently for the first time. These findings highlight the importance of accessible, efficient, and supportive health care encounters for individuals who are unfamiliar with the health care system. Studies of digital health systems also suggest that insufficient integration of digital services and patient-facing tools within existing health care infrastructures can further limit accessibility and usability [14,75].

Cocreating an intervention with international students provided insight into how health care support may need to be tailored to this population. Cocreators preferred concise, practical, and multifunctional digital tools that could support both consultation preparation and broader health care needs.

Qualitative data also indicated that most cocreators actively prepared for consultations by taking notes and researching symptoms, with a motivation to improve communication efficiency and manage emotional stress. Preparation strategies were implemented just prior to appointments and were often used to prompt physicians during the consultation. This mirrors findings from previous studies highlighting that patients who prepare in advance are more likely to participate actively in clinical conversations [45,76]. While cocreators accepted shared responsibility for communication, they generally expected more engagement and empathy from providers, reinforcing the need for bidirectional communication efforts [77,78].

XSL•FO
RenderX

Feedback on the current DiPPT was mixed. Integrated qualitative and quantitative data suggested that perceptions of the intervention were influenced by both the content and delivery format of the lessons. The highest-rated lessons addressed challenges frequently identified by cocreators throughout the workshops, including obtaining clear information, communicating concerns, and preparing for consultations. In contrast, lower-rated lessons were perceived as more burdensome, less relevant to cocreators' immediate needs, or as placing additional responsibility on patients rather than health care providers. This latter finding converges with cocreators' views regarding communication responsibility, with cocreators generally expecting physicians to take the lead role in facilitating effective health care communication. Qualitative data further indicated dissatisfaction with lengthy lessons, quizzes, and open-ended exercises, while quantitative findings showed that the highest-rated lessons were among the shortest and least demanding components of the intervention.

Together, the data suggest that intervention acceptability may depend not only on addressing communication challenges experienced by patients, but also on presenting support in a concise, practical, and low-burden format that aligns with cocreators' expectations of the doctor–patient relationship. Similar to findings in the literature [11,45], digital interventions that incorporate personalized feedback and patient-centered support are more likely to be adopted. However, many cocreators expressed skepticism about routine tool use, emphasizing that added features were necessary to drive engagement [79,80].

Implications

The BCW was used to derive design specifications for a DiPPT tailored to international students [81]. Cocreation insights were mapped onto COM-B determinants (Capability, Opportunity, and Motivation) to identify key behavioral drivers of patient preparedness (the target behavior) among international students (the target audience). Capability-related needs included structured communication support (eg, checklists), opportunity-related factors reflected physician encouragement and system integration, and motivation-related factors emphasized interactive and multifunctional features (eg, chatbots). The relationship between these determinants and resulting intervention features is summarized in Supplement 7 in Multimedia Appendix 7.

As a potential implementation pathway, the intervention may be embedded into university orientation programs and distributed via clinic-based pamphlets, thereby normalizing the practice of patient preparation among students. Moreover, orientation programs may benefit from providing international students with clearer information about how the German health care system functions. This approach is echoed by Abdulai and colleagues [82], who emphasize the importance of considering contextual factors and leveraging existing university support structures when supporting international students. Informing students about available health care services, as well as existing tools and resources for finding clinics, booking appointments, and accessing digital health services, may help alleviate some of the navigation challenges reported by cocreators in the workshops. Taken together, these findings offer a behaviorally grounded and contextually responsive foundation for intervention development.

This study illustrates the value of combining behavioral science frameworks such as the BCW and COM-B model with systematic cocreation methodologies, including the Health CASCADE guidelines [83] and the PRODUCES framework [38]. The PRODUCES framework helped in conceptualizing the problem, communicating the objective and design of, as well as identifying the cocreators to recruit as part of the workshops, and in determining the scaling strategy to use. The BCW played a key role in shaping the sequence and focus of the workshops, facilitating the identification of end-user needs and behavior change determinants. The design of the workshops was also guided by the work of Health CASCADE, who have developed cocreation guidelines [83], to create an inclusive and transparent process and ensure that cocreators' voices were meaningfully integrated into the intervention's design. By combining these methodologies with the BCW and COM-B, the study provides a replicable and scalable roadmap for developing digital health interventions that are grounded in theory and shaped by the lived experiences of users by means of acting as a role model. Together, these frameworks support the creation of interventions that are sensitive to real-world user needs, anchored in validated behavior change methods, and designed with sustainability in mind through participatory development practices.

Feasibility

While the previous section outlines the behavioral determinants and design specifications of the intervention, questions remain regarding its feasibility and potential adoption in real-world settings. Although cocreators expressed preferences for an intervention that would support doctor-patient communication, several indicated that they would likely use such a tool only once or before particularly important medical appointments.

The data also highlighted challenges relating to the digital medium. Together, the limited connectivity and skepticism towards a standalone communication app suggest that the intervention may function primarily as a situational preparation aid rather than a tool intended for continuous engagement. This pattern aligns with broader findings in digital health research showing that initial interest in digital tools often does not necessarily translate into sustained use [84,85]. Many digital health interventions experience rapid declines in engagement following early exposure, even when users report positive perceptions of their usefulness [86,87].

Adoption of digital health tools is also influenced by the broader environment in which they are deployed. Cocreators highlighted that the perceived value of a preparedness tool would increase if it addressed system-level challenges, such as appointment scheduling, clinic navigation, or access to medical documentation. Prior research has shown that digital health interventions are more likely to be adopted when integrated into existing care infrastructures rather than functioning as standalone behavior change tools [88,89].

XSL•FO
RenderX

If the intervention is primarily used as a one-off preparation tool, its effectiveness may therefore depend on where it is embedded within existing systems, such as appointment booking platforms, university health services, or patient portals. Future work should therefore explore which digital tools and communication channels international students currently rely on when navigating health services in Germany, as this may reveal more feasible points of integration. In some contexts, a lightweight intervention embedded within existing platforms or informational resources may be more appropriate than a standalone application.

Limitations

To enhance cocreation and better understand the mutual communication between physicians and patients, future studies should consider involving physicians and clinic administrators as cocreators in the process. Additionally, the coding frame used for qualitative content analysis was limited in distinguishing between specific content, design, and functional preferences for digital tools. Future iterations should further refine coding categories with respect to specific aspects of the DiPPT that should be retained or excluded, and further delineating the miscellaneous categories for cocreator needs of a digital health intervention.

Furthermore, quantitative data were collected anonymously, preventing direct linkage with qualitative insights by person. Future designs should link cocreator data to deepen the understanding of tool acceptability among distinct user profiles.

Finally, cocreation prioritizes depth of insight over statistical representativeness, so the study involved a small sample of international students (n=12), homogeneous with respect to age (19 - 22 y), enrolled at a single English-speaking international university in Germany, limiting generalizability. Therefore, the findings presented here should not be interpreted as reflecting the needs of the broader migrant population in Germany. Moreover, the extent to which the findings are specific to international students, reflect broader migrant experiences, or arise from the intersection of student and migrant identities remains unclear. Further research is needed to disentangle these influences and examine the transferability of the findings to other populations. However, the methodological approach may be transferable to other contexts, and future research should extend this approach to diverse academic institutions, age groups, and include a wider range of cultural backgrounds.

The detailed reporting of the cocreation procedures and the transparent presentation of the coding frame provide a foundation that future researchers can use to inform the design of workshops with other migrant subgroups and settings.

Conclusion

In conclusion, this study identified key communication and system navigation challenges faced by international students in German primary care and translated these into design specifications for a tailored DiPPT. By integrating cocreation methods with the BCW and COM-B model, the study offers a foundation for future intervention development.

Abstract

Background: Telemedicine adoption among health care professionals is hindered by resistance to change (RTC), comprising routine-seeking, emotional reactivity, short-term focus, and cognitive rigidity, which interacts with perceived ease of use (PEU) and anxiety within the Technology Acceptance Model framework.

Objective: This study aimed to test a moderated mediation model in which PEU mediates the association between RTC, assessed both overall and by dimension, and intention to use telemedicine, while telemedicine-related anxiety moderates the association between PEU and intention to use. Participants were recruited from 4 governmental geriatric medical centers in Israel.

Methods: A cross-sectional study was conducted among 377 health care professionals from 4 Israeli governmental geriatric medical centers. Telemedicine use in the participating centers was limited, optional, and consisted mainly of remote patient monitoring. Data collection was conducted between March and June 2024. Data were collected using validated self-administered questionnaires measuring telemedicine-related anxiety, RTC with 4 dimensions (routine seeking, emotional reactivity, short-term focus, and cognitive rigidity), PEU, and intention to use telemedicine. Statistical analyses were performed using SPSS (version 28) and PROCESS Model 14 for moderated mediation analysis.

Results: The moderated mediation analysis revealed that RTC was negatively associated with the intention to use telemedicine through the lower PEU, with this indirect pathway being attenuated but not eliminated by high telemedicine-related anxiety. The overall indirect effect remained negative and statistically significant across all anxiety levels.

Conclusions: Health care professionals' RTC reduced their intention to use telemedicine by lowering PEU, with telemedicine-related anxiety moderating but never eliminating this relationship. These findings suggest that telemedicine implementation in geriatric settings should consider both RTC and PEU. The positive indirect association observed for cognitive rigidity was unexpected and should be replicated before specific practical recommendations are made.

Introduction

Background

Telemedicine, defined as the use of telecommunications technology to provide medical care and health services remotely [1], has emerged as a transformative force in health care delivery [2,3]. This technology encompasses a variety of applications, including virtual consultations, remote patient monitoring, and mobile health apps, which allow health care providers to diagnose, treat, and manage patients without the need for an in-person visit [4]. Despite its potential to increase access to health care, improve patient outcomes, and enhance the efficiency of health care delivery as documented by Alotaibi and Federico [5], the World Health Organization [6], and Bashshur et al [7], telemedicine has faced inconsistent uptake among health care professionals due to various barriers [8,9], with resistance to change (RTC) emerging as a particularly significant obstacle within the Technology Acceptance Model (TAM) framework [10].

