Quality ratings of index RCTs are included in Table S2 in Multimedia Appendix 2. Most disagreements arose in domain 2 (deviations from the intended interventions) and were resolved by discussion between raters (CH and RT). Half (7/14, 50%) RCTs showed some risk of bias, primarily due to bias arising from deviations from intended interventions or outcome measurement [40-44]. The remaining 7 RCTs had low risk of bias [38,45-47].

Index RCT Summary Characteristics

Summary characteristics of index RCTs are reported in full in Table S3 in Multimedia Appendix 2, and intervention characteristics are presented in Table 2. Most DMHIs targeted psychosis specific symptoms (12/14, 86%) and were delivered in a participant-chosen or any setting (9/14, 64%). Many (8/14,

XSL•FO
RenderX

57%) RCTs were conducted from a London-based university [38,44-47] or the University of Oxford [40-42]. One RCT was conducted outside of England in Scotland and Australia, but was included because less than half of the participants were Australian (24/73, 29%) [48]. Based on available data, intervention users were mostly White (656/1023, 64%), male (653/1023, 64%), had a mean age of 38.6 (SD 1.5) years, and a primary diagnosis of a psychotic disorder (890/1023, 87%).

Studies Reporting Process Data Summary Characteristics

Summary characteristics of studies reporting process evaluation data are reported in full in Table S4 in Multimedia Appendix 2 and summarized in Table 3. Most studies were published between 2021 and 2023 (24/45, 53%), quantitative (19/45, 42%), used trial data (31/45, 68%), evaluated the study intervention (39/45, 87%), and did not describe the project as a process evaluation (43/45, 96%).

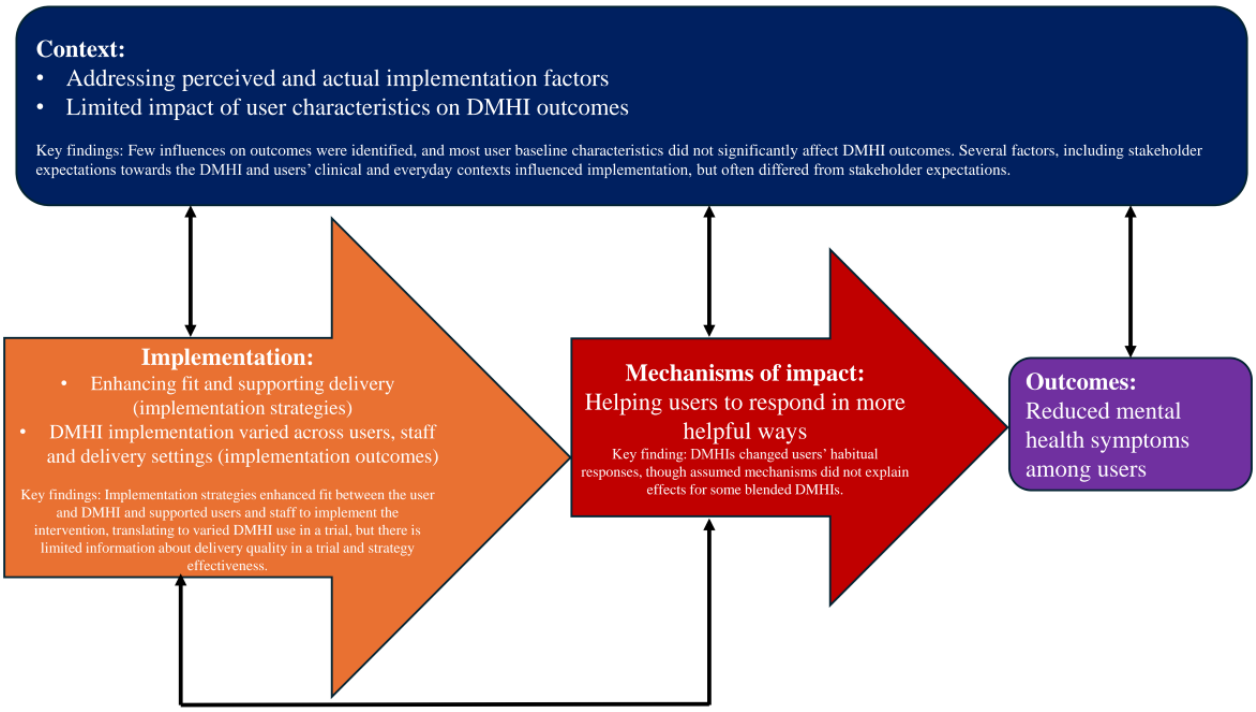
[a]Some papers fall into more than one category, so categories may add to more than the overall total (N=45).

There was a range of participants and contributors to studies reporting process evaluation data (Table S4 in Multimedia Appendix 2), with trial participants comprising the majority (1856/2155, 86%) across 37 (82%) studies. Other contributors included health care professionals (195/2155, 9%) and individuals with lived experience (184/2155, 9%). However, missing sociodemographic data in 17 (37%) studies limited the ability to accurately summarize this information.



Framework Synthesis Findings

Overview

Framework synthesis of process evaluation data generated 5 themes (Figure 4 [13]), all of which were coded within the components deductively derived from the MRC framework (context, implementation, and mechanisms of impact) [13].

XSL•FO
RenderX

Figure 4. Framework synthesis themes summarized using the Medical Research Council process evaluation diagram. DMHI: digital mental health intervention.

Implementation

Overview

Most findings related to implementation, defined in this review as (1) the actions taken by trial teams to support DMHI delivery in an RCT (implementation strategies) [28] and (2) how much and by whom, a DMHI was used and delivered within an RCT, including if an intervention was delivered as planned (implementation outcomes) [27] (38/45, 84% studies; 13/13, 100% DMHIs). Two themes, mapped to the MRC framework, were created: (1) enhancing fit and supporting delivery (implementation strategies) and (2) DMHI implementation varied across users, staff, and delivery settings (implementation outcomes).

Enhancing Fit and Supporting Delivery (Implementation Strategies)

Implementation strategies were identified in 34 (76%) studies across all 13 (100%) DMHIs. These data, identified from stakeholder feedback, trial data, and author interpretation, were summarized in two subthemes: (1) strategies to improve fit and (2) strategies to support use and delivery.

Strategies to Improve Fit

Most trial teams (12/13, 92%) used implementation strategies that aimed to improve the fit between the DMHI and the user. This included the following implementation strategies from the ERIC: adapt and tailor to context, engage consumers, and change infrastructure [28]. Most trial teams (10/12, 83%) designed DMHIs that could be adapted to the user. This included allowing users to personalize virtual reality– (VR), web-, or app-based intervention content in 7 (58%) DMHIs [41,43,49,52-61], (2) offering on-demand access to 4 (33%) interventions, primarily via apps [43,44,49,53,55,59-62], and enabling multisetting delivery for 3 (25%) blended DMHIs [41,42,49,63]. These features could improve fit with users' needs, schedules, or delivery preferences. Stakeholders consistently valued DMHI flexibility [43,55,58,61] or requested it when lacking [17,62,64]. Half of the trial teams (6/12, 50%) also involved patients and potential consumers in the implementation effort, using co-design or user-centered design methods intended to make the DMHI more relevant to end users [49,60,64-69]. Three of these trial teams (Actissist 2.0, AVATAR2, and SloMo) attributed engagement to these approaches [47,49,55,69,70]. Finally, 3 RCTs (Actissist, Actissist 2.0, and MUSE) addressed potential infrastructural barriers by enabling access to the technology needed for the DMHI. This included delivering a blended DMHI using existing National Health Service (NHS) technology [71] and providing study phones, which were used by 70% [49] and 87% [43] of participants.

Strategies to Support Use and Delivery

Trial teams (11/12, 92%) also used implementation strategies that enhanced DMHI delivery and use by assisting intervention users and staff responsible for delivering the intervention. This included the following implementation strategies from the ERIC: training and educating stakeholders and providing interactive assistance [28]. Most strategies focused on supporting users in the RCT. Many (9/12, 75%) teams reported providing interactive assistance to users, primarily via staff involvement, though 2 DMHIs (SloMo and gameChange) also incorporated digitized human support [55,58,65]. In 2 DMHIs (CBM-pa and Actissist), trained researchers provided professional support specifically for the trial [53,64]. Across DMHIs, staff offered practical and technical assistance to facilitate DMHI use [17,46,53,58-60,62,65,72-74]. For blended DMHIs, users frequently highlighted the importance of positive relationships with the delivery staff. Positive relationships were developed

XSL•FO
RenderX

through delivery staff's nonspecific therapeutic skills, including active listening, empathy [17,55,58,60,62,73], and encouragement [58,62,73]. User feedback on interpersonal support was mixed: some users described assistance as central to engaging with the DMHI [58,62,73], while others viewed it as less important or preferred using the intervention independently [46,58,60,61,64]. No clear patterns of user preference emerged according to intervention features. Fewer trial teams reported implementation strategies aimed at supporting delivery staff. A total of 4 (33%) teams reported training and educating delivery staff on the DMHI prior to the RCT [51,55,65,75].

DMHI Implementation Varied Across Users, Staff, and Delivery Settings (Implementation Outcomes)

Implementation outcomes data were identified in 21 (47%) studies across all 13 (100%) DMHIs. Most implementation outcome data focused on individual-level implementation, particularly intervention reach and DMHI use, whereas less information was available about implementation by delivery staff or services.

User-level implementation outcomes are primarily related to intervention reach (the extent to which intended users participated in the intervention) and DMHI use within RCTs (13/13, 100% DMHIs). Reach was often operationalized as participation rates and reported by all but 1 team [49]. Across studies, the proportion of eligible individuals who participated in trials varied substantially, ranging from 27% [46] to 100% [38,41,42,45]. No clear patterns emerged regarding variation in participation rates according to DMHI characteristics or trial team.

Information about who was considered suitable to participate in DMHI trials was often incompletely reported. Several teams stated that participants were excluded because they did not meet eligibility criteria, without specifying which criteria were unmet [43,46,47,52]. Where reasons for exclusion were reported, data most commonly indicated participants were those who were currently experiencing the mental health difficulty targeted by the DMHI [41,42,45], and not receiving concurrent psychological therapy [38,41,45,52] or considered high risk, such as being acutely unwell, hospitalized, or experiencing suicidal intent [42,45]. Just 4 (31%) trials teams reported whether participants were representative of the intended target population, including those experiencing psychosis [38,47,50] or local service populations [51]. Where discussed, representativeness was primarily assessed using basic demographic characteristics. Trial samples were commonly described as predominantly White, male, or unemployed, with these characteristics used to justify representativeness compared to target populations [38,47,50,51].

Quantitative trial data indicated that DMHI use varied among users of both blended (DMHIs are delivered in a session and guided by a member of staff, 9/13, 69%) and self-administered (DMHIs are used independently, 4/13, 31%) delivery models. One intervention (SloMo) used both models, allowing in-session and independent DMHI use [47]. Session attendance for blended DMHIs ranged from 0% to 100% [41,42,45,46,50-52]. For self-administered DMHIs, use was operationalized using adherence criteria, with the proportion of users meeting this ranging between 65.4% [63] and 91% [48]. Two RCTs (Actissist and Actissist 2.0) reported detailed usage data showing that app engagement declined by 67%-67.5% over 12-week intervention periods, with users accessing the app at varied times of day [53,54].

Implementation outcomes relating to DMHI delivery staff and services were less frequently reported (9/13, 69% trial teams). A total of 8 (62%) trial teams reported the adoption (implementation by settings or delivery staff) of DMHIs in an RCT. However, these studies rarely reported formal adoption metrics, such as the proportion of settings or clinicians willing to deliver the DMHI. Instead, adoption was typically inferred indirectly from descriptions of delivery staff and their level of expertise (7/8, 88% trial teams). Across these studies, the representativeness of delivery staff appeared variable, although reporting was generally limited to professional role descriptions. Overall, 4 (58%) blended DMHIs were delivered by therapists who often had expertise in psychological therapies for psychosis [44,45,55]. In contrast, 3 (42%) DMHIs were delivered by staff without specialist psychotherapy roles [51,52,65], such as assistant psychologists or care coordinators. Further, a few trial teams reported how successfully delivery staff implemented the DMHI in an RCT. Only 3 (23%) of these teams assessed therapist adherence and skill in delivering AVATAR1 and MUSE therapies, reporting high fidelity to therapy manuals [45,51,52]. Another trial (CBM-pa) noted successful delivery without supporting data [38]. Finally, only 2 trial teams reported adoption at the service level. EMPOWER recruited and retained all 8 participating community mental health services throughout the trial [48], whereas the MUSE-FEP reported substantial site attrition, with 7 of 15 recruiting sites withdrawing during the trial due to the COVID-19 pandemic [52].

Context

Overview

All interventions reported contextual findings, or external factors that influenced DMHI implementation or functioning in RCTs (33/45, 73% studies; 13/13, 100% DMHIs). Contextual findings were explored quantitatively using moderation analyses (10/33, 30% studies) [41,42,47,48,50,53,54,63,76,77], and qualitatively using stakeholder consultation (11/33, 33% studies) [16,17,46,58,60,61,64,73,78,79], and reasons for trial participation or withdrawal (12/33, 36% studies) [38,43,45,46,49-52,55,58,75,80]. Two themes that aligned with the MRC framework components were created: (1) addressing perceived and actual implementation factors and (2) the limited impact of user characteristics on DMHI outcomes [13].

Addressing Perceived and Actual Implementation Factors

Overview

Contextual data about implementation (factors that influenced how a DMHI was delivered in RCTs) were identified in 26 (58%) studies across 12 (92%) DMHIs. Three subthemes were created from stakeholder feedback [16,17,46,55,57,58,60-62,64,73,78,79], trial data [43-46,48,50,52-55,63,71,75,80], and author description [59]: (1) stakeholder misconceptions about user-related barriers, (2)

XSL•FO
RenderX

service-level barriers: perceptions and realities, and (3) hope and help: positive expectations facilitate implementation.

Stakeholder Misconceptions About User-Related Barriers

Health care professionals and some service users held generalized concerns that psychosis-related and technology-related factors would hinder DMHI implementation. Staff in pre–COVID-19 studies anticipated that users' limited technology access and digital skills would act as key implementation barriers [78,79]. However, process evaluation data contradicted these assumptions: users engaged with a range of DMHI modalities, including computer-based, smartphone-based, and VR-based interventions, regardless of digital confidence [17,46,55,60,64]. Only SloMo reported higher engagement among more technologically confident users before the RCT [63]. Concerns about users' technology-related paranoia or illness severity were also overgeneralized [57,78,79] as not all users had experienced technology-related paranoia [62,73], and some used DMHIs despite concerns [60,67,73].

Actual implementation barriers included different psychosis symptoms (auditory hallucinations [44,59,62] and negative symptoms [46]), everyday life and situational factors outside of therapy (eg, users having other time commitments such as working or studying [17,43,53,73]), and DMHIs not meeting users' treatment needs or preferences (eg, lack of interest in the DMHI or RCT [41-43,45-48,51,52,70] or feeling that the DMHI was not suited to them [17,43,45,55,57,75]). Demographic factors had a limited influence on use in 3 (25%) DMHIs: older age [53,54], White ethnicity [54], and higher baseline smartphone confidence [63] were associated with higher engagement. A number of other factors were generally nonsignificant (gender, education, employment, and prior smartphone ownership) [53,54,63].

Service-Level Barriers: Perceptions and Realities

Stakeholders (service users and staff) often perceived psychosis-specialist services as underresourced for DMHI delivery, citing staff availability, physical space, and technology constraints [57,78,79]. These concerns were particularly noted for interventions requiring clinical involvement (EMPOWER and gameChange) [78,79], the latter with VR-specific equipment and spatial needs [45]. Evidence from 2 RCTs (EMPOWER and MUSE) indicated staff resource constraints linked to high workloads and turnover hindered recruitment [16], staff training [51], and data collection [48]. In contrast, staff perceptions for Actissist did not align with its delivery model [43,78], as the smartphone-based intervention required neither the assumed NHS systems nor staff support for delivery [43].

Hope and Help: Positive Expectations Facilitate Implementation

Positive expectations among users and health care professionals facilitated DMHI use. Most users tried the DMHI expecting personal benefit from use [17,58,60,62,73,79,80], while some users were motivated by helping others [62,80] or trying something different within their treatment [46,62]. Staff reasons for wanting to deliver a DMHI, though less frequently reported, aligned with user expectations as some anticipated benefits for their clients [57,78].

Limited Impact of User Characteristics on DMHI Outcomes

A few contextual factors influenced DMHI functioning. Only 2 (15%) DMHIs (gameChange and MUSE) identified 3 moderators, reporting enhanced effects among participants with higher baseline illness severity [76], earlier psychosis symptom onset [50], and those who felt valued from using the intervention [77]. Across 5 (38%) DMHIs, most user baseline characteristics did not affect outcomes; no consistent patterns emerged, though gender was not found to moderate effects [41,42,47,50,52].

Mechanisms of Impact: Helping Users to Respond in More Helpful Ways

Mechanisms of impact data, or how DMHIs produced change in an RCT, were identified in most (10/13, 77%) DMHIs across 19 (42%) studies. Evidence predominantly came from qualitative sources, including DMHI user feedback (8/19, 42% studies [17,43,58,60-62,64,73]), intervention content (4/19, 21% studies [55,72,74,75]), and author commentary (2/19, 10% studies [51,59]), while only 4 studies quantitatively tested hypothesized mechanisms [38,41,42,47].

Across the 10 (77%) interventions, DMHIs appeared to help users respond to difficult thoughts or situations in more helpful ways by changing their habitual thinking (eg, belief inflexibility, beliefs about voices, or interpretation biases [17,38,41,45,47,55,60,62,64,72,75]) or behaviors (eg, reducing defense behaviors or increasing assertive behaviors [41,42,45,55,58,59,61,72-74]). Many (7/13, 54%) interventions were theoretically informed and targeted putative maintaining mechanisms [17,38,41-43,47,49]. Changes were achieved by replacing unhelpful responses (eg, negative interpretations of everyday situations or avoidance of everyday social situations that were perceived to be unsafe) with more helpful responses (eg, seeking alternative, less personally threatening explanations [38,47,55,58,60,62,64], or entering challenging situations [41,58]). For some users, changing habitual responses was achieved by becoming aware they were responding in unhelpful ways [55,58,60,61,64], understanding why they responded in unhelpful ways [55,72,75], or practicing responding in new ways [55,58,60,62].

However, assumed mechanisms did not consistently explain outcomes in 4 DMHIs with a blended delivery model delivered via an app [47,48] or VR [41,42]. In 3 of these DMHIs, targeted mechanisms (safety beliefs [41,42], defense behaviors [42], or a reasoning bias [47]) did not mediate intervention effects, even when symptom improvement occurred [41,47]. In another DMHI, EMPOWER, user interviews revealed that not all users experienced changes to the targeted mechanism (relapse appraisal) [17].

Discussion

Principal Findings

Overview

We created 5 themes after synthesizing process evaluation data from 45 peer-reviewed papers evaluating 13 DMHIs used by those experiencing psychosis in RCTs predominantly based in the United Kingdom. These themes aligned with deductive

XSL•FO
RenderX

MRC framework domains: implementation, context, and mechanisms of impact [13].

Implementation

Overall, implementation findings indicated that research in trials primarily focused on the implementation at the level of the individual user, with substantially less information available regarding delivery staff and services. Current DMHI implementation research for psychosis has therefore prioritized understanding user engagement, while providing limited insight into whether services can realistically deliver DMHIs.

Implementation data suggested it may be feasible to deliver DMHIs to people experiencing psychosis in a trial. Across studies, users engaged with DMHIs in a trial setting. Where considered, trial participants were often described as broadly representative of populations with psychosis or local services [38,47,50,71], suggesting that DMHI delivery may be feasible among groups currently receiving psychosis care. However, representativeness was inconsistently assessed and typically based on basic demographic characteristics. Further, while DMHI use in a trial varied between individuals, this finding is consistent with previous reviews [10,81,82] and attendance patterns observed in psychological therapies for psychosis more broadly [83]. Consistency in variation may suggest that some level of disengagement could be expected when implementing DMHIs and, importantly, may not indicate implementation failure unique or issues inherent in this delivery mode. Variation in use persisted across blended and self-delivered DMHI using different technology, suggesting that DMHI use may be shaped by external, nontherapy related factors, including fluctuating needs, user autonomy in care, or unmet treatment preferences, all factors identified in this (see the "Context" section below) and other work [84].

Implementation strategies similarly primarily focused on addressing potential barriers at the user level, including intervention accessibility, usability, and user support needs. Trial teams often aimed to improve the fit between the DMHI and the user through intervention flexibility, stakeholder involvement, tailored support, and improving access to necessary technology. These approaches align with broader recommendations both in the DMHI [11,85] and implementation science [28] literature. Consequently, although implementation science frameworks were rarely explicitly used, trial teams were often already undertaking implementation-focused work. However, greater use of implementation science frameworks may help structure, evaluate, and consistently report these efforts and enable a better understanding of how DMHIs can be successfully implemented. Stakeholder feedback highlighted some of these strategies, including ensuring the intervention content, delivery approach, and amount of professional support provided [43,55,58,61], as potential design priorities for future work. However, despite routine use of promising implementation strategies, no studies evaluated whether these strategies improved implementation outcomes, and variation in DMHI use persisted across interventions. Further, despite DMHIs often being discussed as scalable or resource-efficient interventions [86], implementation costs were not reported in the included studies. Our review challenges assumptions that DMHIs are inherently low-resource interventions because many implementation strategies likely require substantial resources, including money (eg, payment for specialist workers and end users in co-design processes) and time (eg, developing and delivering training). Future work clarifying these "hidden" costs, in addition to evaluating implementation strategy effectiveness, would better establish how best to implement DMHIs for psychosis.

In contrast, evidence relating to delivery staff and services remained limited across implementation strategies and outcomes. Available evidence primarily focused on the delivery staff, with less attention given to wider service or organizational implementation requirements. Although all included DMHIs included professional support in delivery, only 3 (23%) trial teams evaluated delivery staff competency [45,51,52], despite staff being important determinants of successful delivery [10]. Few studies reported how staff were trained to deliver DMHIs, limiting understanding of the workforce support required to deliver these interventions consistently and to a high standard. However, blended DMHIs appeared deliverable by staff with differing levels of expertise, ranging from highly specialized therapists to broader mental health workforces in the United Kingdom. This suggests that workforce requirements and implementation demands may differ depending on the specific DMHI. Beyond delivery staff, implementation within health care services is also shaped by organizational factors, including available technology, delivery space, and financial resources [10]. These factors were rarely evaluated in included studies, limiting understanding of what resources are needed to implement DMHIs both in and after trials.

Context

Most studies (33/45, 73%) reported contextual findings, primarily relating to DMHI implementation, whereas few examined the influence of context on DMHI outcomes. Only 2 (15%) DMHIs identified moderators, including some illness factors and feeling valued from DMHI use [50,76]. Across 5 (38%) DMHIs, most user baseline characteristics did not significantly affect treatment outcomes [41,42,47,50,52]. While this could suggest that included DMHIs may work broadly across different user profiles, conclusions about subgroup differences remain tentative due to the small number of studies examining moderators and variability in examined moderators. Notably, the absence of gender moderation across several DMHIs contrasts with previous reviews [10,82], potentially reflecting differences in intervention type or populations. These inconsistencies highlight the need for more nuanced research to determine for whom DMHIs are most effective.

A key finding was the role of stakeholder DMHI appraisals. First, appraisals of the intervention shaped implementation, including stakeholder appraisals about DMHI relevance, fit with treatment needs, and expected benefits [20,48,52,64]. This emphasizes the importance of supporting user choice and aligning DMHIs with individual preferences (see the "Implementation" section above). Second, stakeholder misconceptions about user- and service-related barriers were common. Pretrial assumptions often overestimated difficulties due to users' limited digital literacy, device availability, or

XSL•FO
RenderX

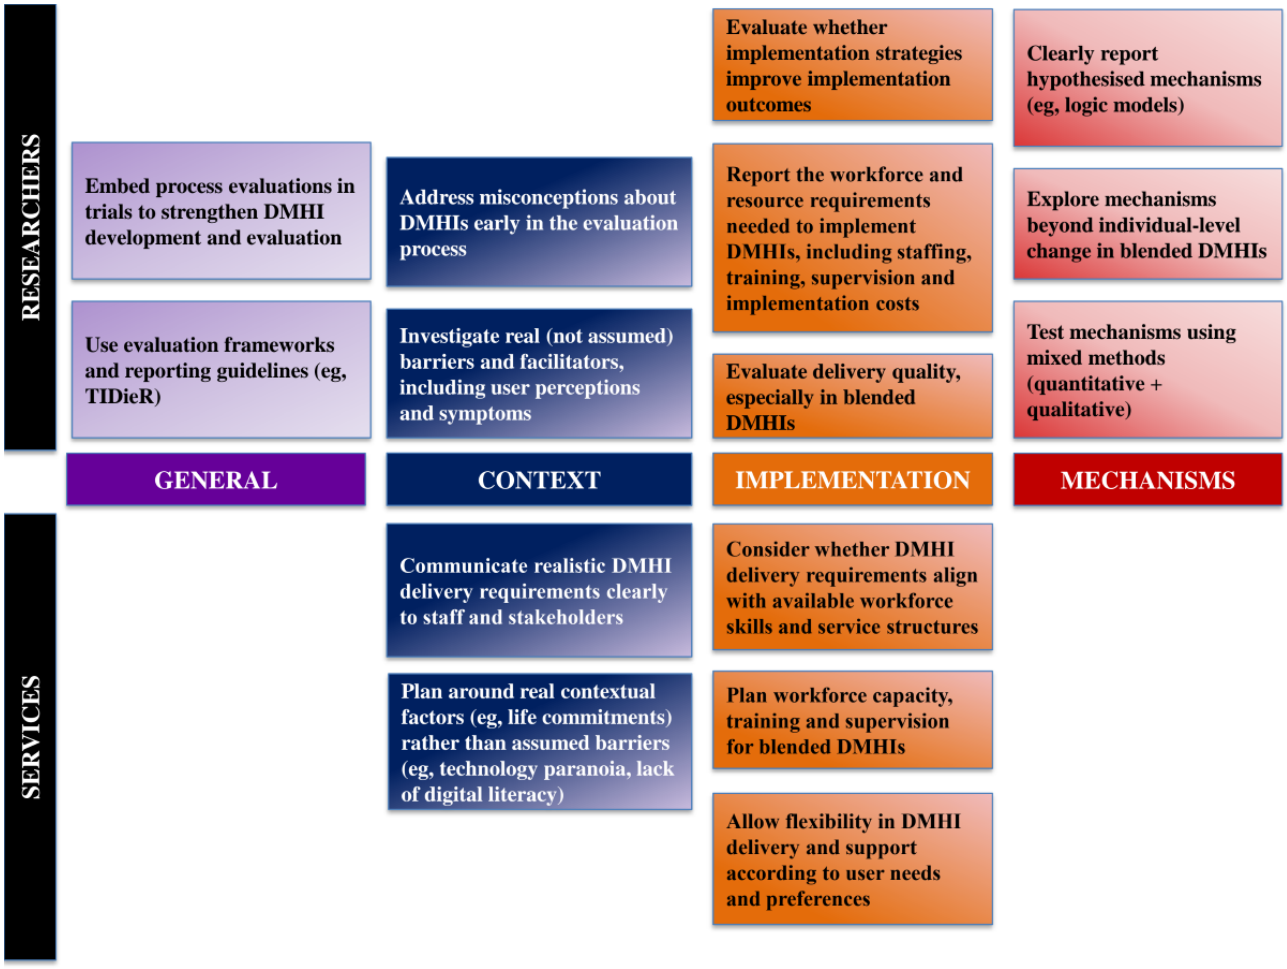
technology-related paranoia [78,79], yet process evaluation data showed users engaged with a range of DMHI modalities regardless of prior digital experience [17,46,55,60,64], and concerns regarding technology-related paranoia were overgeneralized [62,73]. Only 1 intervention (SloMo) demonstrated higher engagement among more digitally confident users [63], suggesting that technological familiarity may enhance, but is not essential for, use. Service-level constraints were also highlighted. Service staff often cited limited resources as barriers [78], though evidence linking resource limitations to implementation was limited but highlighted staff availability as a relevant factor [16,48]. Further, staff perceptions did not always match actual intervention demands [78]. Given staff are important determinants of DMHI implementation [11,87], addressing misconceptions about DMHI users and delivery requirements may be critical. However, most studies predated COVID-19 [78,79], meaning attitudes toward DMHIs and user capability may have changed after the pandemic forced a move to almost entirely remote services in the United Kingdom due to 2 years of prolonged lockdowns [88].

User-reported barriers differed from assumed factors, including other psychosis-related symptoms (auditory hallucinations [59,62] and negative symptoms [46]) and life commitments outside of therapy [17,53]. These findings underscore the importance of addressing real, not assumed, contextual factors; as DMHI use is shaped by both clinical and everyday contexts, this may further reinforce the potential value of flexible intervention design to optimize use (see the “Implementation” section above).

Mechanisms of Impact

Evidence for DMHI mechanisms remains limited. Process evaluation data suggested DMHIs reduced users’ mental health symptoms by supporting more adaptive cognitive and behavioral responses to challenging situations. This mechanism was observed across different intervention modes and targets, though the specific mechanisms varied and were often not clearly delineated as such, which impeded review syntheses. However, evidence for these mechanisms is tentative and is currently insufficiently tested and validated. Most insights were derived from qualitative sources (user feedback or intervention content), rather than recommended quantitative hypothesis-driven approaches [89], which were reported in only 4 (10%) studies [38,41,42,47]. This limited the ability to confirm whether these processes causally explained symptom change. Further, hypothesized mechanisms were not consistently activated. Some blended DMHIs demonstrated effects through assumed mechanisms, such as belief inflexibility or defense behaviors [38,64], while others reported symptom improvements that were not mediated by hypothesized mechanisms (safety beliefs, reasoning, and safety behaviors) [41,42,47], suggesting that DMHIs may work through alternative or nonspecific processes. For interventions delivered via blended delivery models, intrapersonal factors, such as a therapeutic alliance, which has been identified as a driver of change when treating psychosis [90], may play an unrecognized role in driving change. Further, variability in mechanistic responses, such as inconsistent changes to reduced fear of relapse among EMPOWER users [17], highlights the likelihood that mechanisms function differently across users and contexts (see the “Context” section above).

Comparison to Prior Work



Unlike previous reviews focusing on the effectiveness of DMHIs for psychosis [7,8,91], this synthesis of process evaluation data extends the understanding of implementation science in this area. Further, our review extends prior syntheses of process evaluation in other health domains, such as physical health interventions [18,92]. Consistent with broader findings that process evaluation remains underused across research fields [18,92] and that implementation science remains underapplied in DMHI research [93], we found limited use of process evaluation, with only 1 trial explicitly adopting this approach [16,17]. Although most DMHI research remains service-based [9,10], our findings show that both user-related and service-related factors can shape engagement and outcomes, and may provide a starting point for identifying priorities for future research and implementation efforts in and outside of services.

Future Directions

Our review highlights several priorities to strengthen DMHI evaluation and implementation (Figure 5). For researchers, key steps include embedding process evaluation in trials using established frameworks and reporting guidelines, further clarification of how DMHIs reduce user mental health symptoms, and routine assessment of the delivery quality of blended DMHIs. Future research could evaluate which implementation strategies improve implementation outcomes. Further work is needed to clarify the workforce, organizational, and resource requirements needed to deliver DMHIs consistently, including staff training, supervision, and implementation costs. For services, priorities include clearly communicating DMHI requirements to staff, addressing real, not assumed, contextual factors, and adopting flexible delivery approaches.

Review Strengths and Limitations

This review has several strengths. To our knowledge, it is the first review to synthesize process evaluation data in this field. Broad inclusion criteria, aligned with relevant guidance [20], enabled us to capture relevant studies irrespective of authors' use of the term "process evaluation." The lack of date and method restrictions and updated searches ensured comprehensive and up-to-date coverage. Rigorous methods, including review preregistration, double, masked screening, and data extraction and use of an established process evaluation framework for synthesis, helped minimize bias. Finally, unlike other scoping reviews [94], our use of established implementation science frameworks [13,27,28] helped ensure our findings were appropriately documented, which may help inform the broader field.

Several limitations should be noted. As in another review [92], most studies did not explicitly use process evaluation terminology, and data were primarily synthesized by a single author (CH), which may have introduced subjectivity despite the use of an established framework. The framework was operationalized at the theme level to enhance usability, possibly limiting analytical depth. Use of the frequency-based criterion from Graham-Rowe and colleagues [37] in the narrative synthesis may underemphasize less commonly reported findings. Extracting process evaluation data from only the results and discussion sections may have excluded relevant information from the methods sections. Many trial teams (10/13, 77%) described implementation processes (eg, staff training and device provision) in methods sections without supporting data, which were not captured in our syntheses. Finally, 1 included DMHI was implemented in the United Kingdom and Australia [48], which may have introduced variability in country contexts. While we excluded data explicitly linked to Australian contributors to mitigate this risk, some aggregated data may reflect mixed contexts.

Conclusions

There is preliminary evidence that DMHIs can be delivered to people experiencing psychosis in a trial. Where assessed, interventions were generally delivered as intended and often reached participants considered representative of existing psychosis services. DMHIs may reduce symptoms by modifying users' habitual behavioral and cognitive responses, yet mechanistic pathways require further validation. Implementation strategies aimed to improve the fit between DMHIs and users through flexible delivery and stakeholder involvement, and support DMHI use and delivery in trials through professional support and staff training. While these approaches appear promising, engagement with DMHIs varied between users, and the effectiveness of implementation strategies remains largely untested. Contextual factors often differed from stakeholder

XSL•FO
RenderX

expectations, relating to users' everyday factors outside of therapy, treatment expectations, or symptoms, rather than assumed technology-related issues, highlighting the need to address misconceptions and clearly communicate delivery requirements. Process evaluation remains underused; embedding it in future trials is a priority and could clarify mechanisms, guide implementation, and support the translation of effective DMHIs from trials to practice.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Funding

CH is supported by a fully funded University Research Studentship Award from the University of Bath. The funder had no role in the design, conduct, analysis, interpretation, or reporting of this review. Any opinion expressed in the paper does not necessarily reflect the view of the funder. At the time of this work JY was part-funded by the NIHR Biomedical Research Centre hosted at South London and Maudsley NHS Foundation Trust in partnership with King's College London and the Medical Research Council (MRC) Biomedical Catalyst: Developmental Pathway Funding Scheme (DPFS), Reference: MR/V027484/1.

Authors' Contributions

Conceptualization: CH
Methodology: CH, CD, PJ
Data curation: CH
Funding acquisition: CH (lead) PJ (support)
Project administration: CH (lead), PJ, (support), CD (support)
Validation: CH (lead), SD, (support) CF (support), ALT (support), RT (support)

Abstract

Background: Digital applications based on health care conversational agents (HCAs) are increasingly being developed to support health care provision. The usability and user experience of these solutions are critical determinants of their acceptability and, consequently, their impact on health-related outcomes.

Objective: This systematic review aims to synthesize current evidence on the use of valid and reliable subjective instruments for assessing the usability and user experience of HCAs and to examine whether assessment outcomes vary according to their technical characteristics.

Methods: A systematic search was conducted in PubMed, Web of Science, and Scopus from inception to February 2026. Studies were included if they used subjective instruments to evaluate the usability or user experience of HCAs.

Results: A total of 127 studies met the inclusion criteria. The studies examined 3 categories of HCAs—text-based, voice-based, and embodied—applied to patient care, health education and prevention, health data collection, and support for daily activities among older adults. The System Usability Scale (SUS) was the most frequently used assessment instrument. Comparative analysis of SUS scores indicated higher usability ratings for text-based HCAs relative to voice-based and embodied systems. However, SUS and other subjective instruments used in the included studies may not fully capture key dimensions of usability and user experience of HCAs. Additionally, substantial heterogeneity was observed in assessment methodologies across studies.

Conclusions: Comparative analysis suggested that text-based HCAs were associated with significantly higher SUS scores than voice-based and embodied HCAs. However, this finding should be interpreted with caution given the substantial heterogeneity across the included studies in health care application domains, study designs, evaluation contexts, participant populations, and HCAs' implementation and use characteristics, as well as the limitations of the SUS in evaluating the usability of modern HCAs. The variability in assessment approaches underscores the need for standardized protocols and the development of more context-specific evaluation frameworks to enhance methodological consistency and comparability across studies.

Introduction

Since the development of ELIZA in 1966 [1], a rule-based system developed to emulate text-based interactions with a psychotherapist, advancements in information technology have driven the widespread adoption of health care conversational agents (HCAs) [2,3], which are applications designed to support interactive, multiturn communication through written or spoken language [4]. Consumer solutions such as Siri, Google Now, Cortana, and Alexa are well-known examples of agents designed to help users find information and accomplish tasks [5].

Modern HCAs extend well beyond simple rule-based input-output interactions. Advances in large language models have facilitated their evolution from narrowly defined, task-oriented tools into open-domain systems capable of retaining conversational context, following topics across multiple turns, and sustaining coherent, continuous dialogue for more natural interactions [6,7]. In addition, AI techniques have enabled more advanced dialogue management, facilitating the exhibition of human-like behaviors, the recognition of users' emotions and intentions, and the use of various information sources for reasoning and decision-making [8-10].

Building on these advancements, researchers have explored anthropomorphized interfaces, leading to the development of embodied agents, or virtual humans [11,12]. Unlike traditional agents, which rely solely on text or voice, embodied agents combine verbal communication with nonverbal cues (eg, posture, gestures, eye movements, or facial expressions) to foster more lifelike interactions [13-15]. This embodiment enhances users' perception of social presence and engagement, making interactions feel more intuitive and emotionally rich [16,17]. Moreover, the introduction of virtual reality technologies has paved the way for increasingly sophisticated agents designed to promote user engagement through immersive experiences [18].

HCAs are widely used in health care [19], reflecting the widespread adoption of similar agents across other human-centered sectors, including customer service [20], entertainment [21], and education [22].

From a health care research perspective, the assessment of HCAs should consider health-related outcomes, such as symptom reduction, disease knowledge, disease self-management, and quality of life [8]. This assessment should be conducted in the context of continuous use of the applications and preferably supported by randomized controlled trials. However, before conducting randomized controlled trials, it is important to safeguard aspects that might affect health-related outcomes. This means that preliminary assessments (ie, feasibility studies) should be conducted [23] to evaluate the technical characteristics of HCAs or their quality in terms of usability and user experience and, consequently, their potential to promote user engagement among the target users [8,24].

System usability comprises several components (ie, learnability, efficiency, memorability, errors, and satisfaction) and relates to the ease of using the system interface [25]. The rise of new technologies, devices, and interaction methods has expanded the concept of usability into the broader notion of user experience, which encompasses the cognitive, affective, social, and physical aspects of interaction [26-28].

There are 3 main methods for evaluating usability and user experience, namely, inspection, testing, and inquiry [29]. The inspection method consists of a systematic analysis of interaction mechanisms carried out by experts according to specific guidelines, while the testing and inquiry methods are based on the collection of usage data [29]. The testing method involves observing users while they perform tasks with a given system to collect primarily quantitative data (eg, the number of completed tasks) that can provide empirical evidence on how to improve the interaction mechanisms [29]. By contrast, the inquiry method involves collecting qualitative data from users, namely through interviews or subjective measurement instruments such as questionnaires or scales [29]. Examples of commonly used instruments include the Post-Study System Usability Questionnaire (PSSUQ) [30] and the System Usability Scale (SUS) [31]. These instruments have had their measurement properties assessed, particularly validity (ie, how effectively usability or user experience is measured) and reliability (ie, the consistency of measurements when repeated under comparable conditions) [30-33].

In this context, this review aims to synthesize the current evidence on usability and user experience assessments of HCAs using valid and reliable subjective instruments, to identify the purposes and categories of HCAs being assessed, and to determine, through a comparative analysis, how this typification affects their usability and user experience.

Several reviews [34-41] have already focused on different aspects of HCAs (eg, the use of AI or large language models), including usability and user experience assessments (eg, [42-45]); however, these reviews did not perform comparative analyses of usability and user experience across different categories of HCAs. Such analyses are important because different characteristics of HCAs affect how users interact with them (eg, by shaping communication style, pacing, and information processing), as well as cognitive load and perceptions of trust and privacy. Therefore, this review may provide insights to inform better design decisions and the development of standardized evaluation frameworks, enabling researchers and practitioners to benchmark usability and user experience across different HCAs.

Methods

Study Protocol Registration and Scope

The research protocol for this systematic review was registered in the Open Science Framework and followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; see Multimedia Appendix 1) guidelines [46]. The research scope (Textbox 1) was structured using the Population, Concept, and Context framework [47].

XSL•FO
RenderX

Textbox 1. Research scope.

1. Population

Adults (≥18 years) managing their health conditions using digital health applications.

2. Concept

Usability and user experience assessments of health care conversational agents designed for interactive, multiturn communication through written or spoken language to support the management of users' health conditions, supported by validated subjective instruments (ie, questionnaires or scales used to systematically collect users' self-reported evaluations of usability or user experience).

3. Context

Community or institutional care settings.

Literature Search

Scopus, Web of Science, and PubMed were selected as the online databases for retrieving studies included in this review. The search query included keywords representing the following 3 main components:

- HCAs: conversational agent, relational agent, virtual human, virtual agent, virtual assistant, virtual companion, virtual coach, chatbot, enhanced communication agent, embodied communication agent, ECA, and avatar.
- Health care: health care, health care, care, patient, digital health, electronic health, e-health, eHealth, older adults, and elderly.
- Usability or user experience assessment: usability, user experience, acceptance, evaluation, assessment, and test.

The keywords within each component were linked using the Boolean operator OR, whereas the expressions derived from different components were linked using the Boolean operator AND. As an example, Figure 1 presents the search query prepared for the Scopus database.

Figure 1. Search query for the Scopus database.

```
TITLE-ABS-KEY(("conversational agent" OR "relational agent" OR "virtual human" OR "virtual agent" OR "virtual assistant" OR "virtual companion" OR "virtual coach" OR chatbot OR "enhanced communication agent" OR "embodied communication agent" OR ECA OR avatar) AND (patient OR "digital health" OR "electronic health" OR "e-health" OR ehealth OR healthcare OR "health care" OR care OR "older adults" OR elderly) AND (usability OR "user experience" OR acceptance OR evaluation OR assessment OR test)).
```

Inclusion and Exclusion Criteria

To be included in the review, studies had to meet the eligibility criteria presented in Textbox 2.

Textbox 2. Inclusion and exclusion criteria.

1. Inclusion criteria

- Empirical studies published in peer-reviewed scientific journals or conference proceedings.
- Adults (≥18 years).
- Studies evaluating health care conversational agents (HCAs) to support the management of users' health conditions.
- Studies performing usability or user experience assessments of HCAs based on validated subjective instruments.

2. Exclusion criteria

- Review articles, opinion pieces, letters, and editorials.
- Children or adolescents.
- Studies evaluating the integration of HCAs into clinician-oriented digital health applications or applications focused on domains other than health care.
- Studies assessing usability or user experience without using validated subjective instruments or not focusing on this type of assessment.
- Preliminary versions of studies for which a more mature version was included in the review (eg, when a study was published as both a conference paper and later a journal article, the conference version was excluded).
- Studies published in languages other than English.
- Studies for which the full text was not available.

XSL•FO
RenderX

Identification Process

All references retrieved from the databases were imported into a Microsoft Excel spreadsheet. The selection process then followed the general guidelines of the PRISMA flowchart [46]: (1) exclusion of duplicates, (2) title and abstract screening, and (3) full-text screening. Additionally, a backward search was performed based on the reference lists of the articles included for full-text screening.

All stages were performed manually by 2 reviewers (JP and NPR) without the use of automation tools. Disagreements between the reviewers were discussed and resolved collaboratively.

Quality Assessment

The methodological quality assessment of the reviewed studies was conducted using a subset of the Critical Assessment of Usability Studies Scale (CAUSS) [48]. As this scale evaluates both testing and inquiry methods, the reviewers (AGS and NPR) selected 5 items related to assessments using inquiry methods: (1) representativeness of the participants, (2) proximity to the real-world context of use, (3) adequacy of the number of participants, (4) representativeness of the functionalities assessed, and (5) continuous and prolonged use of the app.

The excluded items comprised (1) items related to the validation of measurement instruments, as the eligibility criteria for this review explicitly excluded studies that did not use validated instruments; (2) items related to testing methods involving the direct observation of participants while they performed tasks to collect objective measures, such as error rates or mean task completion time; and (3) the item related to the triangulation of testing and inquiry methods, as testing methods were not considered in this review.

As only a subset of the CAUSS was applied, the resulting scores should not be interpreted as reflecting the overall quality of the usability studies, but rather the quality of the use of subjective measurement instruments.