RTC represents a multifaceted construct encompassing routine seeking, emotional reactivity, short-term focus, and cognitive rigidity [11-13]. More specifically, it refers to the emotional

XSL•FO
RenderX

and behavioral response of individuals or groups when faced with new ideas, practices, or technologies [14-16]. This resistance can manifest as skepticism, reluctance, or outright opposition to adopting changes, often hindering the implementation of new initiatives or technologies, such as telemedicine in health care settings [17]. Oreg [13,18] developed the RTC scale, which was later validated across 17 nations [19], demonstrating its universal applicability. Understanding the dimensions of routine seeking, emotional reactivity, short-term focus, and cognitive rigidity of this construct is crucial for addressing barriers to telemedicine adoption.

The first dimension, routine seeking, reflects the tendency of individuals to prefer established habits and processes over new methods or technologies [20]. This preference often arises from a desire for stability and familiarity, leading to reluctance in embracing changes that disrupt existing routines, as noted by Kotter [21]. The second dimension, emotional reactivity, plays a crucial role as it encompasses the immediate emotional responses individuals experience when faced with change [14,15]. Emotions such as fear, anxiety, or frustration can significantly impact one's willingness to adopt new practices or technologies [22]. The third dimension, short-term focus, is characterized by the inclination to prioritize immediate outcomes and benefits over long-term gains. Individuals with a short-term perspective may resist change due to their concern for the immediate implications of new practices, often overlooking potential future advantages [17]. Finally, cognitive rigidity represents a key element, reflecting the inability or unwillingness to adapt one's thinking or behavior in response to new information or changing circumstances. This rigidity can result in a steadfast adherence to old ways of thinking, making it challenging for individuals to accept and implement change [13].

The adoption and use of telemedicine technologies have been significantly influenced by the interaction between RTC, perceived ease of use (PEU), and anxiety [17,23]. Within the TAM framework, research has shown that the PEU of technology significantly influences an individual's intention to use it, particularly in health care settings [17,24]. The TAM, originally developed by Davis [10], posits that PEU and perceived usefulness are primary determinants of technology acceptance. Recent extensions of TAM and related dual-factor models have added inhibiting factors, including RTC and technology-related anxiety, to the original focus on facilitating beliefs such as PEU [14,17,24]. When users perceive a technology as user-friendly, their likelihood of adopting it increases, as they feel more confident in navigating its features [25]. However, this relationship can be moderated by anxiety related to using technology. Individuals who experience higher levels of anxiety may struggle to engage with even the simplest digital platforms, leading to a decrease in their intention to use such technologies [26,27]. This relationship suggests that while ease of use is a critical factor in technology adoption, addressing the psychological barriers, such as anxiety, is essential for enhancing user intent [28].

Anxiety can significantly impede an individual's perception of ease of use when engaging with telemedicine technologies, as heightened feelings of apprehension may lead to a lack of confidence in navigating these platforms [26]. When health care professionals experience heightened anxiety about adopting new technologies, their perception of these technologies' ease of use tends to decline [29]. Consequently, this diminished perception of ease can adversely affect the intention to use telemedicine services, as users may avoid adopting technologies that they find intimidating or challenging to operate [30]. Furthermore, prior studies have reported an association between RTC and intention to use telemedicine [20,31] as well as an indirect association through PEU [32].

Research has also associated telemedicine-related anxiety with less favorable usability perceptions and weaker intentions to use digital technologies [26,27,29,30,33]. However, previous studies have generally examined these relationships separately, focusing on RTC and telemedicine acceptance [17,24], PEU and intention to use [23], or telemedicine-related anxiety and technology acceptance [27,33]. It is therefore unclear whether telemedicine-related anxiety changes the strength of the association between PEU and intention to use and whether the indirect association between RTC and intention to use through PEU differs across anxiety levels.

Previous studies have also tended to treat RTC as a single overall construct rather than examining its 4 dimensions separately. Although RTC comprises routine seeking, emotional reactivity, short-term focus, and cognitive rigidity [13,18,19], limited evidence is available on whether these dimensions show the same pattern in relation to telemedicine acceptance. Reliance on an overall RTC score may conceal dimension-specific associations with PEU and intention to use. Governmental GMCs provide a theoretically relevant setting for this model because telemedicine must be incorporated into established multidisciplinary workflows rather than adopted as a stand-alone technology [11,34]. In this setting, resistance may shape perceptions of ease of use, while anxiety may weaken the association between PEU and intention to use. The present study extends recent TAM and dual-factor models by examining RTC both as an overall construct and as 4 separate dimensions within 1 conditional process model. It tests whether RTC is associated with intention to use through PEU, whether this indirect association differs across anxiety levels, and whether the same pattern applies to all 4 RTC dimensions [32,35,36].

Main Research Question and Hypotheses

The main research question is as follows: Is the indirect relationship between RTC (overall and its subcategories: routine seeking, emotional reactivity, short-term focus, and cognitive rigidity) and intention to use telemedicine via the mediator ease of use moderated by anxiety among health care professionals in governmental geriatric hospitals in Israel?

Accordingly, the hypotheses are as follows:

- H1: Higher RTC, as well as higher levels of each dimension, will be associated with lower PEU of telemedicine.
- H2: Higher PEU will be associated with a stronger intention to use telemedicine.
- H3: PEU will mediate the association between RTC and intention to use telemedicine. Specifically, higher RTC will be associated with lower PEU, which, in turn, will be

XSL•FO
RenderX

associated with a weaker intention to use telemedicine. This indirect association will also be examined for 4 dimensions of RTC.

- H4: Telemedicine-related anxiety will moderate the indirect association between RTC and intention to use telemedicine through PEU. Specifically, the indirect association will become weaker as telemedicine-related anxiety increases.

Methods

This research used a cross-sectional study design to examine the phenomenon at a single point in time [37]. The study methodology adhered to the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines to ensure methodological rigor and reporting transparency [38]. A completed STROBE checklist is provided in Checklist 1.

Participants

Study participants comprised health care professionals employed in four Israeli governmental GMCs: Dorot Medical Center, Fliman Medical Center, Shmuel Harofeh Medical Center, and Shoham Medical Center. The sample consisted of 377 health care professionals representing caregivers, including physicians, nurses, physiotherapists, speech-language therapists, occupational therapists, and clinical dietitians. At the time of data collection, the target population in these 4 centers totaled 1184 professionals: 146 physicians, 790 nurses, and 248 allied health professionals.

Participant inclusion criteria encompassed health care professionals (physicians, nurses, and multidisciplinary staff including physiotherapists, speech therapists, occupational therapists, and clinical dietitians) employed within the specified governmental GMCs (Dorot, Fliman, Shmuel Harofeh, and Shoham), maintaining employment tenure of at least 6 months, demonstrating Hebrew language proficiency, and providing voluntary informed consent for participation. At the time of data collection, telemedicine use in the participating centers was limited and optional and consisted mainly of remote patient monitoring. The questionnaire assessed telemedicine in general and did not distinguish among audio-only, video-based, remote-monitoring, or hybrid modalities, or between dyadic and triadic interactions. Telemedicine use was neither mandated nor actively discouraged by hospital management. Exclusion criteria consisted of health care professionals with less than 6 months of employment at the GMCs, insufficient Hebrew language competency, and declined consent for research participation. The study sought to reach the entire staff population. Visits were conducted in every department across all work shifts, and questionnaires were offered to all staff present. A total of 377 professionals completed the questionnaire, corresponding to 31.8% of the 1184 professionals employed in the 4 centers. The 377 questionnaires included in the analyses were fully completed. The sample's professional composition was similar to that of the target population (nurses: n=256, 67.9% vs physicians: n=46, 12.2% vs allied health: n=75, 19.9%).

Procedure

Data collection operations were supervised by a designated research coordinator responsible for managing the comprehensive data gathering process across all participating GMCs. The research coordinator maintained ongoing communication with field surveyors and medical center administration while providing oversight for the complete quantitative data collection protocol.

The data acquisition was conducted through self-administered questionnaires distributed by trained student surveyors from the University's School of Health Sciences. Survey implementation followed prescheduled department visits coordinated with departmental supervisors, during which staff members were invited to complete anonymous self-report questionnaires addressing the research variables. Supervisors and hospital managers were not present during questionnaire completion, and data were collected by independent academic surveyors who were not employed by the participating centers. Questionnaires were completed privately in designated rooms and were collected anonymously. Data collection was conducted between March and June 2024 across the 4 participating governmental GMCs.

Upon questionnaire completion, surveyors secured all materials in sealed envelopes and transferred them to the research coordinator for subsequent coding and data entry procedures. This systematic approach ensured data integrity and maintained participant anonymity throughout the collection process.

Instruments

The data collection for this study was carried out using a structured questionnaire that included 5 essential measurement scales designed to assess various aspects of telemedicine use and the participants' reactions.

The first measurement scale focused on telemedicine-related anxiety. Anxiety levels concerning the use of telemedicine in patient care settings were evaluated through a 4-item instrument based on the work of Venkatesh et al [27]. A sample item in this scale was as follows: "I experience concern when using telemedicine in patient care contexts." Participants' responses were captured on a 6-point scale, with 1 indicating strong disagreement and 6 indicating strong agreement. The reliability of this scale, measured by Cronbach α, was found to be α=.89, suggesting a high level of internal consistency.

The second measurement scale addressed RTC, a critical factor in understanding how health care professionals adapt to new technologies such as telemedicine. This scale was based on Oreg [18] 17-item instrument, which examines 4 distinct dimensions of change resistance.

The first dimension, routine seeking, was measured using 5 items. A sample item from this dimension was as follows: "I typically view changes (such as telemedicine implementation) negatively within my workplace." The reliability of this scale was α=.75, indicating moderate internal consistency.

The second dimension, emotional reactivity, consisted of 4 items. A sample item in this category was as follows: "Learning about significant workplace changes (like telemedicine adoption)

XSL•FO
RenderX

would likely increase my stress levels." This dimension had a reliability of α=.84, demonstrating strong internal consistency.