Data Extraction

The following data were extracted:

- Demographic characteristics, namely, the author(s), nationality of the authors' affiliations, type of publication, and year of publication.
- Purposes of the assessed HCAs.
- Technical characteristics of the HCAs and supporting technologies (eg, AI or virtual reality).
- Types of experimental study designs (eg, cross-sectional or longitudinal studies).
- Duration of the longitudinal studies.
- Number and characteristics of the study participants.
- Recruitment and distribution of the participants.
- Validated subjective instruments assessing usability or user experience.
- Results of the use of the validated subjective assessment instruments (ie, scores and SDs).

Data were independently extracted from all included studies by 2 reviewers (JP and RB) using a customized Microsoft Excel form. Discrepancies were resolved through discussion and consensus.

Data Synthesis

Results were synthesized into summary tables, figures, and descriptive text according to the following domains: (1) demographic characteristics (ie, publication types and publication years); (2) purposes of HCAs; (3) technical characteristics of HCAs; (4) study experimental characteristics (ie, experimental design, number and characteristics of the participants, and measurement instruments); and (5) results of usability and user experience assessments.

A quantitative analysis was performed only for studies using the SUS to assess usability. The number of studies using other instruments was insufficient for quantitative analysis. Studies using the SUS were subdivided based on the categories of HCAs being assessed. To compare SUS scores and the number of participants across the categories of HCAs, the Kruskal-Wallis test was used because the data did not follow a normal distribution (Kolmogorov-Smirnov test, $P<.05$). Medians and IQRs were provided for each group. Additionally, a subgroup analysis comparing SUS scores between studies involving older adults and those involving adults was performed for all studies and within each category of HCAs using the Mann-Whitney U test. The Bonferroni correction for multiple tests was applied. The significance level was set at $P<.05$. Analyses were performed using SPSS.

In addition, the effect size r was manually calculated as the standardized test statistic from the Mann-Whitney U test or the Kruskal-Wallis test (z) divided by the square root of the total sample size (N) and interpreted as small (≥0.1), medium (≥0.3), or large (≥0.5) [49]. For the Kruskal-Wallis test, the ordinal eta-squared (η^2H) was calculated as $\eta^2H=(H - K + 1)/(N - K)$, where H is the test statistic, N is the sample size, and K is the number of groups. It was interpreted as small ($\eta^2H \geq 0.01$), medium ($\eta^2H \geq 0.06$), or large ($\eta^2H \geq 0.14$) [49].

Given the substantial heterogeneity among the included studies—including differences in health care application domains, study designs, evaluation contexts, participant populations, and HCAs' implementation and use characteristics—the quantitative comparison of SUS scores was intended as an exploratory synthesis of patterns across studies rather than as evidence of causal differences in usability among HCA categories. Moreover, the SUS may not adequately capture all relevant aspects of the usability of the evaluated HCAs, such as conversational quality. Consequently, the comparative analyses should be interpreted as identifying associations at the study level rather than establishing the intrinsic usability of specific HCA categories.

Results

Identification of Studies

The online search was performed in February 2026, and 8639 references were retrieved. As presented in Figure 2, after the exclusion of 3391 duplicates, the titles and abstracts of 5248 references were analyzed, and 5094 were excluded according

XSL•FO
RenderX

to the eligibility criteria. Therefore, 154 references were included for full-text analysis. During the full-text analysis, 30 references [50-79] were excluded because they did not meet the eligibility criteria (eg, studies that did not apply valid and reliable instruments to measure usability or user experience, or studies focused on the assessment of clinician-oriented applications). Additionally, the backward search identified 3 references, resulting in 127 references [80-206] being included in the review.

Figure 3. Publications by year and type.

Quality Assessment Results

Most CAUSS criteria considered for the methodological quality assessment were met by a majority of studies: (1) representativeness of the participants (113/127, 89%); (2) proximity to the real-world context of use (105/127, 82.7%); (3) adequacy of the number of participants (90/127, 70.9%); and (4) representativeness of the functionalities assessed (96/127, 75.6%). The exception was the criterion related to the continuous use of the application, which was met by only 44/127 (34.6%) studies. In turn, 28/127 (22%) studies met all 5 criteria.

Purposes of the HCAs

In terms of the purposes of the HCAs described in the included articles, 4 major categories were identified:

- Patient care: 73 studies [81,82,85,87,89,92,95-97,104,106,107,111,113-115,119,121,123,124,127,128,130,132,133,135,136,138,140,141,144-151,153-157,159,162,165-170,172-175,177,179-184,187-189,191,194,197,198,203-206].
- Health education and prevention: 33 studies [86,90,93,103,109,110,112,116-118,122,125,129,131,134,137,142,143,158,160,163,164,171,176,185,192,193,195,196,199-202].
- Health data collection: 15 studies [88,91,98,99,101,102,105,108,120,126,139,152,161,178,186].
- Daily activities of older adults: 6 studies [80,83,84,94,100,190].

Concerning patient care, almost half of the respective articles (ie, 34 [81,82,85,92,95,97,103,104,119,121,123,124,132,147,149,150,153,155,165-170,172,173,179,181,184,188,191,204-206]) targeted mental health disorders (eg, depression, anxiety, stress, posttraumatic stress disorder, eating disorders, and suicidal risk), while the remaining 39 [87,89,96,106,107,111,114,115,127,128,130,133,135,136,138,140,141,144-146,148,151,154,156,157,159,162,174,175,177,180,182,183,187,189,194,197,198,203] articles targeted a range of other conditions, including cancer [138,145,182,183,197], chronic kidney disease [144], chronic pain [115,162,198], COVID-19 [135], delirium [146], diabetes [89,96,111,115,140,194], hemophilia [136], heart-related diseases [128,130,133,154,159,174,187,203], hydrocephalus [177], intestinal ostomy [148], neurodegenerative diseases [107,141,157,175], psoriasis [127], sickle cell disease [114], traumatic injuries [106,151,180], and vestibular disorders [189].

Looking at health education and prevention, beginning with health education, some articles [117,131,137,158,160,171,176,185,193,195,196,202] focused on general health education topics, while others focused on specific topics, such as (1) combating misinformation about COVID-19 [109,113,134], (2) endoscopy explanation [164], (3) hematologic malignancies [110], (4) hereditary breast and ovarian cancer [201], (5) perinatal information for parents [143], and (6) vaccine pharmacovigilance [142]. In the studies that focused on health prevention, the assessed HCAs were designed to promote behavior change (eg, physical activity and weight maintenance) [86,93,112,116,118,125,129,199,200], support vaccination (ie, COVID-19 [122] and human papillomavirus [192]), and provide balance training [90,163].

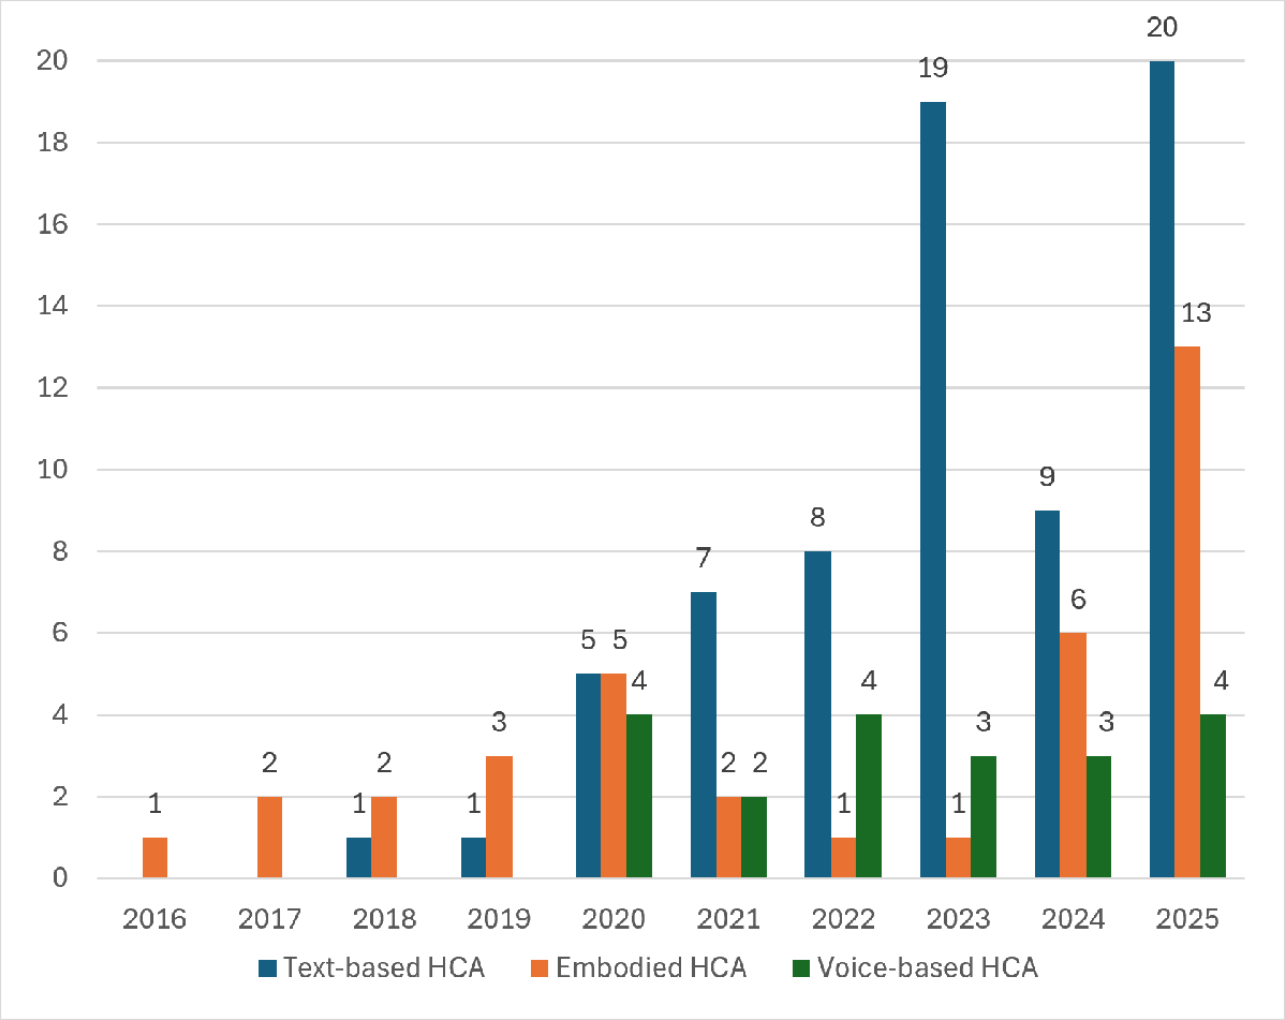
XSL•FO
RenderX

In terms of health data collection, 11 [88,98,101,105,108,120,126,139,152,178,186] studies assessed HCAs for collecting patient-reported outcome measures, 3 [91,99,161] focused on collecting family health history, and 1 [102] described an application designed to collect data for the evaluation of health care services and quality of care.

Finally, 6 [80,83,84,94,100,190] studies assessed HCAs designed to promote the independence and autonomy of older adults by assisting them in managing activities of daily living, including problem-solving [100] and cooking [190].

Technical Characteristics of HCAs

Three categories of HCAs were identified: (1) text-based HCAs, (2) voice-based HCAs, and (3) embodied HCAs.



Five studies [87,98,123,153,169] assessed 2 categories of HCAs: (1) voice-based and embodied [87], (2) text- and voice-based [98,123], and (3) text-based and embodied [153,169]. The remaining studies focused on a single category, according to the following distribution:

- Text-based HCAs: 69 studies [85,86,91,99,100,102,103,105,106,109,110,112-117,119,120,122,125,126,129-134,137-145,147-150,154,157-159,161,164,166,168,170,177,184-187,191,194-206].
- Voice-based HCAs: 18 studies [93,97,101,104,111,118,124,127,135,136,146,155,165,167,172,183,190,192].
- Embodied HCAs: 35 studies [80-84,88-90,92,94-96,107,108,121,128,151,152,156,160,162,163,171,173-176,178-182,188,189,193].

Some studies [91,99,100,102,105,108,109,112,124,126,137,138,147,152,155,161,163,173,178], although maintaining the HCA categories, established different comparisons, namely, (1) HCAs versus regular computer-based questionnaires [91,99,102,105,126,161]; (2) similar applications with different functionalities [108,109,112,137,152,155,173,178] or different intervention strategies [100,124,147,163]; and (3) HCAs versus usual care [138].

Figure 4 illustrates the distribution of studies across publication years by HCA category. According to the figure, the number of studies assessing voice-based HCAs has remained approximately constant, whereas the number of studies assessing text-based and embodied HCAs has increased over the past 3 years. Table 1 presents the relationship between HCA categories and their purposes.

Figure 4. Distribution of studies across publication years, categorized by types of health care conversational agents (HCAs).

Table 1. Relation of the categories of HCAsa and the purposes of the applications.

Purposes	Text-based HCAs	Voice-based HCAs	Embodied HCAs
Patient care—mental health	[85,103,119,123,132,147,149,150,153,166,168-170,184,191,204-206]	[97,104,123,124,155,165,167,172]	[81,82,92,95,121,153,169,173,179,181,188]
Patient care—other	[87,106,114,115,130,133,138,140,141,144,145,148,154,157,159,177,187,194,197,198,203]	[111,127,135,136,146,183]	[87,89,96,107,128,151,156,162,175,180,189]
Health care education and prevention	[86,112,113,116,122,125,129,164,185,195,196,199-202]	[93,118,192]	[90,163,171,193]
Health data collection	[91,98,99,102,105,120,126,139,161,186]	[98,101]	[88,108,152,178]
Older adult daily activities	[100]	[190]	[80,83,84,94]

[a]HCA: health care conversational agent.

Eleven of the embodied HCAs [87,90,92,108,163,171,174,181,182,188,189] were implemented using virtual reality technologies. Of these, 7 [92,108,163,174,181,182,189] were implemented with fully immersive virtual reality technologies, while the remaining 4 used augmented reality [90,171] and mixed reality [87,188] technologies.

Moreover, some studies [80,83,84,89,93,94,96,103,109,110,129,134,155,156,172,179-181] implemented algorithms to recognize users' emotional states. The main reasons for emotion recognition were to enable the HCAs to provide appropriate empathetic responses [80,83,84,89,93,94,96,109,110,129,134,155,156,179] or to suggest specific activities for emotion regulation [155,172,180,181].

Natural language processing based on AI frameworks (eg, Google Dialogflow, Microsoft Language Understanding Intelligent Service, Rasa, or Oscova) was used in several studies to improve dialogue flow [85,86,101,110,112,117,120,124,136,145,167,168,178,179,185,191,195-197,200,202]. In addition, large language models were used in some of the more recent studies [179,185,191,195,196,202].

AI techniques were implemented not only to improve dialogue flow, but also for other purposes, namely, (1) text-based emotion recognition [103,155]; (2) facial emotion recognition [172]; (3) definition of contextualized instructions [171]; (4) avatar generation [176]; (5) prediction of diabetes self-management [194]; and (6) improvement of the consistency and reliability of the information provided [204]. However, most studies did not report evidence of the efficacy of these techniques.

Studies' Experimental Characteristics

Experimental Design

A total of 43 studies [83,84,96,100,104,107,110,112,115,116,118,121,122,124,127-130,132,138,140,141,144,145,149,151,154,160,162,165,170,173,175,177,183,184,197,199-201,203-205] used a longitudinal design, among which 15 studies [100,116,121,124,138,140,141,145,162,173,175,177,184,204,205] randomized participants. The remaining 84 studies used a cross-sectional design.

Cross-sectional studies were conducted in controlled settings, including research or academic settings [81,86,87,89-91,93,97-99,101,103,105,106,108,109,111,113,114,117,120,123,125,126,131,133-137,139,142,143,148,152,153,155-159,161,163,166-169,171,172,174,176,178-181,185-196,198,202], outpatient clinical settings [82,85,88,92,95,102,119,164], hospital clinical settings [146,147,150,182,206], and residential care facilities for older adults [80,94]. In the longitudinal studies, participants used the applications as part of their daily routines, although in some cases data collection was performed in controlled settings. The duration of the longitudinal studies varied from 1 week to 24 weeks: (1) 1 week, 6 [104,110,122,124,129,201] studies; (2) 2 weeks, 8 [100,121,132,151,173,183,197,204] studies; (3) 3 weeks, 1 [140] study; (4) 4 weeks, 7 [96,107,115,128,154,203,205] studies; (5) 5 weeks, 1 [199] study; (6) 6 weeks, 4 [112,160,162,165] studies; (7) 8 weeks, 2 [116,145] studies; (8) 9 weeks, 1 [170] study; (9) 12 weeks, 12 [83,84,118,127,133,138,141,144,149,175,184,200] studies; and (10) 24 weeks, 1 [177] study.

Number and Characteristics of the Participants

Studies included participants from specific age groups (ie, adults or older adults) and health status categories (ie, healthy participants or patients): (1) healthy adults (ie, participants between 18 and 65 years of age) [85-87,92,98,99,101,102,104,105,108-113,117,120-122,124-126,131,132,134,137,142,143,149,152,153,155,158,160,161,163,164,166-168,171-173,177-181,185,186,189,191,192,195,196,199,200,202,204,205]; (2) healthy older adults (ie, participants older than 65 years) [83,84,88,90,93,94,100,115,116,118,123,129,139,141,146,190]; (3) adult patients [81,82,89,95,97,114,119,127,128,130,133,135,136,138,140,144,145,147,150,151,154,156,169,170,176,183,184,187,194,197,198,201,203]; (4) older adult patients [162,165,175,182,206]; (5) healthy adults and adult patients [103,106,148,157,159,174,193]; (6) healthy adults and older adults [91,188]; and (7) healthy adults and older adult patients [80,96,107].

In terms of patients, the following conditions were identified: mental health disorders [81,82,85,92,95,97,103,104,119,121,123,124,132,147,149,150,153,155,165-170,172,173,179,181,184,188,191,204-206], cancer [138,145,182,183,197], heart disease [154], chronic kidney disease [144], chronic pain [105,162,198], COVID-19 [95], delirium [146], dementia [107], diabetes [89,96,111,115,140,194], heart failure [130,187], hydrocephalus [177], hypertension [133,203], intestinal ostomy [148], mild cognitive impairment [141], Parkinson disease [157,175], psoriasis [127], sickle cell disease [114], stroke [128,159,174], traumatic brain injury [151], traumatic injuries [106,180], vestibular disorders [189], and other unspecified chronic diseases [87,156].

XSL•FO
RenderX

Concerning the number of participants, the studies included a total of 7040 participants, of whom 875 were older adults. However, the sample sizes varied considerably across studies. Specifically, 56 studies [82,83,87,91,92,94,95,98-102,107,109,112-116,121,122,124,126,130,134-142,144,145,149,152,153,158,160,161,167,169,170,173,177,180,181,191,194,195,197,200,203,204,206] included more than 30 participants, and 18 of these studies [82,95,100,112,126,139,142,149,158,160,161,170,173,180,181,194,200,204] enrolled more than 100 participants. The remaining 71 studies included 30 or fewer participants.

Validated Subjective Assessment Instruments

Three categories of validated subjective instruments were identified:

- Usability assessment instruments: (1) PSSUQ [30], (2) SUS [31], (3) Chatbot Usability Questionnaire (CUQ) [207], (4) Computer System Usability Questionnaire (CSUQ) [208], (5) mHealth App Usability Questionnaire (MAUQ) [209], (6) Usability Metric for User Experience—Lite Version (UMUX-Lite) [210], and (7) Usefulness, Satisfaction, and Ease of Use Questionnaire (USE) [211].
- User experience assessment instruments: (1) User Experience Questionnaire (UEQ) [212] and (2) User Experience Questionnaire—Short Version (UEQ-S) [213].
- Acceptability assessment instrument: Acceptability E-Scale (AES) [214], which includes a subscale for assessing usability.

Nine studies [86,105,117,119,145,146,174,175,191] applied more than 1 assessment instrument: (1) UEQ and SUS [86,105,117,145,174,175,191]; (2) SUS and USE [119]; and (3) CUQ and SUS [146]. See Table 2 for the validated subjective assessment instruments.

Table 2. Validated subjective assessment instruments.

Instruments	Studies	Total, n
System Usability Scale	[80,81,83-90,92,96-98,100,105-109,111-123,126-130,132,133,135,136,140-142,144-148,150,151,153-157,160-168,170-172,174-177,179,180,182,184,186,190-202]	91
User Experience Questionnaire	[86,101-103,105,110,117,143,145,174,175,178,181,189,191]	15
Chatbot Usability Questionnaire	[125,134,138,146,203,204]	6
Computer System Usability Questionnaire	[91,99,131,139,205]	5
Acceptability E-Scale	[82,95,149,169,206]	5
mHealth App Usability Questionnaire	[159,173,185,187]	4
Usefulness, Satisfaction, and Ease of Use Questionnaire	[94,104,119,183]	4
User Experience Questionnaire—Short Version	[93,152,158]	3
Usability Metric for User Experience—Lite Version	[124,188]	2
Post-Study System Usability Questionnaire	[137]	1

Results of Usability and User Experience Assessments

The usability and user experience scores were generally high. The PSSUQ was applied in only 1 [137] study, which reported a total score of 6.0 (above average, ≥6). Additionally, Table 3 summarizes the ranges of usability and user experience scores for the remaining instruments, based on the studies that reported these scores.

Table 3. Range of the reported usability and user experience scores according to subjective assessment instruments and the standardized scores for each instrument indicating good usability.

Instruments	Score range	Standardized scores indicating good usability or user experience
System Usability Scale	51.4-93.8	≥70.0
Chatbot Usability Questionnaire	40.6-85.9	≥70.0
Computer System Usability Questionnaire	4.6-5.8	≥4.5
Acceptability E-Scale	22.0-25.4	≥24.0
mHealth App Usability Questionnaire	4.8-6.7	≥5.0
Usefulness, Satisfaction, and Ease of Use Questionnaire	4.5-5.7	≥5.0
Usability Metric for User Experience—Lite Version	82.4-86.1	≥70.0
User Experience Questionnaire and User Experience Questionnaire—Short Version	0.4-1.7	≥1.0

Comparative Analysis of the SUS Results

The following comparative analysis should be interpreted as exploratory because it synthesizes SUS scores reported by independent studies rather than direct comparisons conducted under common experimental conditions. Consequently, the observed differences among HCA categories may be influenced not only by the interaction modality itself but also by variations in health care application domains, study designs, evaluation contexts, participant populations, and HCA implementation and use characteristics. In addition, although the SUS is a well-established measure of perceived usability, it may not adequately capture important aspects of HCAs, such as conversational quality, which is influenced by factors including turn-taking, the ability to sustain coherent and continuous dialogue, and the naturalness of interactions.