The third dimension, short-term focus, was assessed using 4 items. An example item was as follows: "Workplace plan modifications (including telemedicine integration) create considerable inconvenience for me." This dimension demonstrated a high level of reliability with α=.88.

The final dimension, cognitive rigidity, was evaluated using 3 items. A sample item for this dimension was as follows: "I rarely modify my opinions once formed." Initially, the reliability for this dimension was suboptimal, with α=.58. However, after removing one poorly performing item, the reliability increased to an acceptable level, with α=.75.

Each of these scales was carefully selected to provide comprehensive insight into the factors influencing health care professionals' attitudes toward telemedicine and their readiness for its integration into their work environments.

The full scale for measuring RTC showed satisfactory internal consistency (α=.86). The scale used a 6-point response format (1=strongly disagree, 6=strongly agree) for all items.

Perceptions of telemedicine's ease of use were assessed using a 6-item adaptation of Davis [10] PEU scale. On a 7-point Likert continuum (1="strongly disagree," 7="strongly agree"), respondents evaluated statements such as "Acquiring the skills needed to use telemedicine in my workplace would be straightforward for me." The scale demonstrated excellent internal consistency (α=.94). Furthermore, intentions to adopt telemedicine were measured with a 3-item behavioral-intention instrument, also derived from Davis [10]. Using the same 7-point response format, participants indicated their agreement with items like "I plan to incorporate telemedicine into my professional practice within the next year." Reliability for this measure was outstanding (α=.95).

To place these perceptions and intentions in context, a structured demographic questionnaire captured key personal and professional characteristics, including age, gender, highest educational qualification, professional role, years of health care experience, and current employment status within geriatric care.

All instruments were translated from English into Hebrew and back-translated into English, with discrepancies reviewed and resolved to ensure semantic and conceptual equivalence. The instruments were based on previously validated scales; prior to the main data collection, the Hebrew versions were pilot-tested among health care professionals working in governmental geriatric facilities to assess item clarity and cultural appropriateness, while internal consistency was evaluated in the full study sample.

Statistical Analysis

Statistical analyses were performed using the SPSS software (version 28).

Prior to analysis, all questionnaires were screened for missing values at both the item and scale levels, and no missing values were identified on any study variable. This completeness is attributable to the mode of administration: questionnaires were completed in the presence of a trained surveyor, who remained available to clarify any item that respondents found unclear and reviewed each questionnaire for unanswered items upon collection. Accordingly, all 377 cases contributed to every analysis.

Multicollinearity was assessed separately for each moderated mediation model using variance inflation factor (VIF) and tolerance statistics. VIF values below 5 and tolerance values above 0.20 were considered acceptable.

Analytical procedures encompassed descriptive statistical measures, frequency distributions, percentage calculations, internal consistency assessments, and correlation analyses. The research hypotheses were evaluated through PROCESS Model 14 (version 4.3) to examine moderated mediation pathways. Separate moderated mediation analyses were also conducted for each RTC dimension (routine seeking, emotional reactivity, short-term focus, and cognitive rigidity) to examine whether the moderated mediation pattern was consistent across the 4 dimensions. These analytical approaches enabled a comprehensive investigation of the relationships among study variables while accounting for the proposed moderated mediation effects within the theoretical model.

Ethical Considerations

Ethical approval for this investigation was obtained from the Ethics Committee of the School of Health Sciences, Ariel University, under protocol code AU-HEA-GG-20231110 - 1. Study participants received comprehensive information regarding research objectives and were provided with assurances concerning data confidentiality and participant anonymity. Participation remained entirely voluntary, with individuals retaining the right to discontinue involvement at any point without penalty or adverse consequences. All participants provided written informed consent before participation.

Data security protocols were implemented to ensure secure storage, with access restricted exclusively to authorized research personnel. Publication of findings adhered to aggregate reporting standards, eliminating any identifying information pertaining to individual participants or participating health care institutions. These measures ensured full compliance with research ethics standards and participant protection requirements.

Results

The mean age varied across professional groups: physicians (mean 40.66, SD 11.51 y), nurses (mean 42.73, SD 12.86 y), and other multidisciplinary staff (mean 37.25, SD 10.02 y), with nurses being the oldest group on average and multidisciplinary staff being the youngest. For other background characteristics, see Table 1.

XSL•FO

[a]Percentages are calculated within professional groups.

[b]*P*<.01.

[c]*P*<.001.

Table 1 shows that most nurses (n=192, 77.7%) and multidisciplinary staff (n=48, 64.0%) had children, compared to 57.1% (n=24) of the physicians. Religious affiliation varied significantly, with multidisciplinary staff being predominantly Jewish (n=55, 73.3%), while nurses and physicians showed more diversity between Jewish and Muslim affiliations. The majority of nurses worked evening or night shifts (n=205, 84.4%), whereas most physicians (n=28, 59.5%) and particularly multidisciplinary staff (n=69, 93.2%) worked morning shifts.

Multicollinearity diagnostics indicated no problematic multicollinearity across the 5 models, with VIF values ranging from 1.064 to 1.504 and tolerance values ranging from 0.665 to 0.940.

Table 2 shows that telemedicine-related anxiety demonstrated positive correlations with RTC variables, particularly with emotional reactivity (r=0.55; P<.001) and routine seeking (r=0.51; P<.001). Conversely, PEU showed negative correlations with all resistance dimensions except cognitive rigidity, which exhibited a positive correlation (r=0.28; P<.001). The strongest relationship emerged between PEU and intention to use telemedicine (r=0.69; P<.001).

Before evaluating the research hypotheses through PROCESS Model 14 (version 4.3) to examine moderated mediation pathways, all variables were standardized (z scores) to facilitate interpretation. The index of moderated mediation for the indirect association between RTC and intention to use through ease of use was statistically significant (index=0.016, 95% CI 0.003-0.035), supporting the presence of a moderated indirect effect. Table 3 presents a detailed description of all analysis steps.

[c]RTC: resistance to change.

[d]PEU: perceived ease of use.

Table . Moderated mediation model predicting intention to use through ease of use, with anxiety as moderator.

Model components	*B* (SE; 95% CI)	*t* test (*df*)	*P* value
Predicting the mediator: ease of use			
RTC[a]	−0.24 (0.05; −0.34 to −0.14)	−4.72 (375)	<.001
Conditional effects of ease of use on intention at different anxiety levels			
Low	0.7 (0.05; 0.61 to 0.80)	14.4 (372)	<.001
Mean	0.62 (0.04; 0.54 to 0.70)	15.01 (372)	<.001
High	0.56 (0.06; 0.45 to 0.68)	9.58 (372)	<.001
Predicting the dependent variable: intention to use			
Resistance	−0.05 (0.04; −0.14 to 0.04)	−1.05 (372)	.29
Ease of use	0.63 (0.04; 0.55 to 0.71)	15.88 (372)	<.001
Conditional indirect effects at different anxiety levels			
Low	−0.17 (0.05; −0.27 to −0.08)	—[b]	—
Mean	−0.15 (0.04; −0.24 to −0.07)	—	—
High	−0.14 (0.04; −0.22 to −0.06)	—	—

[a]RTC: resistance to change.

[b]Not applicable.

RTC was negatively associated with ease of use (*B*=−0.24, SE=0.05, t_{375}=−4.72; *P*<.001), which in turn was positively associated with intention to use (*B*=0.63, SE =0.04, t_{372}=15.88; *P*<.001). The significance of the mediation effect was estimated using 95% CIs calculated based on 5000 bootstrap samples. Since zero was not included in the CIs at all levels of anxiety, the indirect relationships were significant: anxiety (indirect effect =−0.15, 95% CI −0.236 to −0.072).

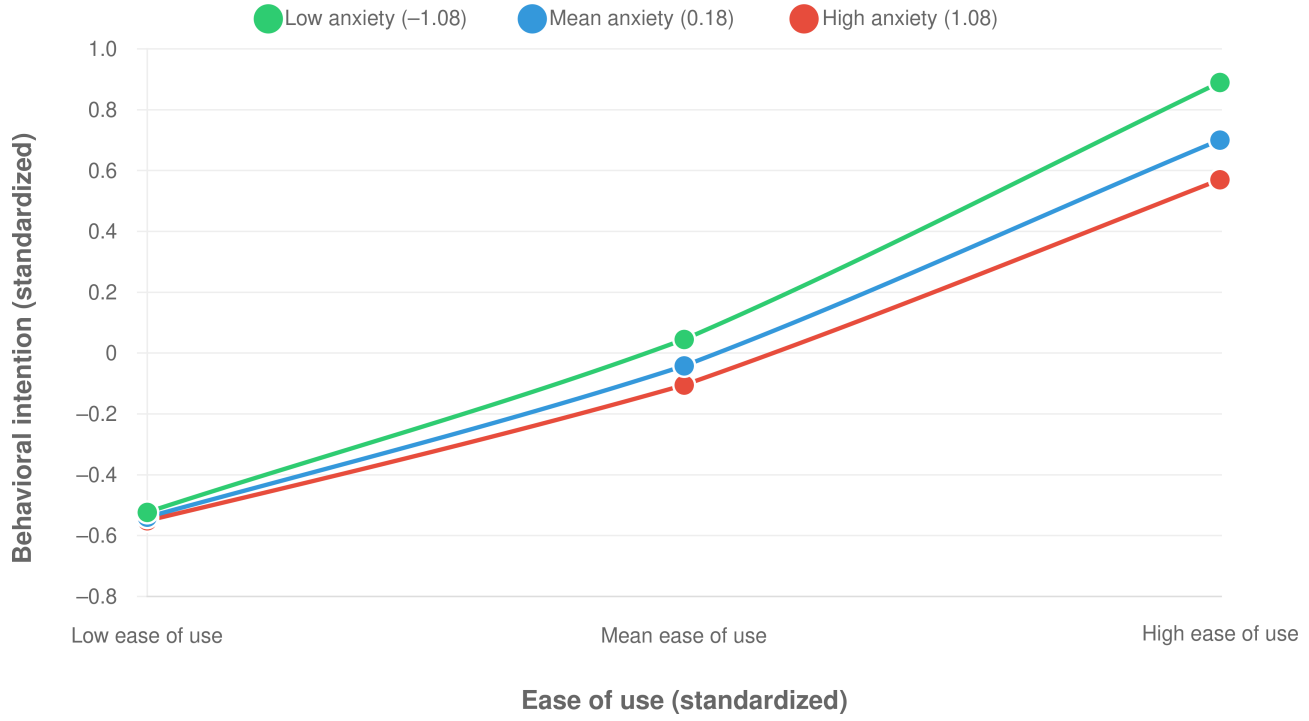
The interaction between ease of use and anxiety was significant (*B*=−0.07, SE=0.03, t_{372}=−1.98; *P*=.04). The decomposition of the interaction into conditional effects of ease of use on intention at different levels of anxiety demonstrates that the positive relationship between ease of use and intention to use weakened as anxiety increased: low anxiety (*B*=0.70, SE=0.05, t_{372}=14.40; *P*<.001), mean anxiety (*B*=0.62, SE=0.04, t_{372}=15.01; *P*<.001), and high anxiety (*B*=0.56, SE=0.06, t_{372}=9.58; *P*<.001).

XSL•FO
RenderX

The conditional indirect relationships show that the negative effect of RTC on intention to use through reduced ease of use weakens as anxiety increases. However, even at high anxiety levels, the indirect relationship remains significant. Therefore, it appears that while anxiety moderates the strength of the indirect effect, it cannot eliminate it entirely.

Figure 1 illustrates how anxiety moderates the relationship between ease of use and intention to use. Three lines represent different levels of anxiety: low (1 SD below the mean), mean, and high (1 SD above the mean). The positive relationship between ease of use and intention to use is the strongest at low anxiety levels (slope =0.70) and weakest at high anxiety levels (slope =0.56), though the relationship remains positive and significant across all anxiety levels. This pattern suggests that while ease of use was consistently associated with intention to use, the magnitude of this association was smaller at higher levels of anxiety.

Figure 1. The moderating effect of anxiety on the relationship between ease of use and intention to use.



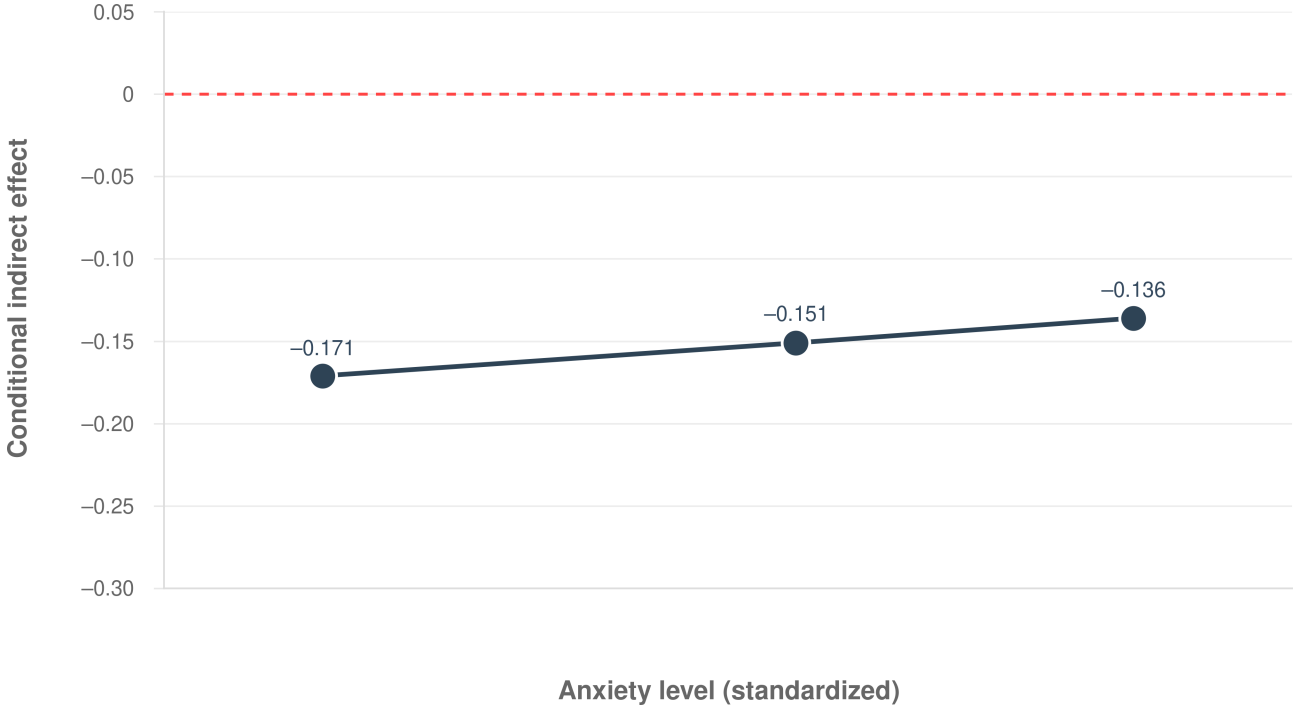


Figure 2 shows that the negative indirect association between RTC and intention to use through ease of use decreases as anxiety increases, from −0.17 at low anxiety to −0.14 at high anxiety. All indirect effects are statistically significant, as indicated by CIs that do not include zero. The pattern demonstrates that while anxiety reduces the indirect effect, it remains significant across all anxiety levels examined.

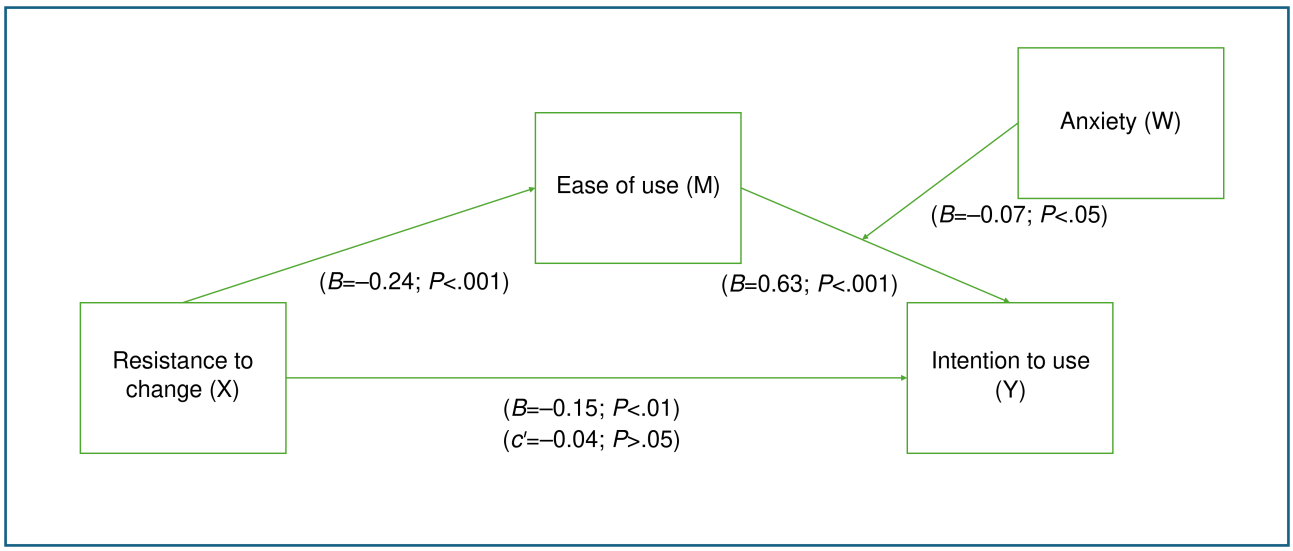
The hypothesized moderated mediation model, in which ease of use mediated the association between RTC and intention to use, with anxiety moderating the association between ease of use and intention to use, is presented in Figure 3.

XSL•FO
RenderX

Figure 2. Conditional indirect effects of resistance to change (RTC) on intention to use through ease of use at different levels of anxiety.



Following the main analysis, each of the 4 dimensions of RTC (routine seeking, emotional reactivity, short-term focus, and cognitive rigidity) was examined separately as an independent variable using Model 14 to test the moderated mediation hypothesis.

The index of moderated mediation for the indirect relationship between routine seeking and intention to use through ease of use, with anxiety as the moderator, was statistically significant (index =0.020, 95% CI 0.003-0.042), supporting the presence of a moderated indirect effect. Table S1 presents a detailed description of all analysis steps in Multimedia Appendix 1.

Routine seeking was negatively associated with ease of use (B=–0.32, SE=0.05, t_{375}=−6.41; P<.001), which in turn was positively associated with intention to use (B=0.62, SE=0.04, t_{372}=15.50; P<.001). The significance of the mediation effect was estimated using 95% CIs calculated based on 5000 bootstrap samples. Since zero was not included in the CIs at all levels of anxiety, the indirect relationships were significant across all anxiety levels.

Figure 3. The research model.

As presented in the results, the interaction between ease of use and anxiety was not significant (B=−0.06, SE=0.03, t_{372}=−1.83; P=.07). Although the simple interaction effect was marginally nonsignificant, Hayes [39] argues that the index of moderated mediation is the more appropriate and sensitive test for detecting moderation in the indirect pathway, as it directly examines moderation of the mediated effect through bootstrap procedures rather than relying on the traditional interaction test which may lack sufficient power to detect subtle moderation effects.