Considering the studies that applied the SUS and reported usability scores, a significant difference among groups was found when comparing usability scores across the 3 HCA categories (P=.001; η^2H=0.11; Figure 5, Table 4). Pairwise comparisons showed significant differences between text-based and embodied HCAs (P=.02) and between text- and voice-based HCAs (P=.006). No significant difference was found between voice-based and embodied HCAs (P>.99). When comparing the number of participants across the 3 HCA categories, no significant difference was found (P=.18; η^2H=0.016).

Figure 5. Median and IQR for System Usability Scale (SUS) scores (group 1, text-based HCAs; group 2, voice-based HCAs; and group 3, embodied HCAs). HCA: health care conversational agent.

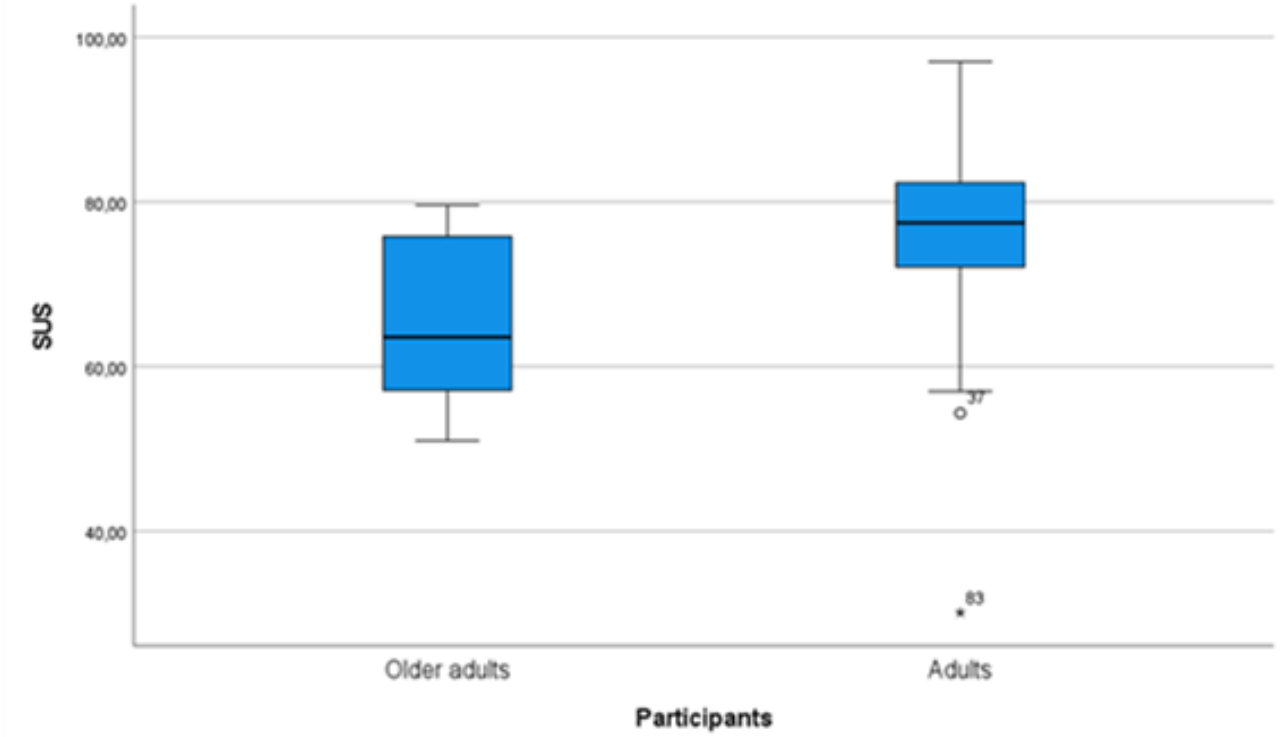
RenderX

Table 4. Comparative analysis of SUS[a] scores across the 3 categories of HCAs[b].

Category	Number of studies, n	Number of participants, median (IQR[c])	SUS scores, median (IQR[c])	SUS range
Text-based HCAs	58	30.00 (11.50-52.75)	78.70 (73.43-83.06)	51.40-97.00
Voice-based HCAs	18	22.00 (13.0-34.25)	69.55 (58.90-78.47)	51.00-85.00
Embodied HCAs	26	18.00 (11.00-26.25)	72.79 (62.29-79.38)	30.13-87.70



[a]SUS: System Usability Scale.

[b]HCA: health care conversational agent.

[c]25th-75th percentiles.

A significant difference in SUS scores was found when comparing studies involving adults with those involving older adults in the overall sample of studies (P<.001; r=0.39; Figure 6, Table 5). Similarly, a significant difference in SUS scores between studies involving older adults and those involving adults was found for text-based HCAs (P=.009; r=0.33), indicating lower SUS scores in studies involving older adults. No significant between-group difference was found for voice-based HCAs (P=.10; r=0.38) or embodied HCAs (P=.20; r=0.25).

Table 5. Comparative analysis of SUS[a] scores across age range (adults vs older adults).

Category and age group	Number of studies, n	SUS, median (IQR[b])
All HCAs[c]		
Adults	82	77.45 (72.06-82.43)
Older adults	19	63.56 (57.07-76.19)
Text-based HCAs		
Adults	51	79.50 (75.00-83.80)
Older adults	6	64.05 (55.58-78.28)
Voice-based HCAs		
Adults	13	72.10 (59.97-81.17)
Older adults	5	59.69 (52.17-72.00)
Embodied HCAs		
Adults	18	74.41 (67.36-81.08)
Older adults	8	63.75 (57.65-77.78)

[a]SUS: System Usability Scale.

[b]25th-75th percentiles.

[c]HCA: health care conversational agent.

Discussion

This review provides an overview of the current evidence on the usability and user experience of HCAs assessed using validated subjective instruments. As HCAs become increasingly widespread, a growing number of individuals interact with them daily, and it is anticipated that these agents will play an important role in future interactive systems. Therefore, it is crucial to investigate the assessment of their usability and user experience, particularly in the context of emerging human-machine interaction, because well-designed assessments contribute to the overall improvement of interactions. Although well-designed interactions do not necessarily mean that digital health applications are effective, their efficacy and effectiveness may be limited by usability and user experience constraints [215].

Patient care emerged as the predominant application domain for HCAs, particularly in mental health. Other reviews [8,216] have already identified the importance of patient care, while the efficacy of HCAs in supporting mental health disorders has been the subject of several systematic reviews (eg, [217,218]) and a meta-analysis (eg, [219]). Among the other application domains addressed, HCAs may support health education and prevention by optimizing the delivery of understandable, personalized health education at scale and by providing interactive and engaging information across platforms (eg, mobile, web, or smart devices) [220,221]. Similarly, health data collection has already been identified as a core use case of HCAs [216,222], namely, in terms of automating diagnostic interviews and longitudinal monitoring of patient-reported outcomes (eg, anxiety or depression scales) to track symptoms and adherence to treatments over time. Furthermore, the use of HCAs designed to promote the independence and autonomy of older adults by assisting them in managing activities of daily living and self-management of health conditions is in line with current interest in developing digital applications to support the care and well-being of older adults [223,224]. Another relevant point is that a high proportion of the studies included older adults, who accounted for 875 of the 7040 (12.43%) participants.

Although text-based HCAs were the most frequently evaluated, all 3 identified categories were applied across different health care domains. This suggests that developers select interaction modalities according to technological feasibility and user requirements rather than the clinical purpose itself.

The increasing integration of virtual reality with embodied HCAs reflects growing interest in immersive human-computer interaction. However, the relatively limited number of studies indicates that these technologies remain at an early stage of adoption in health care, likely due to higher development costs, hardware requirements, and implementation complexity.

Although AI was increasingly incorporated into HCAs, most of these implementations appear to remain at a relatively immature stage, which is consistent with other studies demonstrating the difficulties of translating AI implementations into clinical workflows [225-227].

SUS clearly dominated the assessment of HCAs, despite having been developed for generic interactive systems. SUS is widely used for usability evaluation of different types of digital health applications [215,228-230] because it is an easy and quick tool with a scoring system that has been translated into multiple languages [228]. However, it was not originally developed to assess complex multimodal interaction mechanisms and does not capture the holistic user experience because it focuses only on usability aspects such as ease of use, satisfaction, and learnability.

Although several alternative instruments were identified, CUQ was the only instrument specifically appropriate for assessing HCAs, even though it does not fully capture the multimodal

XSL•FO
RenderX

and AI-driven characteristics of modern HCAs. The absence of recently developed instruments [46], such as the Conversational Agents Scale [231], the Conversational Agent's Usage Scale [232], the User Experience Evaluation of Conversational Agents [233], or the Conversational Agent Scale for User Experience [234], further highlights the need for greater methodological standardization in future evaluations. Moreover, a relevant number of studies were excluded from this review because usability and user experience assessments were based on questionnaires consisting of Likert scale questions developed by the researchers. However, these questionnaires were not validated instruments because they had not undergone psychometric analysis, which is frequently a lengthy process that can be particularly challenging for researchers who lack experience in developing and validating subjective instruments.

Usability and user experience assessments were conducted in both controlled (ie, research or academic settings, outpatient clinical settings, hospital clinical settings, and institutional residences for older adults) and uncontrolled (eg, participants' homes) environments. Controlled experiments generally focus on intensive sessions to capture immediate usability or user experience feedback. These experiments enable consistent data collection, but they may constrain the observation of more natural interaction patterns. By contrast, longitudinal studies conducted in uncontrolled settings allow participants to engage with HCAs more organically, integrating their use into daily routines. Therefore, uncontrolled environments provide authentic user experiences and valuable insights, as well as functional challenges, including connectivity issues, reflecting authentic usage scenarios. Moreover, many longitudinal studies strategically combined uncontrolled environments with data collection in controlled environments.

The participants comprised both patients and healthy adults or older adults. However, the reviewed studies often did not adequately justify their choice of sample sizes. Small samples can undermine the reliability of results by increasing the risk of sampling bias and reducing statistical power. Consequently, the findings may not capture the full variability of the population, thereby restricting their generalizability.

The quality assessment of the components related to the application of subjective measurement instruments highlighted methodological limitations, including insufficient evaluation of prolonged real-world use and inadequate justification of sample sizes, the 2 CAUSS items with lower percentages. These shortcomings reduce confidence in the ecological validity and generalizability of the reported usability findings.

Looking at the assessment results, the usability and user experience of HCAs tend to be above average; however, the results indicate differences among the various HCA categories. The comparison of usability scores across the 3 HCA modalities revealed statistically significant differences, with pairwise comparisons indicating that text-based HCAs achieved significantly higher usability scores than both voice-based and embodied HCAs, whereas no significant differences were observed between voice-based and embodied HCAs. The estimated eta-squared (η^2H=0.11) indicates a moderate effect size, suggesting a moderate association between interaction modality and users' perceptions of usability. No significant differences were found in the number of participants across the 3 HCA categories, indicating that the studies included broadly comparable sample sizes. Consequently, systematic differences in study size are unlikely to fully explain the observed differences in usability.

Several factors may contribute to the higher usability observed for text-based HCAs. Although the reviewed studies did not directly investigate the underlying mechanisms, one possible explanation is users' greater familiarity with text-based communication, particularly through messaging applications. Moreover, text interfaces provide a persistent conversation history that enables users to review previous exchanges, potentially increasing their sense of control and reducing memory demands during interaction. In addition, text-based interactions allow users to engage with HCAs at their own pace, giving them more time to read, reflect on, and formulate responses. By contrast, voice-based HCAs may be affected by speech recognition inaccuracies, environmental noise, and privacy concerns, whereas embodied HCAs introduce additional visual and social interaction elements that may increase interaction complexity without necessarily improving perceived usability.

The results also suggest that older adults tend to perceive HCAs as less usable than adults. This may be associated with older adults generally having lower digital literacy, as well as age-related accessibility needs. For example, age-related sensory, cognitive, and motor changes, together with the higher prevalence of multimorbidity among older adults, may affect their ability to interact effectively with HCAs. Nevertheless, the available evidence from the included studies does not allow this explanation to be confirmed.

Interestingly, the difference between adults and older adults was statistically significant only for text-based HCAs, despite this modality achieving the highest usability scores overall. A potential explanation is that text-based HCAs are currently more widespread than voice-based or embodied HCAs, which may lead to greater differences in familiarity and prior experience between age groups.

Although no statistically significant age-related differences were observed for voice-based or embodied HCAs, the estimated effect sizes were of comparable magnitude across modalities. Therefore, the absence of statistical significance may reflect the smaller number of available studies and limited statistical power rather than provide evidence that age has no influence on perceived usability in these interaction modalities.

These results should be interpreted with caution. The included studies exhibited substantial heterogeneity in terms of application domains (patient care, health education and prevention, health data collection, and support for daily activities), study designs (eg, cross-sectional or longitudinal), evaluation contexts (controlled versus real-world settings), target populations, underlying technologies (eg, AI, large language models, or virtual reality), task complexity, and duration of HCA use (single-session vs prolonged use). Consequently, the observed differences in SUS scores may have been influenced by factors beyond the interaction modality itself. Furthermore,

XSL•FO
RenderX

the SUS assesses perceived usability rather than objective performance or long-term acceptance, and therefore high SUS scores do not necessarily translate into sustained engagement or continued use. Future studies should investigate which specific design characteristics contribute most to usability across different HCA modalities while accounting for user characteristics and contextual factors.

Despite the use of extensive search strategies to locate relevant studies, some articles may have been overlooked due to variations in terminology. Furthermore, the exclusion of non-English publications and gray literature may have limited the overall representativeness of the findings and introduced language and publication bias, as studies published in other languages or unpublished studies with null or negative findings may have been underrepresented.

The wide variety of assessment instruments used meant that it was generally not possible to identify enough studies to enable a comparative analysis of usability or user experience outcomes by instrument across different HCA categories. The only exception was SUS; however, as it was developed in the 1990s, it may not adequately capture relevant aspects of the usability of modern HCAs.

Finally, this review focused solely on the usability and user experience of HCAs and did not address their efficacy or effectiveness.

In conclusion, this review included 127 studies applying validated subjective instruments to assess the usability and user experience of 3 HCA categories: text-based, voice-based, and embodied HCAs. In terms of health care applications, HCAs aimed to support patient care, health education and prevention, health data collection, and daily activities of older adults.

The usability and user experience of HCAs were assessed in cross-sectional and longitudinal studies using the following instruments: SUS, UEQ, UEQ-S, CUQ, AES, MAUQ, UMUX-Lite, USE, CSUQ, and PSSUQ.

This review highlights that, except for CUQ, the identified subjective assessment instruments were not specifically developed to evaluate the usability and user experience of HCAs. Therefore, the findings suggest that such evaluations may be limited by the inadequacy of these instruments.

Considering the comparative analysis of SUS scores, text-based HCAs tend to show higher usability scores than voice-based and embodied HCAs, and older adults tend to perceive HCAs as less usable than adults. However, these findings represent associations observed across the included studies rather than direct evidence that one HCA category is inherently more usable than another, because the studies differ substantially in their health care applications, design, evaluation contexts, participant populations, and implementation and use characteristics. Moreover, a relevant number of studies used small sample sizes, which reduce statistical power, may fail to capture population variability, limit the generalizability of the results, and increase the risk of misleading conclusions. Most HCAs were also assessed in controlled environments at a single point in time, without considering the impact of continuous and long-term use in real-world settings.

Considering the substantial differences in how evaluations were designed and conducted across studies, especially regarding data collection methods, participant selection, testing conditions, and reporting of results, there is a need for standardized protocols and established guidelines to measure the usability and user experience of HCAs. Such standardization would improve methodological consistency and enhance the comparability of findings across studies, enabling researchers and practitioners to benchmark usability and user experience.

Abstract

Background: Although medication reconciliation is known to reduce the frequency of medication errors, its practical implementation can be challenging in several respects. In our institution, pharmacy students perform medication reconciliations at admission under the supervision of a pharmacist or pharmacy resident.

Objective: The objective of the study was to evaluate the impact of peer supervision (ie, the supervision by a pharmacy student of a medication reconciliation performed by another pharmacy student) on the accuracy and efficiency of admission medication reconciliations.

Methods: A prospective, single-center, observational study was conducted in 2 clinical departments at Lille University Medical Center (Lille, France). Initially, organizational procedures were defined and a checklist for reconciliation supervision was developed. A baseline (reference) period without peer supervision was compared with an implementation period with peer supervision.

Results: A total of 317 medication reconciliations were conducted: 102 (32.2%) without supervision and 215 (67.8%) with supervision by a pharmacy student. Peer supervision reduced the pharmacist time required for this task by 52%; the mean time decreased from 23 (SD 11) minutes to 11 (SD 6) minutes. Furthermore, peer supervision was associated with a decrease in the number of errors made by students (from 1.5 to 0.9 per reconciliation) and detected by pharmacists during reconciliation validation.

Conclusions: Student peer validation appears to be an innovative, strategic method for optimizing medication reconciliations, freeing up pharmacist time, and leveraging the skills of pharmacy students.

Introduction

Admission medication reconciliation plays a crucial role in the prevention and interception of medication errors [1,2]. It ensures the accurate and comprehensive transfer of information about patients' home medications among health care professionals [3]. Admission medication reconciliation also addresses other objectives, including continuity of treatment, diagnosis of drug-related iatrogenesis, and establishment of a reliable reference dataset for subsequent medication reviews.

Patient admission is a critical moment for medication safety: the risk of prescription errors is 70% higher on admission than during the rest of the hospital stay [4]. To address this problem, admission medication reconciliation is crucial for the improvement of patient safety and care quality. This practice is now essential in modern health care. With a view to maximizing the benefits of admission medication reconciliation and reducing medication-related errors, our institution (Lille University Medical Center, Lille, France) is now considering

XSL•FO
RenderX

the expansion of this reconciliation technique from high-risk patients only to a broader range of patients [5].

The implementation of clinical pharmacy activities requires changes in organizational practices as a function of available human resources. In our institution, about 50 pharmacy students are assigned to clinical departments. Some of these students conducted medication reconciliations by preparing "best possible medication histories" (BPMHs) [6]. These histories were then compared with admission prescriptions under the supervision of a pharmacist or pharmacy resident [7]. All the pharmacy students attended a standardized program of practical and knowledge-based training sessions developed by 4 of our clinical pharmacists. Each student was then qualified by the supervising pharmacist of the clinical service using a validated checklist of criteria.

Medication reconciliation is increasingly recognized as a critical component of patient safety and is now integrated into care pathways in many health care systems. In France, its implementation is included as a certification criterion by the French National Authority for Health (*Haute Autorité de Santé*, HAS), particularly for high-risk patient groups, such as those in geriatrics and oncology. Despite its recognized importance, medication reconciliation remains challenging in hospital settings, primarily due to the significant time investment required from pharmacists, which competes with their other responsibilities. Its successful implementation depends on both the commitment of health care professionals and the resources allocated, factors that are often limited in practice [8,9]. There are various strategies for optimizing hospital resources, especially when reconciliation involves a number of different health care stakeholders (eg, pharmacy technicians and nurses) [10,11]. The BPMHs drawn up by pharmacy students and pharmacy technicians as part of the medication reconciliation process are accurate and efficient, reduce costs, and provide support for other health care professionals [12]. However, some errors persist, due to the students' limited clinical experience and the relatively short duration of their placements—typically up to 3 months and sometimes on a part-time basis. Therefore, oversight by experienced pharmacists remains essential to maintain the quality and safety of the reconciliation process, given that these individuals are still in training. In our acute geriatric units (AGUs) and internal medicine departments (IMDs), medication reconciliation is particularly time- and resource-intensive; hence, we are exploring organizational changes that can address constraints on pharmacist time. One of these changes might be the introduction of student supervisors as a means of supporting pharmacy residents and pharmacists.

We hypothesized that incorporating peer review, a process commonly used in scientific research for critical evaluation [13], into medication reconciliation could both optimize pharmacist time and maintain high-quality practices. Additionally, supervision and peer review may provide pharmacy students with valuable opportunities to develop essential professional skills, including effective communication, priority management, teamwork, and cohesion.

The objective of this study was to evaluate the impact of a peer supervision process among pharmacy students on the accuracy and efficiency of admission medication reconciliations.

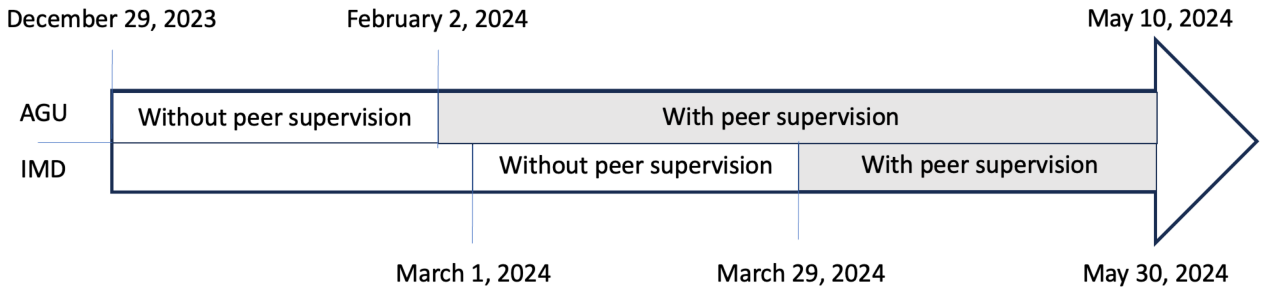
Methods

Study Design

This was a prospective, single-center, observational study conducted at Lille University Medical Center in 2 phases in an AGU and an IMD. In the initial, qualitative phase, we developed an organizational model. In the second phase, we evaluated this organizational model by collecting data on admission medication reconciliations for patients aged 65 years and older.

Medication reconciliation was performed in accordance with the recommendations of Haute Autorité de Santé, which defines four essential steps in its implementation: (1) collection of information on medications currently taken or intended to be taken by the patient, (2) development of a BPMH synthesizing this information, (3) validation of the BPMH, and (4) sharing and use of the BPMH within the care team [10]. The medication reconciliation process was conducted under the responsibility of each clinical pharmacist who was a member of the multidisciplinary team involved in the patient's care. This process did not include medication prescribing by the pharmacist but was based on communication and collaboration with the physician responsible for the patient's follow-up.

To ensure that reconciliations were comprehensively reviewed by supervisors, we considered various tools for guiding the students. Discussions between the initiating investigators thus led to the development of a checklist for the student supervisor. The supervisory checklist was developed through a multistep, consensus-building process [14] (Multimedia Appendices 1-4). First, 2 investigators created a draft version of the checklist and shared it with the reference pharmacists involved in medication reconciliation. The latter evaluated each item, provided feedback, and suggested improvements. The checklist was revised accordingly and sent back to the reference pharmacists for further assessment. This iterative process continued until a consensus on the checklist's content was reached.