XSL•FO
RenderX

The conditional effects show that ease of use remains positively associated with intention to use across all anxiety levels: low anxiety (B=0.69, SE=0.05, t_{372}=13.84; P<.001), mean anxiety (B=0.61, SE=0.04, t_{372}=14.71; P<.001), and high anxiety (B=0.56, SE=0.06, t_{372}=9.53; P<.001). The conditional indirect relationships show that the negative effect of routine seeking on intention to use through reduced ease of use weakens as anxiety increases: low anxiety (indirect effect =−0.22, 95% CI −0.30 to −0.15), mean anxiety (indirect effect=−0.20, 95% CI −0.27 to −0.13), and high anxiety (indirect effect=−0.18, 95% CI −0.26 to −0.11). All indirect effects remained statistically significant across anxiety levels, indicating that while anxiety moderates the strength of the indirect effect, it cannot eliminate it entirely.

The index of moderated mediation for the indirect relationship between emotional reactivity and intention to use through ease of use, with anxiety as the moderator, was statistically significant (index=0.019, 95% CI 0.003-0.040), supporting the presence of a moderated indirect effect. Table 4 presents a detailed description of all analysis steps.

Table . Moderated mediation model predicting intention to use through ease of use, with anxiety as moderator.

Model component	*B* (SE; 95% CI)	*t* test (*df*)	*P* value
Predicting the mediator: ease of use			
Emotional reactivity	−0.27 (0.05; −0.38 to −0.17)	−5.38 (375)	<.001
Predicting the dependent variable: intention to use			
Emotional reactivity	0.003 (0.05; −0.09 to 0.09)	.06 (372)	.95
Ease of use	0.64 (0.04; 0.56 to 0.71)	15.87 (372)	.001
Anxiety	−0.10 (0.05; −0.19 to −0.01)	−2.09 (372)	.03
Ease of use × anxiety	−0.07 (0.03; −0.14 to −0.004)	−2.08 (372)	.03
Conditional effects of ease of use on intention at different anxiety levels			
Low	0.71 (0.05; 0.62 to 0.81)	14.51 (372)	<.001
Mean	0.62 (0.04; 0.54 to 0.71)	15.00 (372)	<.001
High	0.56 (0.06; 0.45 to 0.68)	9.55 (372)	<.001
Conditional indirect effects at different anxiety levels			
Low	−0.20 (0.05; −0.29 to −0.11)	—[a]	—
Mean	−0.17 (0.04; −0.26 to −0.09)	—	—
High	−0.15 (0.04; −0.24 to −0.08)	—	—

[a]Not applicable.

Emotional reactivity was negatively associated with ease of use (B=−0.27, SE=0.05, t_{375}=−5.38; P<.001), which in turn was positively associated with intention to use (B=0.64, SE=0.04, t_{372}=15.87; P<.001). The significance of the mediation effect was estimated using 95% CIs calculated based on 5000 bootstrap samples. Since zero was not included in the CIs at all levels of anxiety, the indirect relationships were significant across all anxiety levels.

The interaction between ease of use and anxiety was significant (B=−0.07, SE=0.03, t_{372}=−2.08; P=.04). The conditional effects show that ease of use remains positively associated with intention to use across all anxiety levels: low anxiety (B=0.71, SE=0.05, t_{372}=14.51; P<.001), mean anxiety (B=0.62, SE=0.04, t_{372}=15.00; P<.001), and high anxiety (B=0.56, SE=0.06, t_{372}=9.55; P<.001).

The conditional indirect relationships show that the negative effect of emotional reactivity on intention to use through reduced ease of use weakens as anxiety increases: low anxiety (indirect effect=−0.20, 95% CI −0.29 to −0.11), mean anxiety (indirect effect=−0.17, 95% CI −0.26 to −0.09), and high anxiety (indirect effect=−0.15, 95% CI −0.24 to −.08). All indirect effects remained statistically significant across anxiety levels, indicating that while anxiety moderates the strength of the indirect effect, it cannot eliminate it entirely.

The index of moderated mediation for the indirect relationship between short-term focus and intention to use through ease of use, with anxiety as the moderator, was statistically significant (index=0.021, 95% CI 0.004-0.044), supporting the presence of a moderated indirect effect. Table S2 in Multimedia Appendix 1 presents a detailed description of all analysis steps.

Short-term focus was negatively associated with ease of use (B=−0.30, SE=0.05, t_{375}=−5.86; P<.001), which in turn was positively associated with intention to use (B=0.64, SE=0.04, t_{372}=15.80; P<.001). The significance of the mediation effect was estimated using 95% CIs calculated based on 5000 bootstrap samples. Since zero was not included in the CIs at all levels of anxiety, the indirect relationships were significant across all anxiety levels.

The interaction between ease of use and anxiety was significant (B=−0.07, SE=0.03, t_{372}=−2.07; P=.04). The conditional effects show that ease of use remains positively associated with intention to use across all anxiety levels: low anxiety (B=0.71,

XSL•FO
RenderX

SE=0.05, t_{372}=14.24; P<.001), mean anxiety (B=0.62, SE=0.04, t_{372}=14.96; P<.001), and high anxiety (B=0.56, SE=0.06, t_{372}=9.56; P<.001). The conditional indirect relationships show that the negative effect of short-term focus on intention to use through reduced ease of use weakens as anxiety increases: low anxiety (indirect effect=−0.21, 95% CI −0.31 to −0.12), mean anxiety (indirect effect=−0.18, 95% CI −0.27 to −0.10), and high anxiety (indirect effect=−0.17, 95% CI −0.25 to −0.09). All indirect effects remained statistically significant across anxiety levels, indicating that while anxiety moderates the strength of the indirect effect, it cannot eliminate it entirely.

The index of moderated mediation for the indirect relationship between cognitive rigidity and intention to use through ease of use, with anxiety as the moderator, was statistically significant (index=−0.020, 95% CI −0.043 to −0.004), supporting the presence of a moderated indirect effect. Table 5 presents a detailed description of all analysis steps.

Table . Moderated mediation model predicting intention to use through ease of use, with anxiety as moderator.

Model component	*B* (SE; 95% CI)	*t* test (*df*)	*P* value
Predicting the mediator: ease of use			
Cognitive rigidity	0.27 (0.05; 0.17 to 0.37)	5.27 (375)	<.001
Predicting the dependent variable: intention to use			
Cognitive rigidity	−0.07 (0.04; −0.15 to 0.01)	−1.71 (372)	.08
Ease of use	0.66 (0.04; 0.58 to 0.74)	15.82 (372)	<.001
Anxiety	−0.08 (0.04; −0.16 to −0.0004)	−1.98 (372)	.04
Ease of use × anxiety	−0.08 (0.03; −0.14 to −0.01)	−2.24 (372)	.02
Conditional effects of ease of use on intention at different anxiety levels			
Low	0.74 (0.05; 0.64 to 0.84)	14.48 (372)	<.001
Mean	0.64 (0.04; 0.56 to 0.73)	15.02 (372)	<.001
High	0.58 (0.06; 0.46 to 0.69)	9.75 (372)	<.001
Conditional indirect effects at different anxiety levels			
Low	0.20 (0.04; 0.12 to 0.28)	—[a]	—
Mean	0.17 (0.04; 0.10 to 0.25)	—	—
High	0.16 (0.04; 0.09 to 0.23)	—	—

[a]Not applicable.

Cognitive rigidity was positively associated with ease of use (B=0.27, SE=0.05, t_{375}=5.27; P<.001), which in turn was positively associated with intention to use (B=0.66, SE=0.04, t_{372}=15.82; P<.001). The significance of the mediation effect was estimated using 95% CIs calculated based on 5000 bootstrap samples. Since zero was not included in the CIs at all levels of anxiety, the indirect relationships were significant across all anxiety levels.

The interaction between ease of use and anxiety was significant (B=–0.08, SE=0.03, t_{372}=–2.24; P=.02). The conditional effects show that ease of use remains positively associated with intention to use across all anxiety levels: low anxiety (B=0.74, SE=0.05, t_{372}=14.48; P<.001), mean anxiety (B=0.64, SE=0.04, t_{372}=15.02; P<.001), and high anxiety (B=0.58, SE=0.06, t_{372}=9.75; P<.001). The conditional indirect relationships show that the positive effect of cognitive rigidity on intention to use through increased ease of use weakens as anxiety increases: low anxiety (indirect effect=0.20, 95% CI 0.12-0.28), mean anxiety (indirect effect=0.17, 95% CI 0.10-0.25), and high anxiety (indirect effect=0.16, 95% CI 0.09-0.23). All indirect effects remained statistically significant across anxiety levels, indicating that while anxiety moderates the strength of the indirect effect, it cannot eliminate it entirely.

Discussion

Principal Findings

The results of the moderated-mediation analyses fit the proposed model: caregivers with stronger dispositional RTC reported weaker intention to use telemedicine, and this link was explained mainly by their lower ease of use. The indirect link was weaker when telemedicine-related anxiety was higher, but it stayed statistically significant across the whole range of anxiety observed. Since the data were collected at 1 point in time and rely on self-report, these findings describe associations and not proven cause and effect. The overall indirect effect of RTC remained negative and statistically significant across all anxiety levels. This profile dovetails with provider-side applications of the TAM, in which PEU has consistently been found to mediate associations between inhibiting traits and usage intentions among nurses, physicians, and allied professionals [40,41].

The buffering role of anxiety accords with hospital studies in which technology-related anxieties were associated with a weaker link between usability perceptions and usage intentions. Kummer et al [33], for example, found that anxieties about a sensor-based medication system suppressed the PEU-intention link among ward staff; our data show a comparable attenuation

XSL•FO
RenderX

and are consistent with PEU operating as a mediator even among highly apprehensive users. These findings add to recent TAM extensions by showing that RTC was associated with intention mainly through PEU and that the pattern differed across RTC dimensions. Routine seeking, emotional reactivity, and short-term focus followed the expected negative pathway, whereas cognitive rigidity did not. This suggests that resistance should not be treated as a single, uniform barrier in technology-acceptance models. Telemedicine-related anxiety changed the strength of the PEU-intention association but did not remove it, supporting its role as a boundary condition of the indirect pathway.

The dimension-specific results provide further detail. Routine seeking produced the largest conditional indirect effect, dropping from –0.22 at low anxiety to –0.18 at high anxiety. It is noteworthy that while the simple interaction effect for routine seeking was marginally nonsignificant, the index of moderated mediation remained significant, consistent with Hayes' [39] argument that the bootstrap-based index provides a more sensitive test for detecting moderation in indirect pathways. Prior evidence from electronic-record roll-outs shows that clinicians who prize habitual workflows are especially sensitive to any additional cognitive effort a new system entails, consistent with our finding that PEU accounted for much of the association in this group [40].

Emotional reactivity and short-term focus followed the same gradient, falling from –0.20 to –0.15 and from –0.21 to –0.17, respectively. Both dimensions capture immediate affective or workload costs, which inflate perceived difficulty during the early learning curve and thus translate into lower intention to use. Reports of caregivers abandoning teleconsultation platforms after initial frustration with interface complexity mirror this mechanism [42].

Unlike the other RTC dimensions, cognitive rigidity was positively associated with PEU (B=0.27), and the corresponding indirect association with intention to use decreased from 0.20 at low anxiety to 0.16 at high anxiety. This direction was contrary to H1 and to the usual interpretation of cognitive rigidity as a barrier to change [13]. The result should therefore be treated with caution. One possible explanation is that some telemedicine procedures follow fixed and rule-based steps that may appear straightforward to professionals who prefer structured working methods. However, the present study did not assess task-technology fit or preferences for structured workflows, and the study by Cady and Finkelstein [34] did not examine cognitive rigidity directly. The finding may also reflect characteristics of the present sample or the modified cognitive rigidity subscale. It does not show that cognitive rigidity facilitates telemedicine use and should be replicated in other samples [34]. Across the RTC dimensions, the PEU × telemedicine-related anxiety interaction was statistically significant in the emotional reactivity, short-term focus, and cognitive rigidity models, but not in the routine-seeking model. The conditional indirect associations nevertheless remained statistically significant at all examined anxiety levels. This suggests that PEU may remain relevant even among professionals reporting higher telemedicine-related anxiety. Routine seeking, emotional reactivity, and short-term focus were associated with negative indirect pathways of different magnitudes. These findings may inform future intervention research, but the present study did not evaluate any tailored strategy or its effectiveness. Because the cognitive rigidity finding was unexpected, no specific practical recommendation should be based on it at this stage.

Limitations and Future Research

The findings need to be interpreted in light of several limitations. Because the data were collected at 1 time point, the temporal order of RTC, PEU, telemedicine-related anxiety, and intention to use cannot be established. The indirect associations identified in the PROCESS analyses therefore do not demonstrate causal pathways. Longitudinal research conducted before and after telemedicine implementation would help clarify how these relationships develop over time.

All variables were measured by self-report in the same questionnaire. The results may therefore have been affected by common method bias, shared measurement variance, or socially desirable responding. The study also examined intention to use telemedicine rather than actual use. Future research could combine questionnaires with system logs or administrative records.

Participants were recruited from 4 governmental GMCs within 1 national health system, and the final sample represented 31.8% (n=377) of the eligible workforce. Although staff were approached across departments and work shifts, participation was voluntary, and those who participated may have differed from those who did not. The findings may therefore not apply to other health care settings, countries, professional groups, or telemedicine systems. In addition, telemedicine use in the participating centers was limited, optional, and mainly related to remote patient monitoring. The questionnaire did not distinguish among specific telemedicine modalities or interaction structures, so modality-specific analyses could not be conducted. The findings should therefore be interpreted primarily in relation to this context. Future studies should examine whether the observed associations differ across audio-only, video-based, remote-monitoring, and hybrid models and between dyadic and triadic interactions.

The positive association found for cognitive rigidity also requires caution. One item was removed from this subscale, and the direction of the result was contrary to the original hypothesis. This finding should be examined again in other samples and with additional assessment of cognitive rigidity.

Conclusions

This study indicates that clinicians' RTC was associated with weaker intention to use telemedicine, an association statistically accounted for by lower ease of use, and that this indirect association was smaller at higher levels of telemedicine-related anxiety while remaining significant throughout the observed range (−0.17 at low anxiety vs −0.14 at high). Routine seeking, emotional reactivity, and short-term focus were each associated with the negative pathway. Cognitive rigidity showed an unexpected positive association with PEU and a positive indirect association with intention to use. This finding should be treated as preliminary and replicated before practical implications are

XSL•FO
RenderX

drawn from it. The findings extend dual-factor approaches to technology acceptance by showing that RTC dimensions did not follow a uniform pattern and that telemedicine-related anxiety conditioned the indirect association between RTC and intention to use through PEU. The findings suggest that RTC and PEU may warrant consideration when developing strategies to support telemedicine use intentions in geriatric practice.

Acknowledgments

We wish to express our deep appreciation and gratitude to the following medical centers for their significant contribution to data collection for this research: G. Mendelsson, MD, manager of Dorot Medical Center & Staff; Inna Shugaev, MD, manager of Fliman Medical Center & Staff; Nadya Kahansky, MD, manager of Shmuel Harofeh Medical Center & Staff; and Yehonatan Hershkovits, Fliman Medical Center.

During the preparation of this manuscript, the authors used ChatGPT by OpenAI and DeepL solely for translation support and language editing, including clarity and readability checks. These tools were not used to generate scholarly content, data, analyses, interpretations, references, or conclusions. The English wording was also reviewed by a native English-speaking academic collaborator. The authors reviewed and edited all outputs and take full responsibility for the final manuscript.

Abstract

Background: Contact-based interventions, where individuals share their lived experiences of mental health difficulties and recovery, appear effective in reducing stigma.

Objective: This study examined the effectiveness of a brief digitized contact-based intervention in reducing mental health stigma and improving help-seeking intentions in young adults. The study also sought a deeper understanding of the perspectives of young adults toward the contact-based intervention.

Methods: A mixed methods study, using quantitative and qualitative analyses, examined mental health public stigma, self-stigma, and help-seeking attitudes in undergraduate psychology students (N=328) before, immediately after, and 1 week following the contact-based intervention, compared to an active control. The intervention comprised a brief video (8 min) of a mental health consumer sharing their lived experience of mental health difficulties and their recovery. Participants were invited to participate in a subsequent semistructured interview (n=12) that further explored their perspectives on the contact-based intervention.

Results: Relative to control participants, those in the intervention group reported small improvements in mental health public stigma and help-seeking intentions using formal sources of help; however, this was not maintained at 1-week follow-up. There was limited evidence that the intervention improved self-stigma or help-seeking intentions using informal sources of help. Improvements in self-stigma were not evident following the intervention, but were observed 1 week later. Additional exploratory analyses showed that participants with high mental distress were more likely to provide negative evaluations of the intervention in terms of the helpfulness of the videos, relatability to the speaker, and showed a decrease in their desire to seek help from friends and family following the videos, compared to those with low mental health distress.

Conclusions: Although this brief digitized contact-based intervention holds promise as an easily disseminated strategy for young adults to reduce mental health public stigma and improve formal help-seeking intentions, these effects show that overall improvements in public stigma and formal help-seeking intentions were short-lived. Furthermore, the potential negative impact of the intervention on informal help-seeking intentions in those with high mental health distress suggests a need to tailor interventions for young adults with high levels of anxiety or depression. The study has important implications for designing brief contact-based interventions and what young adults would benefit from the most over time.

Introduction

Background

Mental health stigma is a significant deterrent to individuals with mental disorders from seeking help through health services [1]. Both public stigma (negative attitudes and stereotypes toward others or groups) and self-stigma (internalized negative attitudes) have a negative impact on help-seeking behaviors and appear to disproportionately impact youth [2]. Stigma is a key barrier to help-seeking behavior, indirectly contributing to the maintenance of untreated mental health difficulties and associated economic and social costs.

XSL•FO
RenderX

Contact-based interventions are one of the most effective strategies for improving mental health stigma [3,4]. Contact-based interventions involve either direct or indirect interaction with an individual from the respective marginalized group to allow opportunity for the disconfirmation of stereotypes and subsequent reduction of prejudicial attitudes [5]. These interventions were derived from Allport's [6] theory of intergroup contact, based on the premise that interaction of a positive nature between individuals of majority and minority groups works to reduce prejudices. The aim of these interventions is to reduce prejudicial beliefs and attitudes through interpersonal contact, which typically involves an individual with lived experience of mental health difficulties sharing and discussing their personal experience. Contact-based interventions can involve varying degrees of interpersonal engagement and activate different psychological mechanisms for attitude change. When evaluating randomized controlled trials, Corrigan and colleagues [5] found that contact-based interventions delivered a small-to-moderate reduction in stigma and were better than education interventions for reducing stigma in adults. Further meta-analyses found pure contact-based interventions to be comparable in their effectiveness with combined contact and education interventions [7], although there is some question about the long-term maintenance of effects [8].

The effectiveness of contact-based interventions does not appear to differ across modalities, such as face-to-face or video. With the increasing accessibility of technology, the growing popularity of telehealth, online services, and immersive technologies, such as virtual reality in the psychological and medical fields, there is a rising interest in the efficacy of scalable, easily implementable digital stigma reduction interventions that are capable of reaching broad audiences. Several studies have found that when compared to live contact-based interventions, interventions consisting of video interpersonal contact have proven to be just as efficacious [7,8]. A review by Janoušková and colleagues [9] showed that video interventions for young adults, which included social contact, were comparable to or better than traditional modalities for improving stigma. However, most studies focused on evaluating the effectiveness of contact-based interventions in addressing public stigma, with few studies on self-stigma, highlighting a gap in the literature [10]. In a young adult sample, one study of a prolonged intervention comprising five 2-hour workshops found that contact significantly improved self-stigma [11]. However, little is known about the effectiveness of brief, more easily disseminated interventions on self-stigma for this population. Given the role of both public and self-stigma in mitigating help-seeking behavior, these factors are crucial to appropriately evaluate and develop antistigma programs, with further research needed on the optimal duration of the intervention and effectiveness of brief interventions.