The study was conducted from December 2023 to May 2024 in an AGU and an IMD at Lille University Medical Center. The evaluation period comprised a baseline phase from December 2023 to February 2024 (during which medication reconciliation data were collected without supervision and without a checklist) and an intervention phase. Although consensus on the final checklist was achieved in April 2024, an initial version was used for supervision in February and March 2024. The evaluation involved a reorganization that allowed trained volunteer students to review, modify, and validate their peers' admission medication reconciliations in collaboration with pharmacists and pharmacy residents. The BPMHs and the medical prescriptions at admission were recorded in our medical center's electronic patient record system (Sillage, version 22.1; MipihSIB).

For each department, the evaluation was carried out over 2 periods (Figure 1). The first period served as a baseline: admission medication reconciliations performed by pharmacy

XSL•FO
RenderX

students were supervised solely by pharmacy residents or pharmacists. The second (intervention) period corresponded to student supervision of admission medication reconciliations conducted by other pharmacy students. The supervising students were trained in 2 stages. Initially, a clinical pharmacist with postgraduate specialty training and 7 years of experience or a final-year pharmacy resident in clinical pharmacy supervised an admission medication reconciliation and demonstrated the method to the student. Once the student had learned the method, they supervised a reconciliation by another student but under the observation of the clinical pharmacist or the final-year pharmacy resident in clinical pharmacy. If the pharmacist validated the student's skills, the latter was allowed to supervise another student's admission medication reconciliations alone.

Figure 1. Study timeline by department. AGU: acute geriatric unit; IMD: internal medicine department.

Variables

The study data were collected by 2 investigators (a clinical pharmacist in the IMD and a final-year pharmacy resident in the AGU) using a standardized collection form. For each reconciliation, the following data were recorded. First, we recorded the total time taken by the student to complete the medication reconciliation [15]. In both phases of the study, this duration included the time spent collecting and checking the patient's medication information for a BPMH, comparing the BPMH with the medicines prescribed at admission, and identifying and rectifying any discrepancies [7]. The BPMH integrates multiple information sources, prioritized according to their reliability, including primary objective data (outpatient pharmacy dispensing records and electronic prescriptions), interviews with community pharmacists, telephone contact with the primary care physician, prior medical documentation of treatment changes, patient or caregiver interviews, and hospital medical records. Patient-reported discrepancies that cannot be independently verified are flagged. Reconciliation accuracy is assessed by comparing the BPMH with clinical judgment and current prescriptions: clinically justified discrepancies (eg, temporary withholding of anticoagulant therapy due to bleeding risk) are considered appropriate when clearly documented and communicated, whereas unintentional discrepancies (such as omissions, duplications, or dosing errors) are classified as medication errors requiring resolution. Second, we recorded the time taken by the pharmacist to validate the medication reconciliation (after the latter had been supervised by a student, if applicable), up until the discussion with the prescriber. Third, we recorded the errors identified and corrected by the student supervisor and/or pharmacist, including the number, type, and medications involved. An "error" was defined as an omission, unjustified addition, or misinterpretation of an element in the student's observation that contradicted the instructions received during the training or a specific item of the validation checklist. All identified errors were analyzed. Fourth, we recorded the total number of medications per BPMH. Fifth, we recorded the adverse drug event risk score developed by Trivalle et al [16], which has been validated in patients aged 65 years and older in France. The score is derived from 3 risk factors: polypharmacy (≥7 medications), antipsychotic treatment, and recent anticoagulant exposure within the previous 3 months. Sixth, we recorded the initials of the student supervisor and the validating pharmacist.

The number of errors identified and corrected by pharmacists, as well as the time required for pharmacists to validate medication reconciliations, was assessed in 2 independent samples before and after the implementation of student supervision. This approach enabled us to estimate the impact of student oversight on the quality and efficiency of admission medication reconciliations performed by peers. No threshold for an acceptable number of errors was defined; all errors were recorded, whether identified by the student supervisor or the supervising pharmacist, without distinguishing between the 2 sources.

Statistical Analysis

The data were entered into computer spreadsheets (Microsoft Excel). Qualitative variables were described as the frequency (percentage). Quantitative variables were described as the mean (SD) or, when the data were not normally distributed, the median (IQR). The normality of distribution was assessed both graphically and with the Shapiro-Wilk test.

The 2 periods (baseline and intervention) were compared using 2-tailed Student *t* test or, when the data were not normally distributed, the Mann-Whitney *U* test. The comparison included all medication reconciliations performed without peer supervision (baseline phase) and all peer-supervised medication reconciliations (intervention phase). Reconciliations performed by student supervisors were not included because they did not involve supervision, as only 1 supervisor was available per week.

The number of errors before and after the introduction of student supervision was analyzed using a generalized linear regression model for count data (negative binomial distribution with log link function), adjusted for confounding factors (the number of medications per BPMH, the adverse drug event prediction score, and time taken by the student to perform the reconciliation). An adjusted rate ratio (RR) with 95% CI was reported as a

XSL•FO
RenderX

measure of association. The time taken by the pharmacist to correct and validate the reconciliation before and after the introduction of student supervision was compared by applying the same method.

Factors associated with the number of errors found in each reconciliation by the pharmacist were identified in a generalized linear regression model for count data (negative binomial distribution with a log link function). Again, the RR (95% CI) was calculated as a measure of association. Factors associated with the time taken by the pharmacist to correct and validate the reconciliation were identified by applying the same method.

The association between the number of errors and the time taken by the pharmacist was assessed by calculating the Spearman correlation coefficient (ρ).

The threshold for statistical significance was set at $P<.05$. All statistical analyses were performed using SAS software (version 9.4; SAS Institute Inc).

Ethical Considerations

No personal data (medical or otherwise) of the patients involved in the reconciliations were collected. In line with French legislation, neither informed consent nor approval by an institutional review board was required or sought. The study database was registered with the data protection officer of Lille University Hospital under the terms of the MR-004 French national reference methodology [17] on the processing of personal data for study, evaluation, or research purposes not involving human subjects.

Results

Overview

The evaluation phase involved various pharmacists and pharmacy students. The first part involved 2 pharmacists, and the second part involved 15 students (including n=8, 53.3% supervisors), 3 pharmacists, and 2 pharmacy residents. Data on 317 admission medication reconciliations were collected: 102 (32.2%) reconciliations were not peer supervised (n=31, 9.8% in the AGU and n=71, 22.4% in the IMD), and 215 (67.8%) were peer supervised (n=191, 60.3% in the AGU and n=24, 7.6% in the IMD). A rotation system had been set up in the AGU: of the 4 pharmacy students involved, 1 supervised the reconciliations for 2 weeks at a time, and the remaining 3 performed the reconciliations. In the IMD, a student supervised the other 2 students.

The Medication Profile of the Patients Included in the Study

The mean number of medications per BPMH was higher during the student-supervised period than during the nonsupervised period (9.6, SD 3.8 vs 8.6, SD 4 medications, respectively), whereas the mean total time needed for reconciliation was shorter (138, SD 42 min vs 174, SD 96 min, respectively; Table 1). The adverse drug event risk score was similar in the 2 periods.

Table . Comparison of the reference and implementation phases regarding patient medication profiles and the duration of reconciliations performed by students.

	Without peer supervision (n=102)	With peer supervision (n=215)	*P* value
Adverse drug event risk score, median (IQR)	3.0 (0-6)	4.0 (1-6)	.10
Total number of medications in the best possible medication history, mean (SD)	8.6 (4)	9.6 (3.8)	.047
Total time taken by the student to complete the reconciliation (min), mean (SD)	174 (96)	138 (42)	<.001

Factors Influencing the Time Taken by the Pharmacist to Validate a Reconciliation

The time taken by the pharmacist was significantly associated with the number of medications per BPMH (RR=1.03, 95% CI 1.01 - 1.04; $P=.001$). However, this time was not influenced by the adverse drug event prediction score (RR=1.02, 95% CI 0.99 - 1.04; $P=.05$) or the time taken by the student to perform the reconciliation (RR=1.02, 95% CI 0.96 - 1.08; $P=.06$).

Factors Influencing the Number of Errors Corrected by the Pharmacist

The number of errors corrected by the pharmacist was significantly associated with the number of medications per BPMH (RR=1.09, 95% CI 1.05 - 1.12; $P<.001$), the time taken by the student to perform a reconciliation (RR=1.19, 95% CI 1.06 - 1.33; $P=.004$), and the adverse drug event prediction (RR=1.10, 95% CI 1.05 - 1.14; $P<.001$).

Impact of Peer Supervision

Our results showed that the number of errors was smaller and the total pharmacist time was shorter during the student-supervised period than during the nonsupervised period (Table 2). The mean time taken by the pharmacist to rectify errors in reconciliation was significantly shorter during the student-supervised period (mean 11, SD 6 minutes) than during the nonsupervised period (mean 23, SD 11 minutes); this corresponded to a time saving of 53% (RR=0.47, 95% CI 0.42 - 0.52; $P<.001$). Moreover, the number of errors corrected by the pharmacist fell from 1.5 to 0.9 (a 36% decrease; RR=0.64, 95% CI 0.49 - 0.83; $P<.001$). For the study period as a whole (N=317 admission medication reconciliations), we observed a significant linear correlation between the time taken by the

XSL•FO
RenderX

pharmacist and the number of errors rectified (ρ=0.45, 95% CI 0.38 - 0.55; *P*<.001).

Table . Impact of peer supervision on the number of errors corrected and the pharmacist validation time.

	Without peer supervision (n=102), mean (SD)	With peer supervision (n=215), mean (SD)	Rate ratio (95% CI)	*P* value
Time taken to validate the reconciliation (minutes)	22.5 (10.9)	11.4 (6.08)	0.47 (0.42 - 0.52)	<.001
Number of errors corrected	1.5 (1.51)	0.9 (1.24)	0.64 (0.49 - 0.83)	<.001

Analysis of Errors

We identified 143 errors corrected by student supervisors or pharmacists (Multimedia Appendix 5). Not all errors were described in detail. The most frequent error (accounting for n=25, 17.5% of all errors) was the omission of the precise administration frequency for as-needed (ie, on-demand) medications. The second most frequent error (n=13, 9.1%) was the misinterpretation of differences between the patient's medication history and the admission prescriptions.

The analysis of reconciliation errors also enabled us to identify the most frequently involved drug classes: other analgesics and antipyretics were involved in 28 (19.6%) errors, followed by antihypertensives (n=18, 12.6%; Multimedia Appendix 6).

Discussion

Principal Findings

Peer validation of admission medication reconciliations by pharmacy students proved to be effective in optimizing the pharmacists' working time; the average pharmacist time per reconciliation decreased from 23 minutes to 11 minutes, and the average number of errors made by the student conducting the reconciliation fell from 1.5 to 0.9. However, these reconciliation time savings must be balanced against the time required to train the student supervisors, that is, 2 to 4 half-days. We observed a significant linear correlation between the time spent by pharmacists and the number of errors rectified (*P*<.001), which confirmed the validity of our data.

In France, the current regulations do not specify how admission medication reconciliations should be validated. Here, we chose to have all student-conducted and student-supervised reconciliations validated by a pharmacist or a resident to ensure the quality of the work performed. Accordingly, the pharmacy students entered their reconciliation reports into our medical center's electronic patient record system so that the validated reconciliations could be consulted by the prescribers. According to the French Society of Clinical Pharmacy (Société française de pharmacie clinique), the pharmacist is the guarantor of the reconciliation process [18] and the validation of certain steps in this process [15].

Peer evaluation in pharmacy education is a valuable pedagogical tool that helps students develop key skills such as communication, teamwork, priority management, and critical thinking [19]. It fosters accountability, self-reflection, empathy, and cultural sensitivity within a supportive, student-centered environment. Peer learning also enhances satisfaction for both students and supervisors, promotes lifelong learning, and is cost-effective [20]. Although commonly used in research and initial training, peer evaluation is less documented in hospital pharmacy settings [21-23]. However, studies show that peer mentoring improves academic success [24] and practical skills. Peer supervision encourages open feedback [25], motivation, and confidence by creating a less hierarchical and collaborative learning atmosphere [26]. However, successful implementation relies on a culture of transparency and mutual trust. Peer supervision may also improve the quality of patient care and can help pharmacy students to acquire skills that will be essential in their careers.

With a view to improving the student supervision of admission medication reconciliations, we developed a checklist. This type of tool is known to be effective because it ensures that no details are overlooked, saves time (by providing a written reference instead of relying on memory), and enhances overall organization. Checklists are widely used in the medical field in general and operating rooms in particular; the cross-checking of essential criteria before, during, and after each operation helps increase levels of safety and efficiency [27].

It has been reported that the empowerment of students with medication reconciliation tasks positively influences their perception of future responsibilities and helps them develop field-specific, general, and organizational skills [28]. Active participation enhances the students' perceived level of autonomy [29]. In a questionnaire, the pharmacists stated that they favored student supervision of admission medication reconciliations under certain conditions, such as those with specialty-specific issues and medication switching. Student involvement allows health care institutions to free up pharmacist time and reinforces trust in medication histories [30]. Trust—based on training, evaluations, and qualifications—is crucial for assigning tasks and peer supervision. Key concepts guiding supervising students are professionalism, self-awareness, and communication [31]. Training in medication reconciliation is essential and improves students' comfort, confidence, and skills [32]. Supervisors require specific training and experience to assess their peers' work accurately. Learning programs enable students to contribute to continuity of care activities and are crucial in pharmacy faculties for enhancing preparation for practice, adding value to patient care, and benefiting the health care system [33].

Although these positive outcomes were evident, the student supervisors' impact on admission medication reconciliations might have been underestimated. During the reference phase (ie, with nonsupervised reconciliations), the pharmacy students were well integrated into the team and were actively engaged in discussions with prescribers before validation. This high level

XSL•FO
RenderX

of integration might have reduced the number of errors (relative to what might be expected with novice students) and thus might have partly masked the true benefits of supervision. Furthermore, reconciliations performed by student supervisors were not included in the evaluation phase because they did not involve supervision, which explains the lower number of reconciliations. Other limitations of our study should be acknowledged, including an imbalance in recruitment between the 2 departments and the single-center nature of the study, which warrants confirmation of our findings in other organizational contexts.

This research could be extended by an evaluation of the system in other health care departments, a comparison of the clinical pharmacists' activity indicators with and without student pharmacist supervision, and the measurement of levels of satisfaction among students, pharmacists, and prescribers [34].

Analysis of errors in our geriatric population showed that first-line analgesics were most frequently involved, with the main error being students' failure to specify the dosing frequency for as-needed medications. It remains unclear whether these errors were due to knowledge gaps or simple oversight, as we did not distinguish between errors made under supervision by more or less experienced supervisors. Further evaluation of pharmacist interventions and the context of these errors would help clarify whether they stem from carelessness on the part of the student or a lack of professional practice-based knowledge.

Supervision develops autonomy and can be viewed as an entrustable professional activity, that is, a specific task that a student can perform independently once competent [35]. This approach balances autonomy against safety, especially in areas such as geriatrics, where there is a high risk of adverse drug events and potentially unfamiliar medication switches. Supervision creates a training pathway toward autonomous practice, although senior verification is still required to ensure care quality and patient safety. According to the literature on medication review analysis, the integration of a checklist into an artificial intelligence process might enhance efficiency, reduce errors, and improve traceability [36]. However, final validation by a pharmacist is still essential for maintaining rigorous standards and high-quality outcomes amid ongoing technological progress.

Conclusions

A new peer supervision method for admission medication reconciliations by pharmacy students optimized pharmacists' working time and was successfully integrated into our IMDs and AGUs. This validation process helped identify and correct potential errors or inconsistencies before reconciliations were finalized. Peer supervision reduced errors through the use of a standardized procedure and specific training. By decreasing the number of errors to be corrected, this approach reduced the time that pharmacists spent validating reconciliations. This new organizational model had a positive impact by improving pharmacists' time management and availability for other activities, while also providing students with substantial educational benefits in medication reconciliation.

Acknowledgments

The authors would like to thank the pharmacy students and pharmacists who participated in the development and evaluation of the organizational model.

Abstract

Background: Centralized electronic surveillance systems are widely used in intensive care settings to support continuous physiological monitoring and patient safety. Failures in health information technology (HIT) infrastructure can disrupt workflows, reduce situational awareness, and create latent risks for serious harm. Understanding such events requires analytic approaches that go beyond single-classification frameworks.

Objective: This study aimed to classify and analyze an HIT-related incident that involved loss of central surveillance data in a heart intensive care unit using multiple complementary patient safety and human factors frameworks.

Methods: This study is a qualitative case report analysis of an incident in which a central surveillance system intermittently lost server connectivity, resulting in unavailability and loss of monitoring data. The narrative was derived from an incident report and supporting documentation and was translated and linguistically adapted for publication. The incident was independently classified using 5 frameworks: the International Classification for Patient Safety (ICPS), the Health Information Technology Classification System (HIT-CS), Systems Engineering Initiative for Patient Safety (SEIPS) 2.0, the sociotechnical model by Sittig and Singh, and the Human Factors Analysis and Classification System for health care (HFACS-Healthcare). Findings were synthesized across frameworks.

Results: All 5 frameworks characterized the event as an HIT-driven system failure involving information unavailability, delayed detection, and multi-patient impact. The HIT-CS identified a technical failure in system availability and recovery. The ICPS classified the event as a documentation or information incident with potential for severe harm. The SEIPS 2.0 and sociotechnical models highlighted disruptions to monitoring tasks and the organization's reliance on IT intervention. The HFACS-Healthcare attributed the event primarily to organizational influences and preconditions for unsafe acts, with no frontline unsafe acts identified. Convergence across frameworks emphasized system-level contributors.

Conclusions: HIT-related monitoring failures in high-acuity settings are best understood as sociotechnical system events rather than isolated technical faults or individual errors. A multi-framework approach provided complementary insights into detection, recovery, and governance vulnerabilities, supporting improved learning and resilience in clinical surveillance systems.

Introduction

Health information technology (HIT) is increasingly embedded in high-acuity clinical environments, where system reliability is critical for patient safety. Centralized electronic surveillance systems are widely used in intensive and cardiac care units to support continuous physiological monitoring, early detection of deterioration, and retrospective review of patient data [1,2]. While such systems offer substantial safety benefits, failures in HIT infrastructure can disrupt clinical workflows, obscure patient status, and create latent risks for severe harm [3,4]. Therefore, understanding and learning from HIT-related incidents remains a priority for patient safety research [5,6].

Incident reporting systems capture a wide range of adverse events and near-misses, but single-classification approaches often fail to fully capture the complexity of HIT-related failures [6,7]. To address this limitation, several complementary classification frameworks have been developed, each emphasizing different aspects of safety incidents. The World

XSL•FO
RenderX

Health Organization's International Classification for Patient Safety (ICPS) provides a standardized, high-level taxonomy for categorizing incident types, patient outcomes, and contributing factors, supporting comparability across settings and jurisdictions [8]. However, the ICPS does not explicitly focus on the mechanisms underlying HIT failures [9].

To more precisely characterize HIT-related safety events, Magrabi, Jabin, and colleagues developed the Health Information Technology Classification System (HIT-CS), which focuses on information flow, technical failure modes, and outcome manifestations specific to HIT [6,10,11]. The HIT-CS enables detailed identification of where and how HIT failures arise, such as system unavailability, data loss, or delayed detection, and has been widely used in analyses of technology-induced errors [12-14]. Previous research has highlighted limitations in existing incident reporting structures for HIT-related events and emphasized the need for refined classification systems to support meaningful learning and governance [15]. Strengthening classification frameworks is particularly important in high-acuity environments where system-level failures may have multi-patient implications.

In parallel, human factors and systems engineering frameworks offer additional perspectives on how technology interacts with people, tasks, and organizations. The Systems Engineering Initiative for Patient Safety (SEIPS) 2.0 model conceptualizes patient safety as an emergent property of the work system, encompassing interactions among technology, tasks, people, organizational structures, environments, and processes [16]. SEIPS supports the analysis of how HIT failures disrupt clinical work and contribute to unsafe conditions rather than focusing solely on technical faults [17].

Similarly, the sociotechnical model proposed by Sittig and Singh [18,19] emphasizes that HIT safety incidents arise from interdependencies among technical infrastructure, clinical content, human-computer interfaces, workflows, organizational policies, external pressures, and system monitoring. This framework is particularly useful for identifying latent conditions and design vulnerabilities that may not be apparent when incidents are examined through a single disciplinary lens [20].

Finally, human factors classification systems such as the Human Factors Analysis and Classification System (HFACS) for health care (HFACS-Healthcare) provide a structured approach to examine human, supervisory, and organizational contributors to safety events [21]. HFACS-Healthcare allows differentiation between frontline actions, preconditions for unsafe acts, supervisory factors, and organizational influences and is especially valuable for demonstrating when incidents are driven by system-level factors rather than individual error [22,23].

This case report describes an HIT-related incident involving loss of central patient surveillance data in a heart intensive care unit. To provide a comprehensive and methodologically rigorous analysis, the incident was classified using 5 complementary frameworks: ICPS, HIT-CS, SEIPS 2.0, the Sittig and Singh sociotechnical model, and HFACS-Healthcare. By applying multiple classification systems to a single incident, this study aimed to illustrate how different frameworks contribute distinct and complementary insights into HIT-related patient safety risks and to support more comprehensive learning from HIT failures.

Methods

Study Design

This study is a qualitative case report that describes and analyzes an HIT-related patient safety incident that occurred in a heart intensive care unit. A single-incident case design was chosen to enable an in-depth examination of technical, organizational, and human factors contributing to the event. Case reports are well suited for studying rare or complex HIT failures and for generating transferable safety insights when experimental or quantitative approaches are not feasible [1,3,12,24].

Ethical Considerations

This study involved secondary analysis of a fully deidentified incident report obtained from a national incident reporting repository. The data contained no patient identifiers or confidential information. Ethical advice was obtained from the Ethical Advisory Board in southeast Sweden (Dnr 934 - 2023). Based on the retrospective analysis of anonymized quality and safety data, formal ethical review and informed consent were not required under applicable regulations (the Swedish Ethical Review Act 2003:460) [25].

Data Source and Incident Selection

The incident analyzed in this study was obtained from a national incident reporting repository that captures medical device–related and HIT-related events reported by health care professionals and clinical engineering staff. The incident reports in the repository typically include structured fields and free-text narratives describing the incident, the results of any internal investigation, and measures taken in response [26-28]. A single incident was selected for analysis on the basis of the following criteria:

- involvement of a medical device with embedded software,
- manifestation of the incident during active clinical care,
- relevance to HIT-mediated information loss, and
- availability of sufficient narrative detail to support qualitative analysis.

The incident report included 3 core narrative components: an incident description, a summary of investigation findings, and a summary of measures. These components formed the primary data for analysis (Textbox 1). The incident description was translated and linguistically adapted from the original incident report to improve clarity and readability, without altering the factual content.

XSL•FO
RenderX

Textbox 1. Description of a health information technology–related incident involving loss of central patient surveillance data in a heart intensive care unit, including incident description, investigation findings, and implemented or proposed safety measures.

Incident description

On January 18, 2026, the central surveillance system in a heart intensive care unit lost connection with its server on 2 occasions, around 11 AM and 1 PM. During these periods, real-time patient monitoring data were unavailable and not stored. The issue was not detected immediately and became apparent at 4 PM when staff attempted to review recorded surveillance data. A trained superuser attempted to restart the system using previously distributed instructions, but the restart command did not respond, and the system interface subsequently froze. The IT department was contacted and performed a restart of the main computer.

Summary of investigation

The investigation identified a failure in the health information technology infrastructure, specifically the loss of server connectivity affecting the central surveillance system. The incident was compounded by delayed detection, as there were no real-time alerts indicating loss of data capture or system disconnection. Restart procedures that relied on local user action were ineffective, and the system entered an unresponsive state requiring IT intervention. The event highlighted dependencies between clinical monitoring, server availability, and recovery procedures, as well as limitations in system resilience and monitoring transparency.

In a heart intensive care unit, continuous centralized surveillance supports early detection of life-threatening arrhythmias, hemodynamic instability, and acute clinical deterioration. Therefore, loss of real-time and stored monitoring data creates a risk that critical physiological changes may go unnoticed or recognition may be delayed, particularly in settings where centralized monitoring complements bedside observation. Although no confirmed patient harm was identified in this case, the interruption of surveillance constituted a significant patient safety vulnerability.

Summary of measures

Immediate measures included restarting the central surveillance system with assistance from the IT department to restore functionality. Planned and recommended measures focused on improving system reliability and patient safety, including implementation of automated alerts for loss of server connectivity, clarification and testing of restart and recovery procedures, improved collaboration between clinical staff and IT services, and evaluation of redundancy or fail-safe mechanisms to prevent loss of monitoring data during system downtime.

Data Preparation and Deidentification

The original incident report was written in a language other than English and contained informal clinical and technical expressions typical of voluntary incident reporting. The report was translated into English using a direct linguistic translation approach focused on preserving semantic accuracy. No interpretive synthesis or restructuring of factual content was performed. Following translation, minor language editing was undertaken to improve clarity, including grammatical corrections and standardization of terminology, without altering the original meaning or sequence of events. The translated version was reviewed by a clinical engineer experienced in medical device incident management to ensure technical accuracy and contextual fidelity.

To ensure confidentiality and compliance with ethical and publication standards, all potentially identifying information, including names of individuals, institutions, manufacturers, locations, dates, and device identifiers, was removed prior to analysis. The final narrative was reviewed to confirm that it remained fully deidentified while retaining sufficient detail for analytical purposes [29].

Analytical Approach

To provide a comprehensive and systems-oriented analysis, the incident was classified using five complementary patient safety and human factors frameworks: (1) ICPS, (2) HIT-CS, (3) the SEIPS 2.0 model, (4) the sociotechnical model for HIT safety proposed by Sittig and Singh, and (5) HFACS-Healthcare.

Each framework was applied independently to the same incident narrative to capture different dimensions of the event, including incident type and outcome (ICPS), HIT-specific failure mechanisms (HIT-CS), work system interactions (SEIPS 2.0), sociotechnical dependencies (Sittig and Singh sociotechnical model), and human and organizational contributors (HFACS-Healthcare).

International Classification for Patient Safety

The ICPS was used to classify the incident at a high level, including incident type, detection, patient outcome, and degree of harm. It provides an internationally standardized taxonomy for patient safety incidents and supports comparison across settings and reporting systems [8]. The framework was applied descriptively to characterize the incident without attributing causality.

Health Information Technology Classification System

The HIT-CS, developed by Magrabi, Jabin, and colleagues, was used to classify the HIT-specific characteristics of the incident, including the primary issue type, secondary technical issues, outcome manifestation, workflow location, and impact scale [6,10,11]. The HIT-CS focuses on information flow and technical failure modes and is particularly suited for identifying technology-induced risks and system unavailability events [30,31].

SEIPS 2.0 Work System Analysis

The SEIPS 2.0 framework was applied to examine how the incident affected and emerged from interactions among technology, tasks, people, organizational structures, environment, and processes [16]. This analysis emphasized that the surveillance system failure disrupted continuous monitoring and retrospective data review and that recovery depended on organizational coordination with IT services.

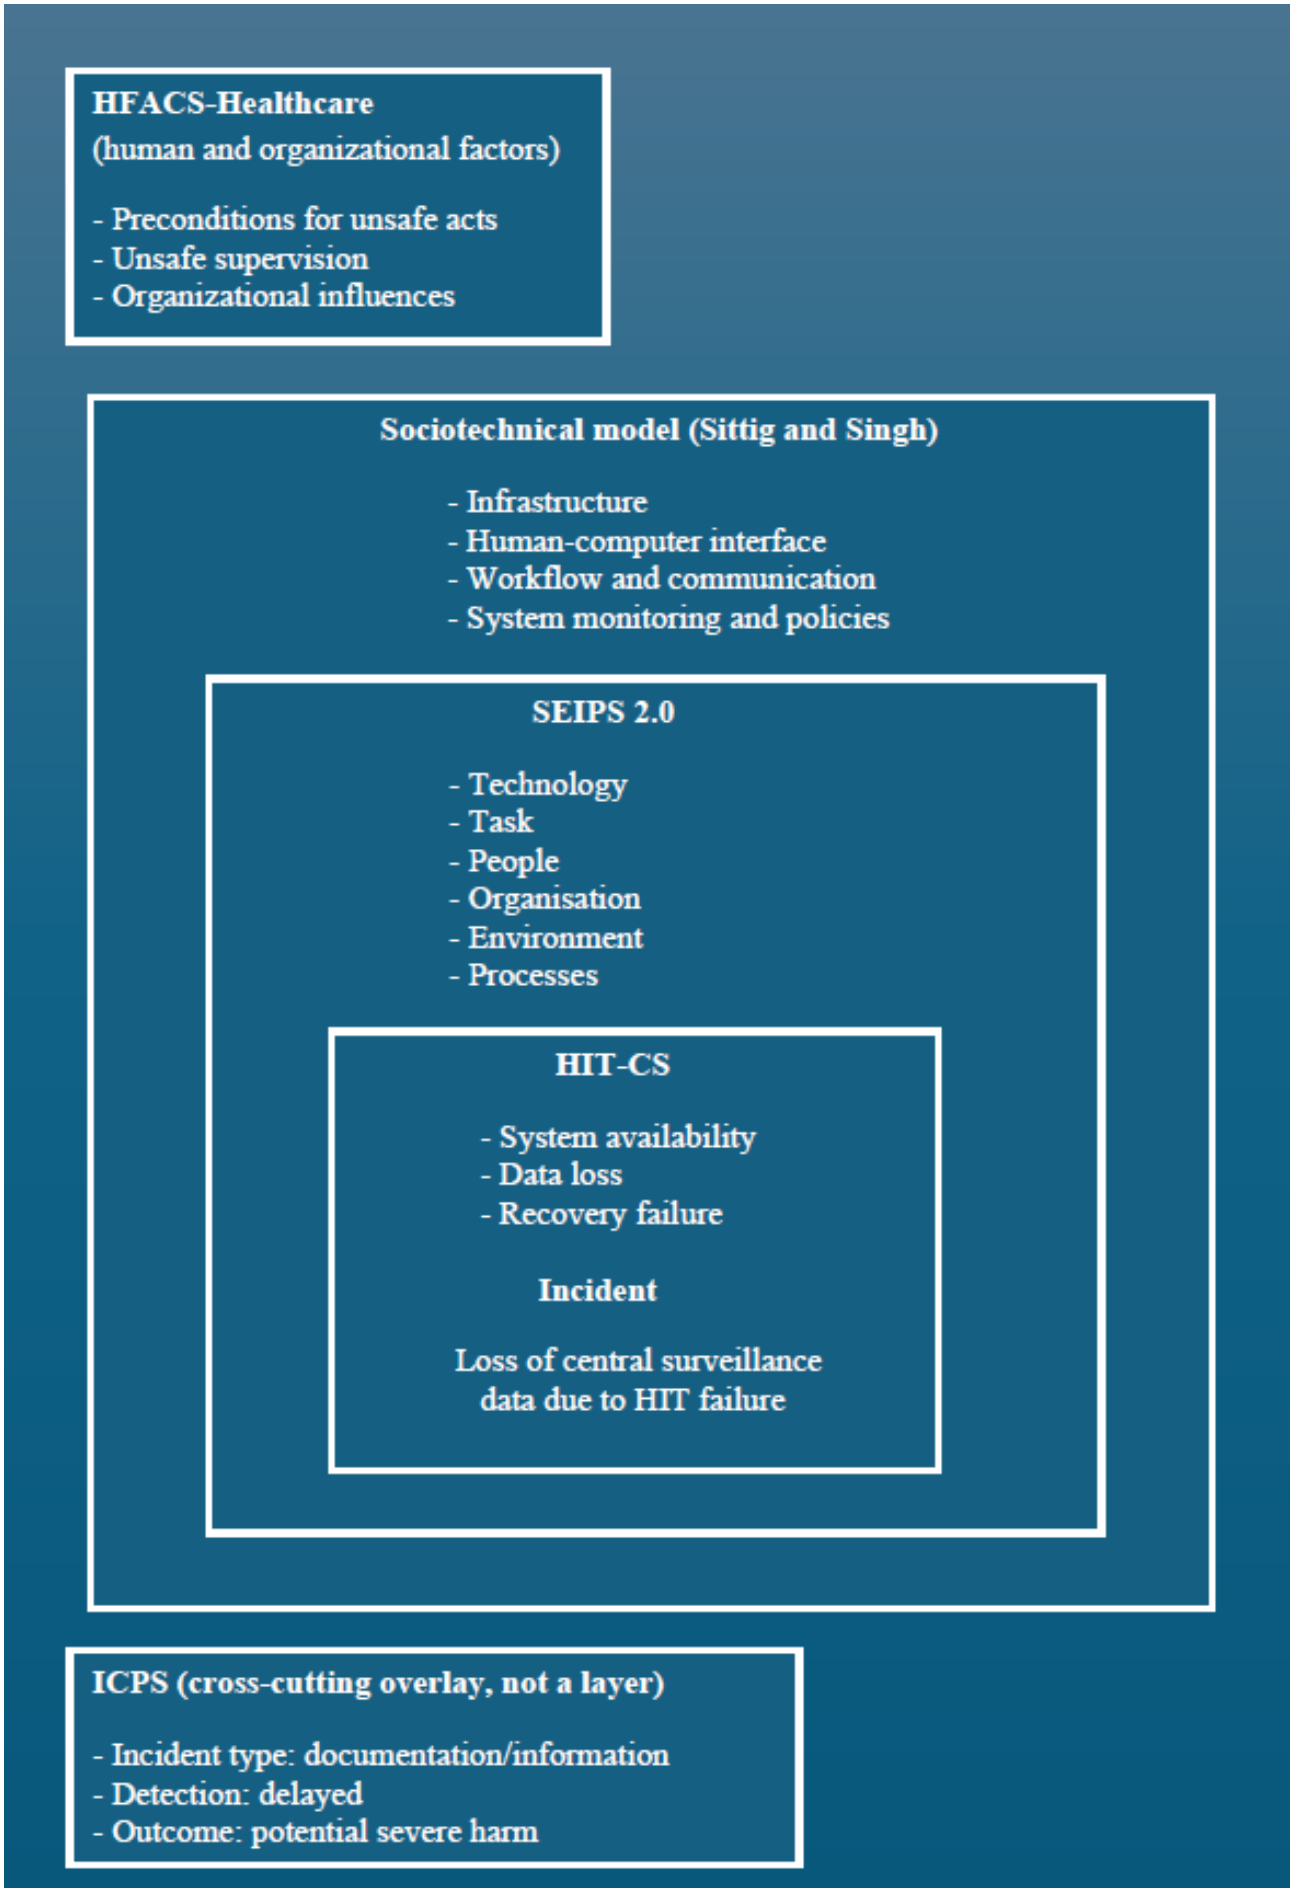
Sociotechnical Classification

The sociotechnical model proposed by Sittig and Singh [18,19] was used to analyze interdependencies among technical infrastructure, clinical content, human-computer interfaces,

XSL•FO
RenderX

workflows, organizational policies, and system monitoring. This framework was applied to identify latent conditions such as lack of system status visibility and centralized architecture that contributed to delayed detection and multi-patient impact [4,18,20].

HFACS-Healthcare Classification



HFACS-Healthcare was applied to examine human and organizational contributors to the incident across 4 levels: unsafe acts, preconditions for unsafe acts, unsafe supervision, and organizational influences [21,32]. This framework was used to distinguish between frontline performance and system-level factors and to assess whether human error contributed to the incident. HFACS-Healthcare was applied analytically rather than punitively, consistent with its use in health care safety research [22,23,33].

Figure 1 illustrates the conceptual relationship among the 5 classification frameworks applied in this study and their complementary roles in characterizing the incident.

Results

Overview of Incident Classification

The incident was analyzed using 5 complementary classification frameworks to capture its patient safety, technical, sociotechnical, and human factors dimensions. This section summarizes the classification results according to each framework. Together, these analyses demonstrated that the incident was primarily driven by HIT system failures and latent organizational and design factors rather than by frontline human error.

ICPS Classification

Using the ICPS, the incident was primarily classified as a documentation/information incident, with unavailable and lost patient monitoring data as the central safety concern. A secondary classification under medical device/equipment reflected the role of a centralized electronic surveillance system in clinical monitoring. Detection was classified as delayed, as the system failure was identified retrospectively during data review rather than at the time of occurrence. No confirmed patient harm was identified; however, the incident was classified as having potential for severe harm due to the risk of missed or delayed recognition of life-threatening cardiac events. Table 1 presents the detailed ICPS classification, including incident type, detection, degree of harm, and contributing factors.

Table . Classification of the incident according to the International Classification for Patient Safety (ICPS).

ICPS domain and classification	Description applied to this incident
Incident type (primary)	
Documentation/information	Unavailable and lost patient monitoring data due to a loss of connection between the central surveillance system and the server
Incident type (secondary)	
Medical device/equipment (health information technology)	Failure of a central electronic surveillance system supporting physiological monitoring
Patient outcome	
No harm (outcome unknown)	No confirmed patient injury was identified; patient impact could not be fully assessed due to missing data.
Degree of harm	
No harm/potential harm	Potential for severe harm due to the risk of missed or delayed detection of life-threatening cardiac events
Detection	
Delayed detection	The incident was identified retrospectively when staff attempted to review stored monitoring data.
Contributing factors/hazards	
Organizational/system factors	Lack of automated alerts for system disconnection; reliance on a centralized monitoring infrastructure
Technical factors	Server connectivity failure; ineffective restart function; system freeze requiring IT intervention
Mitigating factors	
Human factors	Presence of a trained superuser who attempted recovery procedures
Ameliorating actions	
System-level response	Restart of the main system by the IT department and review of system recovery procedures

No confirmed patient harm was identified; however, the incident was classified as having potential for severe harm due to the risk of missed or delayed recognition of life-threatening cardiac events. In high-acuity cardiac care, even short periods of absent surveillance may increase the risk of undetected arrhythmias or delayed response to clinical deterioration.

HIT-CS Classification

Using the HIT-CS, the incident was classified as a technical HIT failure that affected system availability and connectivity. The primary issue type was classified as a software/hardware (technical) failure, specifically loss of system availability due to server disconnection. A secondary technical issue involved a system recovery failure: user-initiated restart commands did not function, and the system became unresponsive. The outcome manifestation was classified as information unavailable/data loss, reflecting both an interruption of real-time monitoring and a permanent loss of stored surveillance data.

The HIT-CS analysis also highlighted the workflow location of the failure within continuous physiological surveillance and retrospective data review, as well as a multi-patient scale

XSL•FO
RenderX

characteristic, given that the central surveillance system supported simultaneous monitoring of multiple patients. Similar multi-patient propagation patterns following HIT failures have been reported in Swedish incident analyses, where system-level disruptions affected care management across multiple patients simultaneously [30]. Table 2 summarizes the HIT-CS classification dimensions and their application to the incident.

Table . Classification of the incident using the Health Information Technology Classification System (HIT-CS) framework.

HIT-CS dimension	HIT-CS category	Specific subtype (per HIT-CS)	How it applies to this incident
Primary issue type	Software/hardware (technical)	System availability/connectivity failure	Loss of connection between the central surveillance system and the server caused intermittent unavailability of real-time and stored patient monitoring data.
Secondary technical issue	Software/hardware (technical)	System recovery/restart failure	Restart commands initiated via the system interface did not execute, and the system entered an unresponsive (frozen) state requiring IT intervention.
Outcome manifestation	Information (machine/output)	Information unavailable/data loss	Patient monitoring data were not displayed in real time or stored, resulting in permanent gaps in surveillance records.
Optional contributing factor	Information (use/human)	Delayed detection/delayed monitoring	The system failure was not immediately apparent and was detected retrospectively when staff attempted to review recorded data several hours later.
Workflow location (contextual)	HIT-mediated[a] clinical monitoring workflow	Continuous physiological surveillance/data review	The failure occurred at the stage where the central surveillance system transmits, displays, and archives physiological data.
Scale characteristic	HIT system behavior	Multi-patient impact	The central surveillance system supports the simultaneous monitoring of multiple patients; therefore, the loss of functionality affected all monitored patients during downtime.

[a]HIT: health information technology.

SEIPS 2.0 Classification

Using the SEIPS 2.0 framework, the incident was characterized as a disruption of the clinical work system arising from interactions among technology, tasks, people, organization, environment, and processes. The technology domain captured the central surveillance system's loss of reliability. The task analysis showed that neither continuous monitoring nor retrospective data review could be performed as intended. The people domain indicated appropriate user actions, with staff following established restart instructions without success.

At the organizational level, system recovery depended on escalation to IT services, highlighting the reliance on centralized technical support. The environment domain reflected dependency on a single central surveillance workspace, while the processes domain identified delayed incident detection and reactive response as key characteristics. The outcome domain captured the potential for patient harm due to unavailable monitoring data. The SEIPS 2.0 classification is presented in Table 3.

XSL•FO
RenderX

Table . Classification of the incident according to Systems Engineering Initiative for Patient Safety (SEIPS) 2.0.

SEIPS 2.0 domain	Classification	How it applies to this incident
Technology and tools	Central surveillance system reliability	Loss of server connectivity and failure of system restart functionality rendered the monitoring system unavailable.
Tasks	Continuous physiological monitoring and data review	Real-time surveillance and retrospective review of patient monitoring data could not be performed as intended.
People	Clinical staff and superusers	Staff appropriately followed established restart instructions but were unable to recover system functionality.
Organization	IT support and escalation pathways	Resolution depended on the IT department's intervention, highlighting the reliance on centralized technical support.
Environment	Central surveillance workspace	The monitoring environment depended on a single central system, amplifying the impact of system failure.
Processes	Incident detection and response	The lack of automated alerts led to delayed detection and a reactive response after a retrospective data review.
Outcomes	Potential patient harm	Risk of missed or delayed detection of life-threatening cardiac events due to unavailable monitoring data

Sociotechnical Classification (Sittig and Singh Model)

The sociotechnical analysis identified multiple interacting system components contributing to the incident. Hardware and software infrastructure failures resulted in system unavailability and data loss, while deficiencies in the human-computer interface limited users' ability to understand the system state or recover functionality. The workflow and communication dimensions revealed delayed awareness and escalation due to the absence of system status alerts.

At the organizational level, recovery procedures depended on IT intervention, and the system lacked redundancy or fail-safe mechanisms to maintain monitoring during outages. The system measurement and monitoring dimension highlighted the absence of automated alerts for loss of connectivity or for data capture failures. These interacting sociotechnical factors created latent conditions that amplified the impact of the technical failure and increased patient safety risk. Table 4 presents a comprehensive sociotechnical classification of the incident.

XSL•FO
RenderX

Table . Sociotechnical classification of the incident (Sittig and Singh model).

Sociotechnical dimension	Classification	How it applies to this incident
Hardware and software computing infrastructure	System connectivity and availability failure	Loss of connection between the central surveillance system and the server caused intermittent system unavailability and data loss.
Clinical content	Availability and completeness of monitoring data	Physiological monitoring data were unavailable in real time and not stored, resulting in gaps in clinical information.
Human-computer interface	Lack of system feedback and controllability	Restart commands produced no visible response, and the system interface became unresponsive, preventing user-led recovery.
People	Roles, training, and system use	A trained superuser followed established restart instructions appropriately but was unable to restore functionality.
Workflow and communication	Monitoring, review, and escalation processes	The absence of real-time alerts delayed detection; escalation occurred only after a retrospective review of missing data.
Internal organizational policies and procedures	System recovery and downtime procedures	Recovery depended on contacting IT services, indicating limited local recovery capability and unclear resilience to downtime.
External rules, regulations, and pressures	Patient safety and monitoring requirements	Continuous cardiac monitoring is a regulatory and clinical safety expectation; system failure undermined this requirement.
System measurement and monitoring	System health visibility and alerting	No automated alerts indicated loss of server connectivity or data capture failure, contributing to delayed detection.
System configuration and upgrades	Configuration resilience	Centralized system architecture lacked redundancy or fail-safe mechanisms to maintain monitoring during server outages.
Outcomes and consequences	Potential patient harm	Risk of missed or delayed detection of life-threatening cardiac events affecting multiple patients simultaneously.

HFACS-Healthcare Classification

The HFACS-Healthcare analysis demonstrated that the incident was not associated with unsafe acts by frontline staff. At the level of preconditions for unsafe acts, technological environment factors such as poor system feedback and centralized system dependency reduced situational awareness and limited recovery options. At the unsafe supervision level, reliance on manual detection and the absence of real-time system oversight contributed to the delayed recognition of the failure.

At the organizational level, resource management and system design decisions, including limited redundancy and reliance on centralized IT support for recovery, were identified as key contributors. Overall, the HFACS-Healthcare analysis indicated that the incident arose primarily from latent system and organizational factors rather than from individual human error. The HFACS-Healthcare classification is summarized in Table 5.