Few studies have investigated improvements to help-seeking following contact, beyond stigma improvement [12]. Encouragingly, recent studies targeting young adults have found improvements in help-seeking intentions following pure video contact and combined contact and education interventions [13,14]. Factors such as openness to seeking help and increased mental health literacy have improved help-seeking intentions and attitudes in young adults. Moreover, mental health stigma research has predominantly focused on stigma toward more severe psychiatric illnesses. For example, individuals with schizophrenia are often stigmatized and perceived as dangerous, unstable, or unpredictable, with lower likelihood of recovering from their disorder [15]. Research focused on more common mental health difficulties, such as anxiety and depression, is limited, despite being the leading cause of mental health burden in young people [16]. In a recent review, Curcio and Corboy [17] indicated that individuals with mood or anxiety disorders are perceived differently, with stigma relating to perceptions around fault and responsibility [18]. Thus, the nature and intensity of mental health stigma can differ across mental disorders and further research on contact-based interventions that target common mental health difficulties, such as anxiety and depression, is needed.

A further critical gap in the literature concerns the evaluation of moderating variables that may enhance the effectiveness of interventions. Some studies have found participant variables such as age, gender, and ethnicity to moderate the effectiveness of contact interventions [19]. Contact theory stipulates that similarity and equality between the individual of the stigmatized group and the majority group member maximizes the applicability and credibility of the intervention and resulting efficacy [20]. Indeed, Kruger and colleagues [13] found that tailoring contact intervention videos to college students by using individuals who were college students themselves increased help-seeking intentions, while the generic contact intervention did not.

Another factor to consider when tailoring contact-based interventions is an individual's previous or current experiences with mental health difficulties, which can impact subsequent help-seeking behaviors. Brennan and McGrew [21] found differences in how mental health consumers and nonconsumers perceived a contact-based intervention, with nonconsumers significantly more likely to find the intervention educational, endorse feelings of encouragement, and express beliefs that recovery is possible. Further, Clement et al [1] reported that when discussing mental health stigma, individuals with previous mental health difficulties were more likely to report feelings of shame and embarrassment and less likely to report weakness or social rejection, compared to those without previous mental health difficulties. Cerully and colleagues [22] reported that while contact-based interventions are effective for those with and without personal experiences of mental health difficulties, they are less effective for those with prior personal experiences. Thus, there is currently a gap in the literature with few studies investigating how individual characteristics, such as previous or current mental health difficulties, may impact the efficacy of the intervention.

This Study

The batyr@uni program, run by the mental health organization batyr, is a contact-based intervention aimed at reducing general mental health stigma and increasing help-seeking for university students. The intervention is delivered to university students as well as to schools, with a focus on common mental health

XSL•FO
RenderX

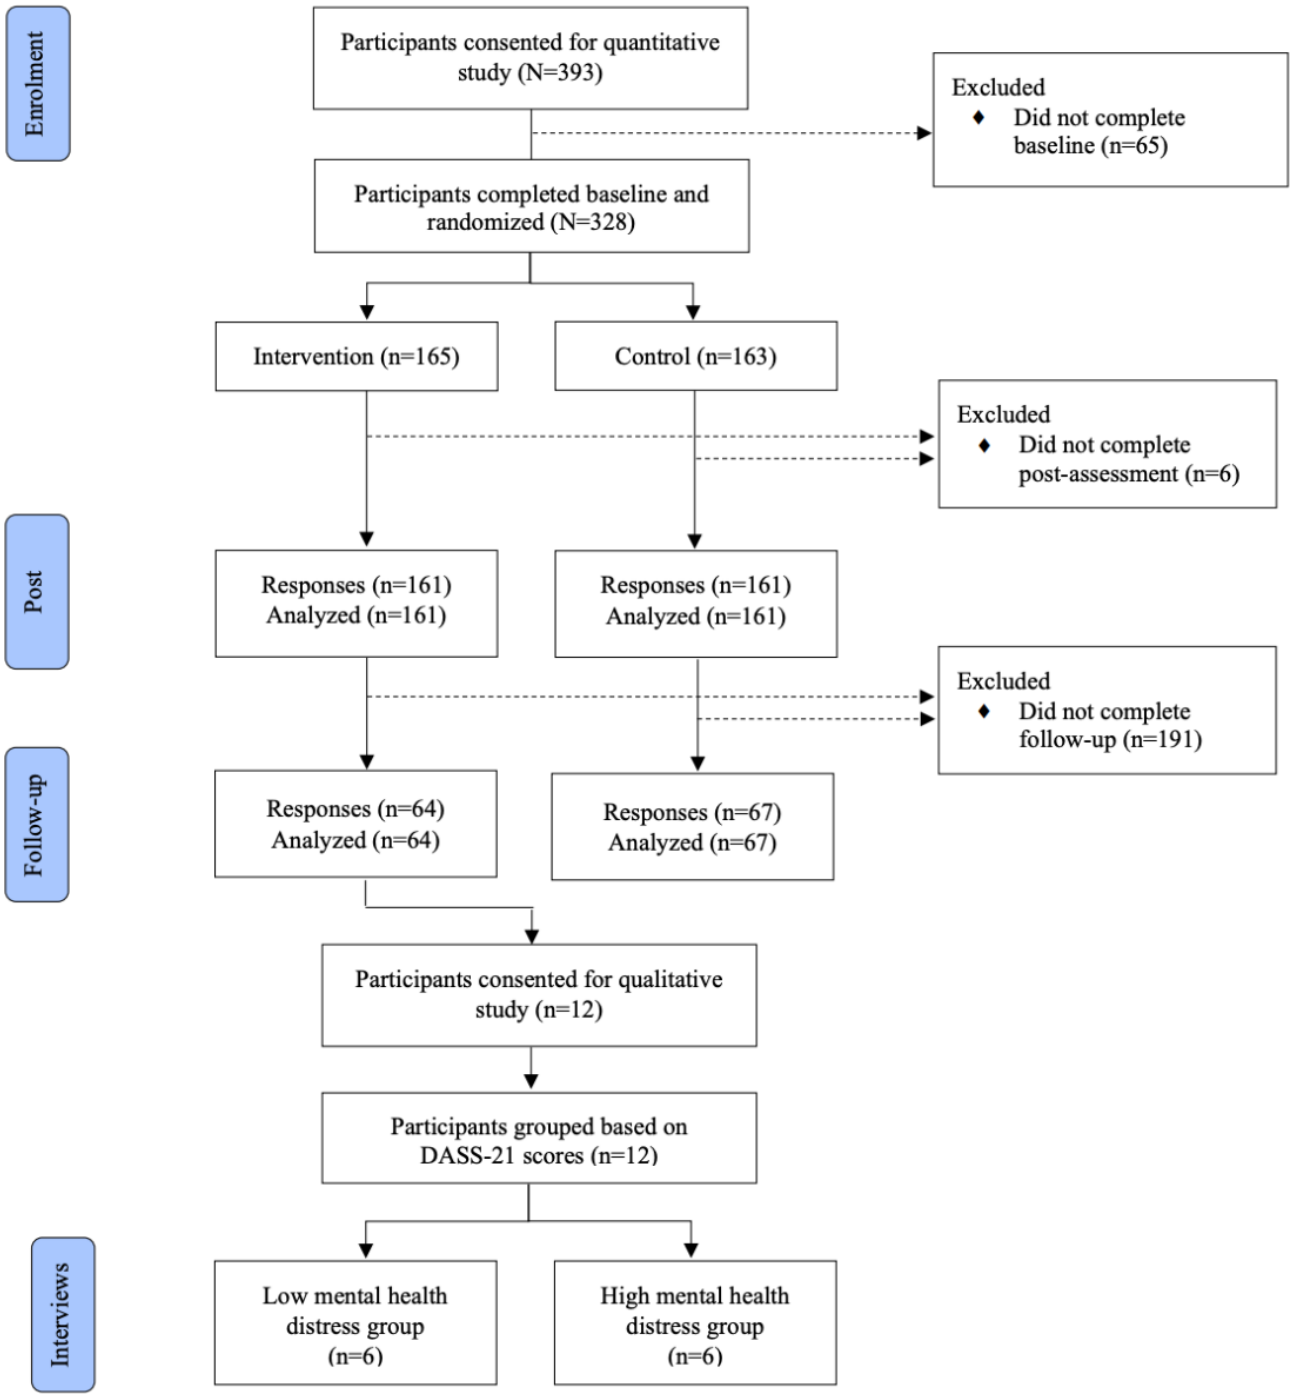
difficulties such as anxiety and depression. The batyr@uni program (60 - 90 min in duration) can be delivered face-to-face or online and focuses on sharing the lived experience stories of individuals with mental health difficulties and their subsequent recovery via help-seeking. The lived experience stories (delivered live or through brief digital videos) provide valuable insights into how young adults can support their peers, strategies, and self-care practices to maintain good mental health, help identify signs and symptoms of mental ill health, and access support. The program involves young people from diverse backgrounds (eg, age, gender, and geographical context) and experiences to optimize relatability to audience members. During the COVID-19 pandemic, the batyr@uni program transitioned from traditional face-to-face to online video delivery.

The aim of this study was to quantitatively examine the effectiveness of one component of the digitized contact-based intervention (ie, an 8-min video of lived experience stories targeting anxiety and depression) in reducing mental health stigma and improving help-seeking intentions in young adults. We also used a qualitative approach to provide a deeper understanding of young adults' perspectives on the brief contact-based intervention. Further, the study aimed to identify potential differences in whether young adults experiencing high or low mental health distress respond differently to the intervention.

Based on previous literature, it was hypothesized that those in the intervention group would experience greater reduction in both public and self-stigma, and greater improvements in help-seeking intentions (using formal and informal sources of help), relative to the active control group, and that these effects would be maintained at 1-week follow-up. In addition, it was hypothesized that individuals experiencing high mental health distress would perceive mental health stigma differently and find the intervention more beneficial, compared to individuals with low mental health distress. For the qualitative data, we used reflexive thematic analysis to identify themes around participants' perceptions of the intervention [23].