XSL•FO
RenderX

Table . Classification of the incident according to the Human Factors Analysis and Classification System (HFACS)-Healthcare.

HFACS-Healthcare level and category	Classification	How it applies to this incident
Level 1: unsafe acts		
Errors	No unsafe acts identified	Clinical staff and the superuser acted appropriately and followed established restart procedures; no misuse or deviation was identified.
Level 2: preconditions for unsafe acts		
Technological environment	Poor system feedback and controllability	The surveillance system provided no feedback when restart commands were issued and became unresponsive, limiting users' ability to understand or manage the system state.
Physical/technological environment	Centralized system dependency	A single central surveillance system supported multiple patients, thereby increasing the impact when it failed.
Cognitive factors	Reduced situational awareness	Staff were unaware of the system failure until retrospective review, indicating diminished awareness of system status rather than clinical oversight.
Level 3: unsafe supervision		
Inadequate supervision	Insufficient monitoring of system health	There was no active oversight mechanism or real-time alerting to detect loss of server connectivity or data capture.
Planned inappropriate operations	Reliance on manual detection	Continued operation without automated system status alerts assumed that failures would be noticed through routine use.
Level 4: organizational influences		
Resource management	Limited redundancy and resilience	The surveillance architecture lacked redundancy or fail-safe mechanisms to maintain monitoring during server outages.
Organizational climate	Separation between the clinical and IT domains	Recovery depended on IT intervention, reflecting organizational boundaries that limited frontline recovery capacity.
Organizational processes	Downtime and recovery procedures	Restart instructions existed but were insufficient for nonresponsive system states, requiring escalation beyond clinical control.

Cross-Framework Synthesis

Across all 5 classification frameworks, the incident was consistently characterized as an HIT-driven system failure with delayed detection, multi-patient impact, and potential for severe harm. While each framework emphasized different aspects of the incident, all converged on the absence of frontline human error and the presence of latent technical, organizational, and design vulnerabilities. The combined use of the ICPS, HIT-CS, SEIPS 2.0, sociotechnical, and HFACS-Healthcare frameworks provided a comprehensive and complementary understanding of the incident and its patient safety implications. To facilitate comparison across frameworks and to synthesize key findings, Table 6 presents an alignment of major incident characteristics as identified by the ICPS, HIT-CS, SEIPS 2.0, Sittig and Singh sociotechnical model, and HFACS-Healthcare. Despite differences in terminology and analytical focus, the frameworks showed strong convergence in identifying the incident as a technology-driven failure with delayed detection, multi-patient impact, and predominant system-level and organizational contributors rather than frontline human error.

XSL•FO
RenderX

Table . Cross-framework alignment of key findings from the classification of a health information technology–related incident using the ICPS[a], HIT-CS[b], SEIPS 2.0[c], Sittig and Singh sociotechnical model, and HFACS[d]-Healthcare, highlighting convergent and complementary perspectives on incident nature, detection, human contribution, organizational factors, and impact.

Analytic theme	ICPS	HIT-CS	SEIPS 2.0	Sociotechnical (Sittig and Singh) model	HFACS-Healthcare
Primary incident nature	Documentation/information	System availability failure	Technology domain	Infrastructure failure	Preconditions (technological environment)
Detection	Delayed detection	Delayed detection	Process failure	Lack of system monitoring	Unsafe supervision
Human contribution	Not specified	Appropriate use	People domain	Human-computer interface	No unsafe acts
Organizational factors	Contributing factors	Workflow location	Organization	Policies and procedures	Organizational influences
Scale of impact	Potential severe harm	Multi-patient impact	Outcome	Centralized architecture	Resource management
Recovery	Mitigation actions	Recovery failure	Processes	IT dependency	Supervisory dependence

Discussion

Principal Findings

This case report demonstrates that an HIT failure in a high-acuity clinical setting can pose a substantial patient safety risk despite appropriate frontline actions. Across all 5 applied classification frameworks—that is, ICPS, HIT-CS, SEIPS 2.0, the Sittig and Singh sociotechnical model, and HFACS-Healthcare—the incident was consistently characterized as a system-driven failure involving loss of monitoring information, delayed detection, and multi-patient impact. The absence of frontline human error identified across frameworks aligns with prior research showing that many HIT-related safety events arise from latent system conditions rather than individual mistakes [3,4,11,19].

Importantly, the incident should not be interpreted as a benign technical malfunction. In high-acuity cardiac settings, centralized surveillance serves as a safety layer to detect arrhythmias and sudden physiological deterioration. Interruption of this layer introduces a window of vulnerability during which time-critical events may be missed or responses delayed, underscoring the clinical seriousness of HIT availability failures. Incident report analyses have demonstrated that software-related challenges frequently reflect latent system conditions rather than isolated user errors, reinforcing the importance of sociotechnical interpretation of HIT failures [34].

The alignment of findings across frameworks (Table 6) illustrates how different taxonomies emphasize complementary dimensions of the same event. The ICPS provided a standardized patient safety classification [7,8], the HIT-CS enabled precise characterization of HIT-specific failure mechanisms [9,10], and the SEIPS, sociotechnical, and HFACS-Healthcare frameworks highlighted how interactions among technology, workflows, supervision, and organizational context shaped the emergence and impact of incidents [13,15,19].

Methodological Contribution

This study contributes methodologically by demonstrating the value of multi-framework incident classification. Prior work has noted that reliance on a single taxonomy may obscure important aspects of HIT-related risk [6,11]. In this case, the HIT-CS clarified technical failure modes; the SEIPS and sociotechnical models contextualized the disruption to clinical work; and the HFACS-Healthcare provided a structured explanation of how organizational and supervisory factors contributed to the disruption, without attributing blame to frontline staff [18,19].

The integrative alignment table (Table 6) supports synthesis across frameworks and reduces interpretive fragmentation. Similar alignment approaches have been recommended to strengthen learning from complex safety events and to improve translation of analytic findings into practice [22,24].

Technological Failures as System-Level Safety Events

Failure of centralized HIT should be interpreted through the lens of systemic safety governance, rather than isolated technical faults. Complex care, such as extracorporeal treatments, requires structured communication, protocols, and organizational support to mitigate clinical risk. Nalesso et al [35] emphasize the importance of proactive and reactive safety management in critical care settings, including multidisciplinary risk assessment, procedural checklists, and safety culture tools to reduce clinical incidents in high-risk technologies.

High-risk technologies in critical care demand governance approaches that extend beyond device functionality to include organizational coordination, communication, and monitoring infrastructure. In complex therapies such as extracorporeal blood

XSL•FO
RenderX

purification, safety governance includes structured protocols, feedback loops, and systematic risk analysis to prevent latent failures that could lead to patient harm [18,35]. Digital incident reporting systems themselves require quality governance to ensure meaningful learning from HIT failures. Prior work has demonstrated variability in documentation quality and analytic depth within digital reporting systems, underscoring the need for structured governance frameworks [28].

Remote Monitoring and Alerting: Benefits and Limitations

Remote monitoring and device control can improve patient care and staff safety, but such systems must be interpreted in context with cognitive load and alert management. Garzotto et al [36] describe how remote control of medical devices reduced risk and unnecessary interventions in the intensive care unit during the COVID-19 pandemic, highlighting operational benefits and the potential for remote surveillance to support safety in critical settings [37].

Remote monitoring and control of medical devices can reduce direct exposure risks and streamline clinical workflows, particularly during infectious outbreaks. Garzotto et al [36] reported that remote device control decreased unnecessary interventions and supported patient safety in intensive care environments [37,38]. However, as with all automated systems, trade-offs such as increased alert burden and clinician cognitive load must be considered to ensure that alerting improves situational awareness without inducing fatigue [37,38].

Telemedicine and Remote Surveillance Concepts

Although not specific to intensive care unit central surveillance, telemedicine and remote monitoring paradigms offer conceptual bridges for understanding distributed monitoring and alerting across care settings. Ricci and Ronco [39] describe telemedicine support for peritoneal dialysis, illustrating how continuous remote surveillance of treatment data provides clinical oversight and improves outcomes in chronic care. These principles parallel the reliability of centralized surveillance; both involve automated data capture, transmission, and interpretation to support timely clinical decisions [35,40,41].

Concepts from telemedicine and continuous remote monitoring provide relevant frameworks for ensuring the reliability of centralized surveillance. Remote monitoring of chronic therapies such as peritoneal dialysis involves continuous data transmission and clinician oversight, improving the detection of therapy deviations and enabling timely intervention [35,41,42].

IT and Safety in Critical Care Therapies

Early literature emphasizes that IT in critical care therapies (such as continuous renal replacement therapy) impacts patient safety, monitoring, and documentation. Ricci and Ronco [39] underscored that IT contributes to practice variation, patient assessment, monitoring, and documentation in critical care, highlighting the potential for technology to influence safety outcomes when integrated with governance and quality systems [4].

IT implementation in critical care therapies can enhance patient assessment, documentation, and therapeutic monitoring, but it also introduces new failure modes that must be governed within broader safety and quality infrastructures [4,37,39].

Implications for Clinical Practice

Early Detection of HIT Failures

Delayed detection emerged as a dominant theme across all classification approaches. Similar delays in recognizing HIT failures have been described in prior studies, particularly in settings that rely on retrospective review rather than real-time system monitoring [11,28]. These findings underscore the importance of implementing automated system status alerts and monitoring dashboards to support timely detection of connectivity loss, data capture failure, or system degradation [16,26].

From a practical perspective, health care organizations should consider the following:

- Deployment of automated system status alerts distinct from physiological alarms
- Real-time monitoring dashboards accessible to both clinical units and IT services
- Clear escalation pathways triggered by connectivity or data integrity failures

However, implementation of automated alerts must be carefully designed to avoid unintended consequences such as alert fatigue and increased cognitive load among clinical staff. Excessive or nonspecific alerts may desensitize users and reduce responsiveness, particularly in intensive care environments already characterized by high alarm burden [1,2]. Therefore, system status alerts for surveillance failures should be prioritized, clearly distinguishable from routine physiological alarms, and integrated into existing workflows to balance early detection with usability and clinician attention.

Managing Operational Vulnerabilities in HIT Environments

Similar operational disruptions following software modifications, including security patching, have been documented in health care settings, illustrating how even routine IT maintenance may introduce unintended workflow vulnerabilities [27]. This reinforces the need for structured change management processes and proactive risk assessment before implementing system updates in high-acuity environments.

Evidence from quality improvement interventions in radiology demonstrates that structured system redesign and multidisciplinary engagement are more effective than isolated procedural adjustments, further supporting system-level corrective strategies for HIT-related failures [43,44]. Accordingly, mitigation efforts should emphasize the following:

- Multidisciplinary planning for HIT upgrades and maintenance
- Prospective hazard analysis before system changes
- Integration of IT governance with clinical safety leadership

XSL•FO
RenderX

Recovery Capacity and Local Resilience

The case also highlights limitations in frontline recovery capacity. Despite appropriate use by trained superusers, recovery required IT intervention, reflecting a lack of graduated recovery mechanisms at the clinical unit level. Human factors research emphasizes that resilient systems should support adaptation and recovery close to the point of failure, rather than relying solely on centralized escalation [22,23].

Designing HIT systems that provide meaningful feedback during recovery attempts and clearly guide escalation pathways may reduce downtime and associated patient risk. Practical measures may include the following:

- Transparent system status indicators during restart attempts
- Tiered recovery protocols with defined thresholds for escalation
- Simulation-based training for downtime scenarios

Governance, Redundancy, and Architectural Risk

From an organizational perspective, the incident illustrates the safety implications of centralized HIT architectures without redundancy. Central surveillance systems offer efficiency but can amplify harm when failures occur, a phenomenon previously described in analyses of large-scale HIT incidents [26,28]. Explicit assessment of single points of failure and investment in redundancy or fail-safe monitoring strategies are therefore critical in intensive care environments.

Broader analyses of digital technology implementation during crisis conditions have demonstrated that technological reliability, equity, and organizational readiness are critical determinants of safe digital transformation in health care systems [45,46]. These findings support the need for the following:

- System-level governance structures overseeing HIT safety
- Regular auditing of architectural vulnerabilities
- Investment in redundancy for high-acuity monitoring systems
- Integration of clinical, technical, and leadership oversight

Translation of Multi-Framework Findings Into Action

Building on the findings from the multi-framework analysis and the implications outlined above, a set of corrective and preventive strategies were devised to mitigate the risk of similar HIT-related surveillance failures in high-acuity care settings (see Textbox 2). These strategies were developed by synthesizing insights from the ICPS, HIT-CS, SEIPS 2.0, the sociotechnical model of Sittig and Singh, and HFACS-Healthcare, with an emphasis on system-level resilience, early detection, recovery capacity, and organizational coordination rather than on individual performance.

XSL•FO
RenderX

Textbox 2. Preventive and corrective strategies to mitigate health information technology–related central surveillance failures.

System reliability and infrastructure resilience

- Establish redundancy for central surveillance systems, including failover servers or mirrored systems, to reduce the impact of single points of failure in high-acuity settings.
- Implement automatic buffering or local storage of monitoring data to prevent data loss during temporary server connectivity disruptions.
- Ensure routine stress testing and resilience testing of surveillance systems under peak load and failure scenarios.

System monitoring, detection, and alerting

- Implement real-time system health monitoring with automated alerts for loss of server connectivity, data transmission failure, or interruption of data storage.
- Ensure that system status indicators are clearly visible to clinical users, indicating whether monitoring data are actively being captured and stored.
- Configure alerts to notify both clinical units and IT services simultaneously to enable parallel awareness and response.

Recovery procedures and contingency planning

- Develop and validate clear, stepwise recovery procedures for surveillance system failures, including criteria for escalation to IT support.
- Design restart and recovery functions that provide explicit user feedback (eg, confirmation messages or error notifications) to avoid ambiguity during recovery attempts.
- Formalize fallback monitoring workflows during downtime, such as increased bedside monitoring or alternative documentation processes, to maintain patient surveillance.

Human factors and training

- Provide regular training for clinical staff and designated superusers on recognition of abnormal system behavior, limits of local recovery actions, and early escalation pathways.
- Conduct interdisciplinary simulation or tabletop exercises involving clinical staff and IT personnel to rehearse detection, response, and recovery from HIT failures.
- Reinforce a nonpunitive reporting culture to encourage early reporting of HIT anomalies and near-misses.

Organizational governance and coordination

- Clearly define roles and responsibilities between clinical units, IT services, and vendors for surveillance system maintenance, monitoring, and incident response.
- Integrate HIT failure scenarios into organizational risk management and patient safety governance structures.
- Ensure that timely communication mechanisms are in place to inform all affected clinical staff of unexpected system downtimes and recovery status.

System design and integration

- Design surveillance systems to align with clinical workflows, minimizing reliance on retrospective data review for detection of system failures.
- Ensure interoperability between bedside monitoring devices and central surveillance systems to support continuity of monitoring during partial system failures.
- Incorporate human-centered design principles to improve system transparency, controllability, and usability in safety-critical situations.

The proposed strategies are grouped into key sociotechnical domains to facilitate practical implementation and learning.

Strengths and Limitations of the Study

A key strength of this study is the systematic application of 5 established classification frameworks to a single HIT-related incident, enabling a comprehensive and triangulated analysis. This approach aligns with calls for richer sociotechnical analyses of HIT safety events [15,16]. Additionally, focusing on an incident with high potential severity but no confirmed harm supports proactive safety learning, consistent with modern patient safety principles [5,23].

Several limitations should be acknowledged. The analysis is based on a single incident report, limiting generalizability and precluding causal inference. Patient outcomes could not be fully assessed due to missing monitoring data, which constrained the classification of harm under ICPS [7]. Furthermore, while the frameworks used are well established, their application involves interpretive judgment; alternative analysts might emphasize different dimensions. Nevertheless, the strong convergence of findings across frameworks suggests robust analytical results.

In addition, the reconstruction of the event relied primarily on the narrative documented in the incident report; it is possible that relevant contextual factors were not recorded and therefore could not be captured within the analytic frameworks applied.

XSL•FO
RenderX

Implications for Future Research

Future research should examine whether similar patterns of delayed detection, limited recovery capacity, and organizational dependency are observed across larger samples of HIT-related incidents using comparable multi-framework approaches [11,28]. Comparative studies evaluating how different classification systems influence safety recommendations could further guide methodological choices in HIT safety research.

There is also a need for empirical evaluation of design and governance interventions, such as real-time HIT health monitoring, redundancy strategies, and improved IT-clinical coordination models, to assess their effectiveness in reducing risk in high-acuity settings [16,26,29]. Finally, integrating resilience-oriented concepts such as Safety-II into HIT safety analysis may offer additional insights into how systems can better support adaptive clinical work under failure conditions [22,23].

Conclusions

This case report demonstrates that HIT-related safety incidents in intensive care settings are best understood as emergent properties of complex sociotechnical systems rather than isolated technical malfunctions or individual errors. The combined application of ICPS, HIT-CS, SEIPS 2.0, the sociotechnical model, and HFACS-Healthcare revealed convergent system-level vulnerabilities involving delayed detection, limited recovery capacity, and architectural and organizational design factors. These findings underscore the importance of governance structures, redundancy planning, and human-centered alerting strategies in high-acuity monitoring environments. Integrative, multi-framework analysis may strengthen learning from HIT failures and support safer design, implementation, and resilience of clinical surveillance systems.

Acknowledgments

The author thanks the health care professionals and medical technology staff for their contributions to incident reporting and investigation, which made this analysis possible. The author especially acknowledges Dr Abdullah Hassoun for his assistance in reviewing and verifying the translated incident narrative. The author also recognizes the important role of national incident reporting systems in facilitating learning from health information technology–related safety events.

Artificial intelligence–based tools were used to assist with language refinement and manuscript organization. The author reviewed and verified all content and takes full responsibility for the accuracy and integrity of the work.

Funding

No specific funding was received for this study.

Data Availability

The data analyzed in this study consist of a deidentified incident report obtained from a national incident reporting repository. For ethical and confidentiality reasons, the underlying data are not publicly available. Reasonable requests for access to the deidentified data may be considered by the corresponding author, subject to applicable data governance and institutional policies.

Authors' Contributions

MSRJ developed the protocol, obtained ethical approval, and drafted the manuscript. MSRJ performed data analysis and devised the set of strategies. MSRJ reviewed and edited the manuscript and approved the final version.

Conflicts of Interest

None declared.

Abstract

Background: The integration of robots into industrial settings has rapidly advanced, aiming to reduce human involvement in demanding tasks while improving overall efficiency. As collaborative robots (cobots) become more prevalent, assessing the physical strain during joint tasks is essential to promote long-term well-being in the workplace.

Objective: This study aimed to investigate how human-robot collaboration influences workers' postural control and musculoskeletal load during manipulation tasks performed in parallel.

Methods: Fourteen healthy male participants performed manipulation tasks under 3 conditions: without robotic assistance, with a cobot providing load support (Robot Free [RF]) and a cobot constrained to horizontal movement (Robot Plane [RP]). Center of pressure trajectories were computed, and nonlinear recurrence quantification analysis indicators (recurrence rate [REC], determinism [DET], and their ratio) were calculated in the anteroposterior, mediolateral, and anteroposterior-mediolateral planes

Results: Statistical analysis showed greater postural sway in robot-assisted conditions compared to Free. Mean distance increased from 1.7 (SD 0.6) cm in Free to 2.4 (SD 0.6) cm in RF (P<.001) and 2.3 (SD 0.6) cm in RP (P<.001). Mean velocity increased from 2.9 (SD 0.9) cm/s in Free to 4.3 (SD 1.4) cm/s in RF and RP. Confidence ellipse area increased from 7.6 (SD 4.1) cm^2 in Free to 24.9 (SD 14.2) cm^2 in RF and 23.1 (SD 13.4) cm^2 in RP. Sway area increased from 1.5 (SD 0.7) cm^2/s in Free to 2.9 (SD 1.2) cm^2/s in RF and RP. Nonlinear metrics revealed lower recurrence rates in robot-assisted conditions, decreasing from 0.31 (SD 0.08) in Free to 0.2 (SD 0.08) in RF and 0.2 (SD 0.04) in RP in the anteroposterior-mediolateral plane (P<.001), from 0.33 (SD 0.08) in Free to 0.28 (SD 0.07) in RF (P=.02) and 0.16 (SD 0.03) in RP (P=.007) in the mediolateral direction, and from 0.36 (SD 0.07) in Free to 0.3 (SD 0.06) in RF (P=.009) and 0.26 (SD 0.03) in RP (P<.001) in the anteroposterior direction. Determinism remained stable (values close to 1), leading to higher determinism-to-recurrence ratios for robot-assisted conditions, increasing from 3.41 (SD 0.87) in Free to 5.41 (SD 1.69) in RF and 5.51 (SD 1.11) in RP in the anteroposterior-mediolateral plane (P<.001), from 3.11 (SD 0.63) in Free to 3.64 (SD 0.72) in RF (P=.02) and 3.92 (SD 0.48) in RP (P=.007) in the mediolateral direction, and from 2.82 (SD 0.48) in Free to 3.47 (SD 0.57) in RF (P=.009) and 3.46 (SD 0.45) in RP (P<.001) in the anteroposterior direction. No significant differences were found between the robot-assisted conditions.

Conclusions: Interaction increases postural sway, indicating reduced stability and higher physical demand. This could reflect impaired balance or adaptation. Nonlinear analysis reveals that postural control remains structured. Results also suggest that the mere presence of the cobot is the primary driver of these postural changes.

Introduction

Industry 4.0 has brought transformative changes to manufacturing, emphasizing the integration of industrial robots to minimize workers' involvement in repetitive tasks [1]. Robots are now widely used in industrial settings to assist or replace workers in physically demanding tasks, offering benefits such as lower error rates, higher productivity, lower costs, and

XSL•FO
RenderX

improved product quality. Recent advancements in robotics have also facilitated closer interactions between humans and robots, giving rise to human-robot collaboration (HRC), which has become a key focus in robotics research [2-4]. In HRC, humans and robots work side by side toward shared goals, engaging in continuous interactions where they adapt and respond to each other's actions [5]. This synergy enhances efficiency and productivity, as human abilities complement robotic precision, strength, and endurance [6]. However, while HRC helps both workers and companies, its impact on physical and cognitive well-being requires careful assessment.