Methods

Participants



Participants were undergraduate psychology students (N=328) aged 17 to 24 (mean 18.95, SD 1.61) years. The majority of participants were female (269/328, 82%) and self-identified their ethnicity as Caucasian (173/328, 52.7%), Asian (77/328, 23.5%), self-identified (35/328, 10.7%), Middle Eastern (31/328, 9.5%), African (6/328, 1.8%), Hispanic (5/328, 1.5%), and Aboriginal and/or Torres Strait Islander (5/328, 1.5%). From this larger sample, 12 participants volunteered to participate in a subsequent qualitative study. These participants were aged 18 to 24 (mean 20.75, SD 2.70) years, and 5 identified as male, 5 as female, and 2 reported their gender as "Self-identified." Half of the participants identified as Caucasian (n=6) and half as Asian (n=6). Participants were recruited via a university research portal and received course credit in return for their participation. The study was advertised to first-year psychology undergraduate students through the university research portal and was conducted online via the LimeSurvey platform (LimeSurvey GmbH). A G-Power analysis was used to determine adequate sample size (power=.95, Cohen*d*=0.25, and α=.05).

Study Design

Quantitative data were collected at 3 time points (baseline, postintervention, and 1-wk follow-up) to evaluate the effectiveness of a brief digitized contact-based intervention (one component of the batyr@uni program) in reducing mental health stigma and improving help-seeking intentions in young adults. In addition, participants were invited to participate in a subsequent qualitative study comprising a semistructured interview relating to their perspectives and attitudes about the contact-based intervention. This mixed methods study used both a quantitative and qualitative approach to provide a deeper insight into mental health stigma in young adults (refer to Figure 1 for study flow).

Ethical Considerations

This study was approved by the Macquarie University Human Research Ethics Committee (reference no. 52021904124875). As the authors changed institutions after data collection, but before analysis could be completed, the study was also reviewed and approved by the University of New South Wales Research Ethics and Compliance Committee (reference no. iRECS7757). This study was not initially defined as a clinical trial by the Macquarie University Human Research Ethics Committee as participants were randomly allocated to receive 2 educational videos designed to change attitudes rather than biomedical or health outcomes. As a result, the study was not preregistered as a clinical trial. However, following the University of New South Wales' broader definition of a clinical trial, the study was retrospectively registered with the International Standard Randomized Controlled Trial Registry (reference no. ISRCTN65081246). Informed consent was obtained from all participants prior to participation, with the right to withdraw at any time. Participant privacy and confidentiality were maintained through deidentification of data, and participants received course credit in return for their participation.

XSL•FO
RenderX

Quantitative Study

Intervention

Participants allocated to the intervention group viewed 1 of 4 videos (8 min) of a mental health consumer sharing their lived experience of mental health difficulties, specifically relating to anxiety and depression, and their recovery. The videos provided by batyr are being delivered as part of their mental health stigma intervention, the batyr@uni program, and included a short prerecorded debrief by a batyr representative who emphasized key themes. To increase diversity of the speakers across the control and the intervention group, 4 versions of the video were used, varying the gender and perceived racial appearance of the speaker: a female speaker with a White racial appearance, a male speaker with a White racial appearance, a female speaker with a non-White racial appearance, and a male speaker with a non-White racial appearance. Racial characteristics were coded based on visual appearance only; speakers did not self-report race or ethnicity. All speakers were young adults, approximately matching the age range of the study population. Participants were randomly allocated to watch 1 of the 4 videos.

Active Control

Participants in the control group viewed 1 video (8 min) of an individual speaking about the benefits of healthy eating. The information on healthy eating was adapted from an Australian Government resource (Australian National Health and Medical Research Council, 2013), and all videos followed the same script. The individual speaker in the video for the active control group was matched with the video in the intervention group in terms of approximate age, gender, and ethnicity.

Qualitative Study

Participants were eligible to participate in the qualitative study if they had previously completed the quantitative study and were allocated to the intervention group. Participants in the intervention group were provided with an opportunity to express their interest in participating in an interview to discuss their perspectives on the brief contact-based intervention.

Measures

Demographics

Demographics such as age, gender, ethnicity, and whether participants identified as Aboriginal or Torres Strait Islander are reported in Table 1.

Table . Demographic characteristics of participants at baseline.

Variable	Intervention	Control	Total
Age, mean (SD; range)	18.91 (1.51; 17-24)	18.96 (1.67; 17-24)	18.95 (1.61; 17-24)
Sex, n (%)			
Female	143 (43.6)	126 (38.4)	269 (82)
Male	19 (5.8)	33 (10.1)	52 (15.9)
Do not want to say	3 (0.9)	0 (0)	3 (0.9)
Self-identified	0 (0)	4 (1.2)	4 (1.2)
Ethnicity, n (%)			
Caucasian	92 (28)	81 (24.7)	173 (52.7)
Asian	35 (10.7)	42 (12.8)	77 (23.5)
Self-identified	18 (5.5)	17 (5.2)	35 (10.7)
Middle Eastern	14 (4.3)	17 (5.2)	31 (9.5)
African	3 (0.9)	3 (0.9)	6 (1.8)
Hispanic	2 (0.6)	3 (0.9)	5 (1.5)
Don’t want to say	1 (0.3)	0 (0)	1 (0.3)
Aboriginal and/or Torres Strait Islander, n (%)			
No	162 (49.4)	160 (48.8)	322 (98.2)
Yes	3 (0.9)	2 (0.6)	5 (1.5)
Don’t want to say	0 (0)	1 (0.3)	1 (0.3)

Public Stigma

Mental health stigma was measured with a modified version of the Generalized Anxiety Stigma Scale (GASS)—Personal Stigma Subscale. This 10-item scale measures public stigma related to anxiety [24] and was adapted in this study to measure general mental health stigma. To achieve this, the word “anxiety” in each item was replaced with “mental health problems” to create a new Mental Health Stigma Scale (MHSS).

Participants rated each item on a 5-point scale ranging from strongly disagree to strongly agree. The total score is the sum of all items, with higher scores indicative of greater stigma toward mental health. This measure has demonstrated good internal consistency, test-retest reliability, and validity in adults

XSL•FO
RenderX

[24,25] and young adults [26]. In this study, the modified MHSS showed good reliability across time points (Cronbach α=0.84, 0.89, and 0.89) and high correlations with the GASS at each time point (ranging from *r*=0.80 to 0.90).

Self-Stigma

The Self-Stigma of Mental Illness Scale (SSOMI) measured internalized stigma of mental illness [27]. Participants rated 10 items on a 5-point scale ranging from strongly disagree to strongly agree. Items are summed to derive a total score, with higher scores indicative of greater self-stigma of mental illness. As the SSOMI uses future-tense language (ie, "I would feel..."), the questionnaire could be used with individuals who do not currently have clinical levels of a mental health diagnosis, and as a result, this is best considered as anticipated self-stigma. The SSOMI has good internal consistency, test-retest reliability, and validity in young adults [27,28]. The SSOMI in this study showed good reliability across time points (Cronbach α=0.81, 0.82, and 0.87).

Help-Seeking Intentions

The General Help-Seeking Questionnaire (GHSQ) assesses intentions to seek help [29]. Participants were asked, "if you were having a personal or emotional problem, how likely is it that you would seek help from each of the following sources?" Participants indicated how likely, on a 7-point scale (extremely unlikely to extremely likely), they would seek help from each source. The GHSQ contains two subscales: (1) mean intentions to seek formal sources of help (ie, mental health professional, phone helpline, family doctor or general practitioner [GP], and teacher or tutor) and (2) mean intentions to seek informal sources of help (ie, partner, friend, parent, relative, or family member). Higher scores indicated greater help-seeking intentions. The GHSQ has demonstrated good internal consistency, test-retest reliability, and validity in young adults [30]. In this study, the formal subscale yielded good reliability (Cronbach α=0.80, 0.81, and 0.80), while the informal subscale demonstrated low reliability (Cronbach α=0.51, 0.55, and 0.55).

Mental Health Distress

The Depression, Anxiety, and Stress Scale - Short Form (DASS-21) is a 21-item self-report measure that assesses depressive, anxious, and stress-related symptoms [31]. Participants rated each item on a 4-point scale (ie, never, sometimes, often, and almost always), indicating the extent to which each item applied to them over the past week. Total scores were summed into 3 subscales (depression, anxiety, and stress), with higher scores indicating greater distress; categorized into normal, mild, moderate, severe, and extremely severe based on the DASS manual. The DASS-21 has consistently demonstrated good reliability [25,32] and excellent internal reliability in this study (Cronbach α=0.95).

Procedure

Prior to the study, participants were provided with participant information and consent forms that included details about the quantitative study. Once informed consent was obtained, participants completed demographic questions (age, gender, and ethnicity) and baseline assessments (public stigma, self-stigma, help-seeking intentions, and current levels of mental health distress). Participants were then randomly allocated to an intervention group (ie, brief digitized contact-based intervention video) or an active control group (ie, healthy eating video) through random number generation implemented in the LimeSurvey platform. After viewing the full video, participants completed assessments immediately after the video and at 1-week follow-up.

After completing the quantitative study, participants had an opportunity to participate in a qualitative study involving an interview relating to their perspectives and attitudes about the intervention. Participants completed individual semistructured interviews with a researcher through Zoom (Zoom Communications, Inc). Each participant was asked the same open-ended questions relating to their previous relevant experiences, help-seeking attitudes, perspectives on the contact-based intervention, and thoughts about the speaker in the intervention (refer to Multimedia Appendix 1). Participants were asked additional follow-up questions to provide further clarification. All Zoom interviews (26 min on average, ranging from 17 to 32 min) were audio-recorded with the participants' permission and transcribed verbatim.

Data Analysis

Quantitative Study

This study used mixed model analysis of covariance (ANCOVA), with time (baseline, postintervention, and 1-wk follow-up) as the within-subjects factor and group (intervention or active control) as the between-subjects factor.