Numerous studies have explored how HRC affects workers, focusing on various aspects such as ergonomics, cognitive workload, safety, and overall well-being. Evaluating physical and mental demands in collaborative settings has been highlighted as a key factor [7], as ergonomic risk factors and comfort directly impact workers' long-term health [8,9]. Although collaborative robots (cobots) aim to reduce physical strain by assisting workers in repetitive or strenuous tasks, they do not completely prevent work-related musculoskeletal disorders (WMSDs), which may arise from improper postures or behaviors [10]. WMSDs are a major concern in industries with manual labor and repetitive motions, potentially leading to chronic pain, reduced productivity, and long-term health problems [11,12]. When work tasks are performed in quasi-static conditions, direct measures of posture could reveal insights into the stability and balance of workers and can thus be used to improve ergonomics during HRC [13]. Poor or sustained postures can cause musculoskeletal imbalances, increased strain on joints and muscles, and altered movement patterns over time [14]. Posturography data could help evaluate musculoskeletal load, identify ergonomic risk factors, and develop strategies to mitigate them.

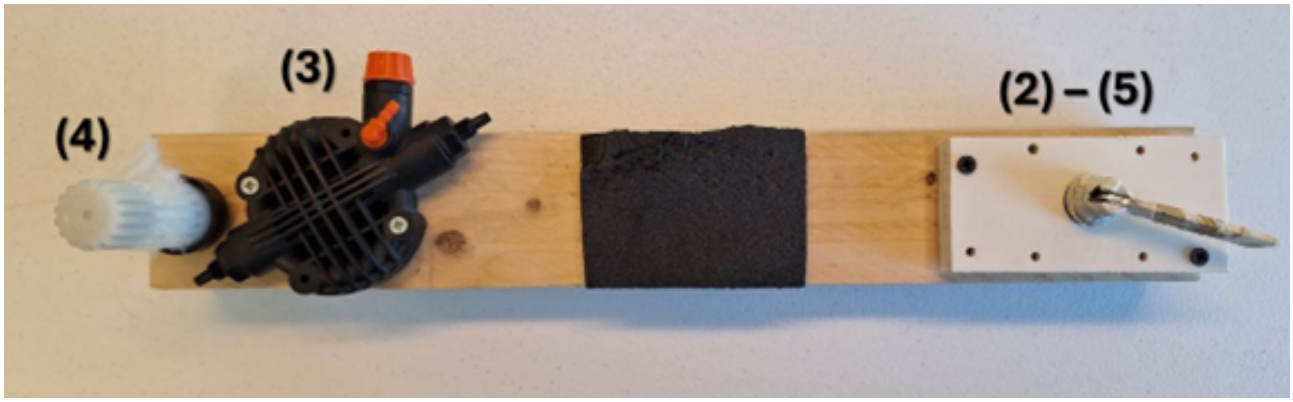
Traditionally, sensory-motor and cognitive mechanisms involved in balance control are studied using conventional center of pressure (COP) measures. COP represents the point where the resultant ground reaction force is applied during standing or movement, and its displacement over time provides valuable insights into postural stability and balance. Standard COP metrics include mean amplitude and mean distance (reflecting the extent of the postural sway), mean velocity (representing the speed of postural adjustments), and confidence ellipse area and sway area (characterizing the distribution of the sway) [15]. These parameters are crucial for understanding how the body maintains equilibrium, particularly during tasks that involve dynamic movement or changes in posture. Additionally, variations in COP data can help identify deviations from normal posture, which may indicate potential risks for musculoskeletal discomfort or injury.

However, some researchers have argued that traditional analyses of the spatial dynamics of postural activity are insufficient to fully understand the mechanisms underlying postural control and, in particular, cannot provide a complete understanding of stability and instability in the control of posture [16,17]. These measures offer an overall view of postural sway and may be linked to the adopted muscular strategy, but they do not directly refer to the adopted control strategy or to the attentional demand allocated to the control of balance. Specifically, these traditional parameters primarily focus on linear characteristics of postural control and may not fully capture the complexity of human balance regulation. This limitation suggests that nonlinear analysis could complement traditional measures of the extent and distribution of postural sway, offering a more comprehensive perspective on postural dynamics [18]. Deepening understanding of the mode of control and its underlying mechanisms has encouraged researchers to call for more powerful and relevant techniques of analysis [19].

Among the indicators recently introduced to capture distinct aspects of the nonlinear temporal dynamics of time series data, recurrence quantification analysis (RQA) has been hypothesized as a viable method to capture aspects linked to balance maintenance [20-26]. RQA describes the temporal structure of a dynamic system by quantifying the number and duration of repeated states [27]. Crucially, RQA does not merely describe the magnitude or variability of movement, as traditional COP metrics do, but reveals how postural adjustments evolve. This includes capturing aspects such as the repetitiveness of the displacement trajectory, the complexity of the control strategy, and the system's predictability or adaptability [18], also in conditions where balance maintenance is challenged by the presence of repetitive supra-postural tasks [28]. Some of the most commonly used RQA parameters are the relative amount of recurrence and determinism [18].

Hence, traditional COP parameters offer a general overview of gesture characteristics, while RQA provides complementary insight by capturing the temporal structure and regularity of postural adjustments. Accordingly, this study combines both types of metrics to assess postural control and biomechanical risk during the execution of manipulatory tasks performed with and without robotic assistance. The experimental task followed a structured sequence consisting of rest, object grasping, object manipulation, object release, and rest. For this analysis, we focused only on the manipulation phase, when the participant actively interacted with the object, while grasping, release, and rest periods were excluded. This approach allows for a specific assessment of postural control precisely during sustained object handling. Unlike previous studies [13,29], which focused on sequential task execution with a cobot, this work examines a parallel task configuration, where the human and the cobot interact simultaneously, sharing the same space and concurring on the same task [30], thus introducing fundamentally different interaction dynamics. Accordingly, the goal of this work is twofold: first, to investigate whether the assistance of the cobot influences postural control and musculoskeletal load compared to performing the task alone; and second, to explore whether varying the mode of robotic collaboration within parallel tasks elicits distinct biomechanical responses. Ultimately, this approach aims to facilitate real-time monitoring of workers' physical strain and support the development of ergonomic strategies to reduce WMSDs and enhance workplace safety.

Methods



Experimental Setup

The experimental setup was designed using a 2 × 1 m table on which a cobot (Franka Emika Panda, Munich, Germany) was

XSL•FO
RenderX

positioned opposite the participant, who stood in an upright posture, to simulate a collaborative workbench environment. Participants were instructed to cyclically perform a manipulation task using a custom-designed tool (Figure 1), specifically developed to simulate common and functionally relevant manipulation activities. The tool is a wooden beam equipped with 4 interactive mechanisms: a white knob, a rotating component with a high-positioned orange knob, a black padded section designed for grip, and a white lever mounted on a rectangular structure.

Figure 1. Object designed to be manipulated in the task. The numbered labels identify the items to be manipulated at each corresponding step of the task sequence.

The manipulation task consisted of the following steps: (1) take the object, (2) open the lever on the right by rotating it 90° counterclockwise, (3) rotate the high-positioned orange knob until it reaches the end of its stroke, (4) unscrew the white knob on the left for 2 full turns, (5) close the lever that was opened at step 2, and (6) return the object to its original position. After completing this sequence, participants rested with their arms at their sides. Following a brief pause, they independently decided when to initiate the next cycle of manipulation. The experiment included three conditions:

1. Free: the participant performed the task independently. The object was positioned on an elevated support on the right side of the table for easy access. Using their right hand, the participant grasped the object and executed a predefined sequence of movements. The task was considered complete once the object was returned to its initial position.
2. Robot Free (RF): the cobot assisted the participant by securely holding the object at its central part, simulating a "gravity compensation" condition, thus minimizing the load the participant was required to support. In this condition, the cobot could move freely in response to the participant's needs. The task began with the cobot holding the object, after which the participant approached and performed the required sequence of movements. The task ended when the participant guided the cobot back to its starting point on their right.
3. Robot Plane (RP): similar to the RF condition, the cobot securely held the object at its central part. However, in this condition, the robot's movement was constrained to a virtual horizontal plane, locking the object's vertical movement and allowing free movement in other directions. The task shared the same starting and ending configurations as the RF condition. The height of the simulated plane was kept fixed for all experiments, regardless of the participant.

The inclusion of 2 distinct robot-assisted conditions was motivated by the hypothesis that varying the mode of collaboration could elicit different effects on human motor behavior and postural control. Specifically, the RP condition implements a gravity-compensation scenario in which the object is virtually weightless, and its vertical position is fixed. This constraint results in a different interaction with the cobot, while in the RF condition, participants need to continuously support and stabilize the cobot with 1 hand while performing the task with the other. In the RP condition, they can rely on the cobot's fixed height, potentially leading to the adoption of different motor strategies. Moreover, the inability to move the robot vertically may require participants to adapt their posture or reposition themselves to comfortably perform specific movements. This distinction between RF and RP thus allows the researchers to examine how different kinematic constraints and interaction modes with the cobot influence postural control and task execution. An illustrative photo of an individual performing the task under robot-assisted conditions is shown in Figure 2.

Participants were free to move naturally in all conditions, with the only requirement being the use of their right hand to grasp the object. Each condition was repeated 3 times, with each trial consisting of 5 repetitions of the manipulation task. The trials were conducted in a randomized order to minimize potential learning effects and ensure natural task execution.

XSL•FO

Figure 2. Example of a manipulation task with robotic assistance.

Data Acquisition and Processing

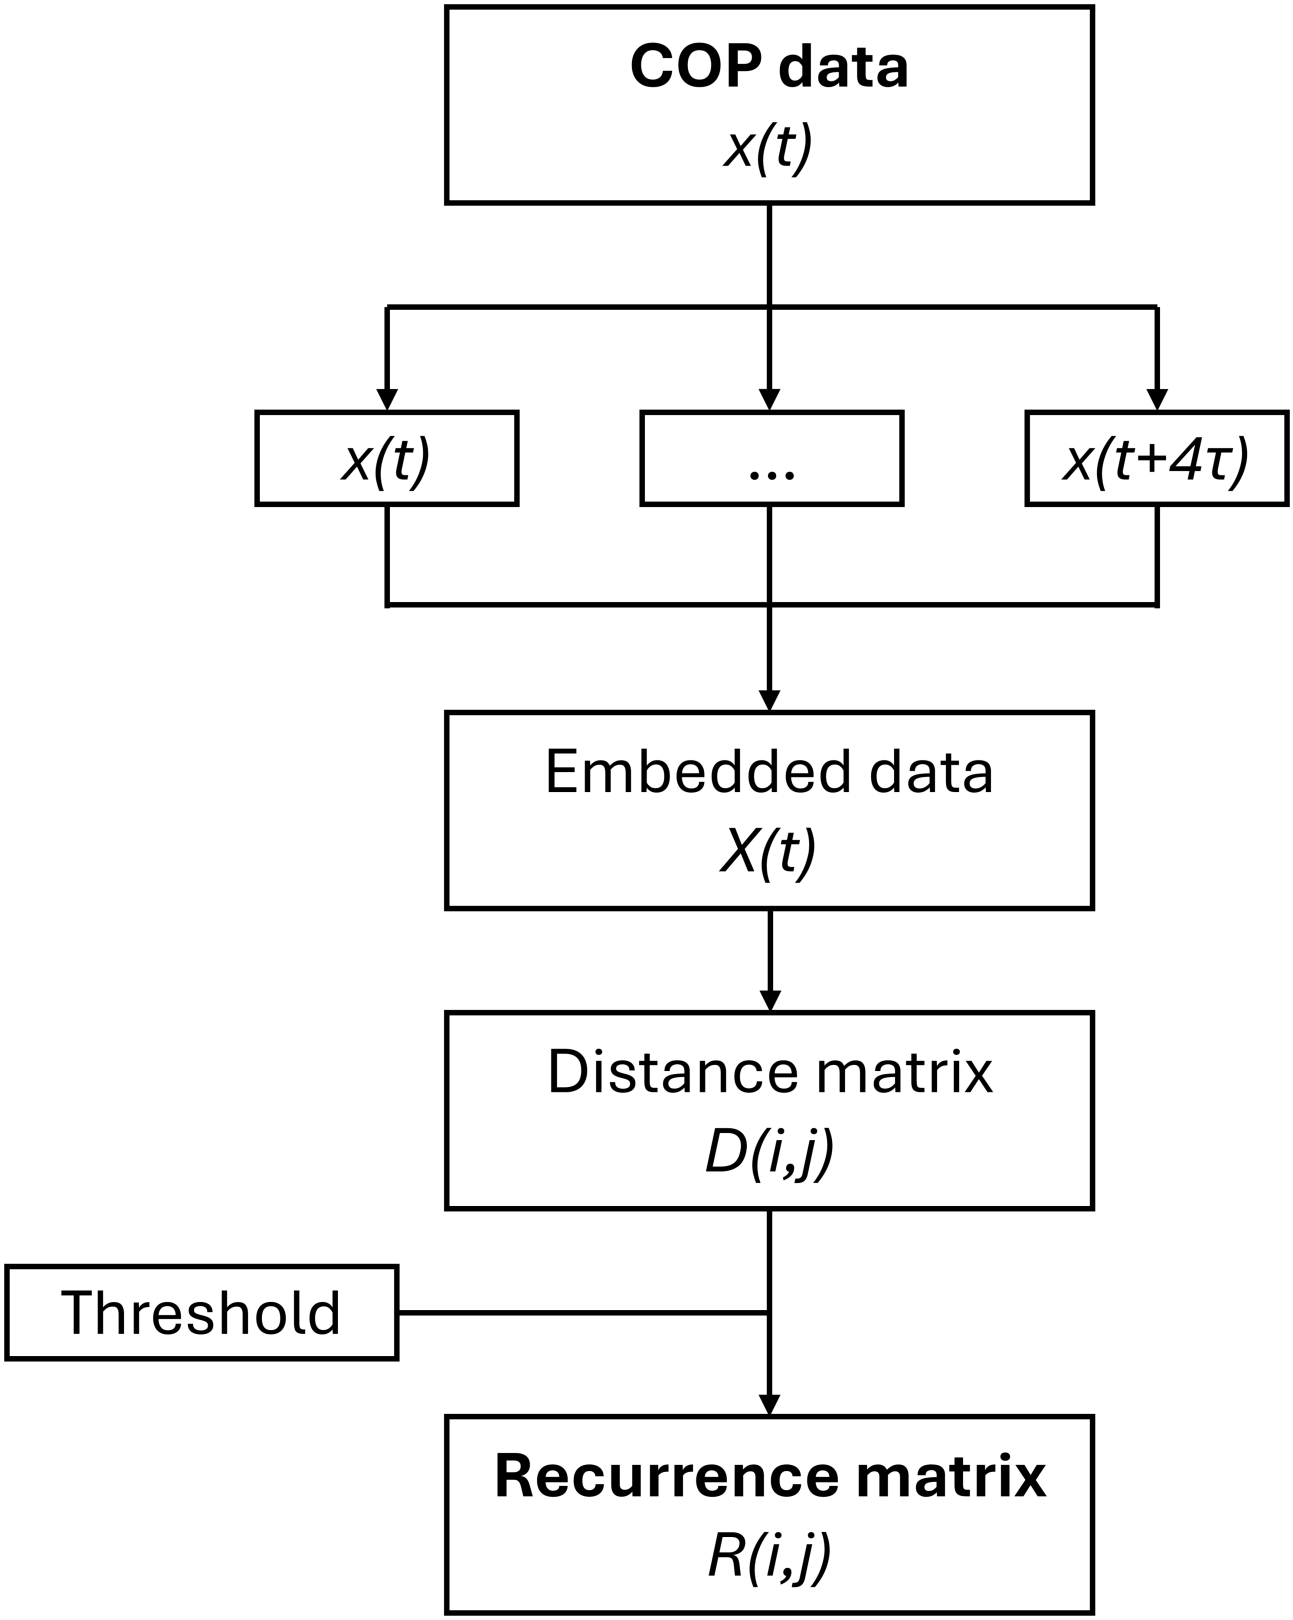
Fourteen healthy right-handed male participants took part in the study (age: mean 26, SD 3 years; height: mean 177, SD 6 cm; and weight: mean 71, SD 7 kg). Participants were recruited based on their nonfamiliarity with the task and the absence of any known musculoskeletal, neurological, or visual impairments. The study was approved by the local ethical committee of Roma Tre University.

Two 6-component force platforms (BTS P-6000 and BTS Bioengineering) were positioned under the participants' feet to record ground reaction forces and to derive the COP coordinates. Force data were collected at a sampling frequency of 500 Hz. Each platform was positioned under 1 foot. Additionally, a marker-based optoelectronic system (BTS SMART-DX 6000 and BTS Bioengineering) was used to segment and identify each task repetition, with passive markers placed at key anatomical landmarks. These kinematic data were acquired using a sampling frequency of 250 Hz. Force platform data were then resampled at the same rate.

Data Processing and Analysis

Trajectories of the COP for each of the lower limbs (ie, COP-right and COP-left) were extracted from the force platform data. The total COP was then obtained as the weighted average between COP-right and COP-left, and its displacement was defined by both the anteroposterior and the mediolateral coordinates with respect to a reference system centered between the 2 force plates. Cycles of the movement were identified using motion capture data: segmentation was made by detecting the time instant when the marker on the right wrist reached the maximum rightward excursion in the mediolateral direction, indicating the completion of a repetition. Only manipulation phases were extracted for the analysis, as the focus was specifically on these active interactions, excluding the other phases (ie, rest, object pick-up, and object release).

XSL•FO
RenderX



Four COP-derived sway parameters were selected to evaluate postural stability and quantify balance changes: mean distance, mean velocity, 95% confidence ellipse area, and sway area. These metrics were chosen based on their ability to capture distinct yet complementary aspects of postural control and stability. Mean distance quantifies the extent of postural displacement, reflecting the range of movement and how far the COP deviates from a reference point. Mean velocity measures the speed of postural displacement, indicating how quickly the individual adjusts their posture. The ellipse area captures the spread of the COP, providing insights into postural control by assessing variability and dispersion. This metric was preferred over the confidence circle area, as the elliptical estimate accounts for the directionality of sway—a relevant feature when COP trajectories are not uniformly distributed but follow a predominant path [13]. The sway area provides a measure of the extent of postural instability during task execution. For each cycle of the task repetition in each experimental condition, these parameters were calculated as defined in [30]. Mean values were then computed and subjected to inferential statistical analysis to assess potential differences across conditions.

In addition to these conventional analyses, an RQA was performed to explore the underlying dynamical patterns of postural sway. These measures provide insight into the temporal organization, predictability, and adaptability of postural control—aspects that are especially relevant in dynamic and interactive tasks—and are not influenced by participants' anthropometric characteristics. To investigate dynamics on a cycle-based time reference, the time delay was set to the average length of the cycle evaluated for each trial. The processing steps adopted for extracting the recurrence maps, similar to those used in [29], are reported in Figure 3.

RQA was carried out on the radial component of the COP, as well as on the anteroposterior and mediolateral components alone. Specifically, 3 parameters were calculated to analyze the dynamics of postural sway [29]. The recurrence rate (REC), also known as the density of recurrence points in the recurrence plot [18], quantifies the percentage of recurrent states in the COP trajectory, reflecting the overall stability of postural sway. Determinism indicates the proportion of those recurrence points that form structured diagonal lines, which is associated with the predictability and regularity of sway patterns. The ratio, defined as the ratio between determinism and REC, represents the extent to which the recurring patterns are deterministic in nature.

XSL•FO
RenderX

Figure 3. Flowchart for the embedding of center of pressure (COP) data and the extraction of the recurrence matrix.

Statistical Analysis

Normality of sway parameters and RQA indicators was assessed using the Shapiro-Wilk test. Since at least 1 of the distributions of each parameter was not normal, nonparametric statistical analyses were applied. To evaluate differences in both traditional and RQA-based parameters across the 3 experimental conditions, a Friedman test was performed. When a significant main effect was found, pairwise comparisons were conducted using the Wilcoxon rank-sum test. The significance level was set to 0.05, 0.01, and 0.001 (indicated by *, **, and ***, respectively). Effect sizes were calculated to quantify the magnitude of observed differences and are reported as correlation coefficients (*r*), with thresholds of 0.1 - 0.3,

XSL•FO
RenderX

0.3 - 0.5, and >0.5 denoting small, medium, and large effects, respectively.

Ethical Considerations

Before participation, all participants provided informed consent, and the study was approved by the Ethical Commission of Roma Tre University (BRIC2022-CoRoMan approval r.01-24/06/2025). Participants did not receive any compensation for the participation, and all data was anonymized for maintaining privacy and confidentiality of the information.

XSL•FO
RenderX

In the Free condition (Figure 4A), COP trajectories exhibit a compact pattern for all considered participants, extending roughly 5 cm in both mediolateral and anteroposterior directions. Paths remain well-contained within a small spatial envelope, showing limited variability across cycles. In the RF condition (Figure 4B), COP trajectories display a broader pattern compared to those observed in the Free condition (Figure 4A), particularly along the anteroposterior axis. The range of displacement remains around 5 cm in the mediolateral direction but increases to approximately 15 cm in the anteroposterior direction. Intrasubject variability across cycles remains limited. Similar to what is observed in the RF condition (Figure 4B), COP trajectories in the RP condition (Figure 4C) exhibit a broader pattern compared to those in the Free condition (Figure 4A), particularly along the anteroposterior axis. Displacement in the mediolateral direction remains around 5 cm, while in the anteroposterior direction, it increases to approximately 10 cm. Intrasubject variability across cycles remains generally limited. These patterns were observed across all participants, with limited intersubject variability, demonstrating the consistency of the findings. Refer to multimedia appendices for the complete set of COP traces of all participants and all experimental conditions (refer to Multimedia Appendix 1 for Free, Multimedia Appendix 2 for RF, and Multimedia Appendix 3 for RP).

The qualitative differences observed in COP trajectories are supported by the statistical analysis of sway parameters, as illustrated in Figure 5. The results reveal significant differences between the Free condition and both robot-assisted conditions, with the latter exhibiting consistently higher values across all parameters. In contrast, no significant differences were found between the 2 robot-assisted conditions for any of the parameters analyzed. Mean distance increased from 1.7 (SD 0.6) cm in Free to 2.4 (SD 0.6) cm in RF (P<.001; r=0.86) and 2.3 (SD 0.65) cm in RP (P<.001; r=0.86). Mean velocity increased from 2.9 (SD 0.9) cm/s in Free to 4.3 (SD 1.4) cm/s in RF and RP (P<.001; r=0.88). Confidence ellipse area increased from 7.6 (SD 4.1) cm^2 in Free to 24.9 (SD 14.2) cm^2 in RF (P<.001; r=0.88) and 23.1 (SD 13.4) cm^2 in RP (P<.001; r=0.88). Sway area increased from 1.5 (SD 0.7) cm^2/s in Free to 2.9 (SD 1.2 cm^2/s) in RF and RP (P<.001; r=0.88).

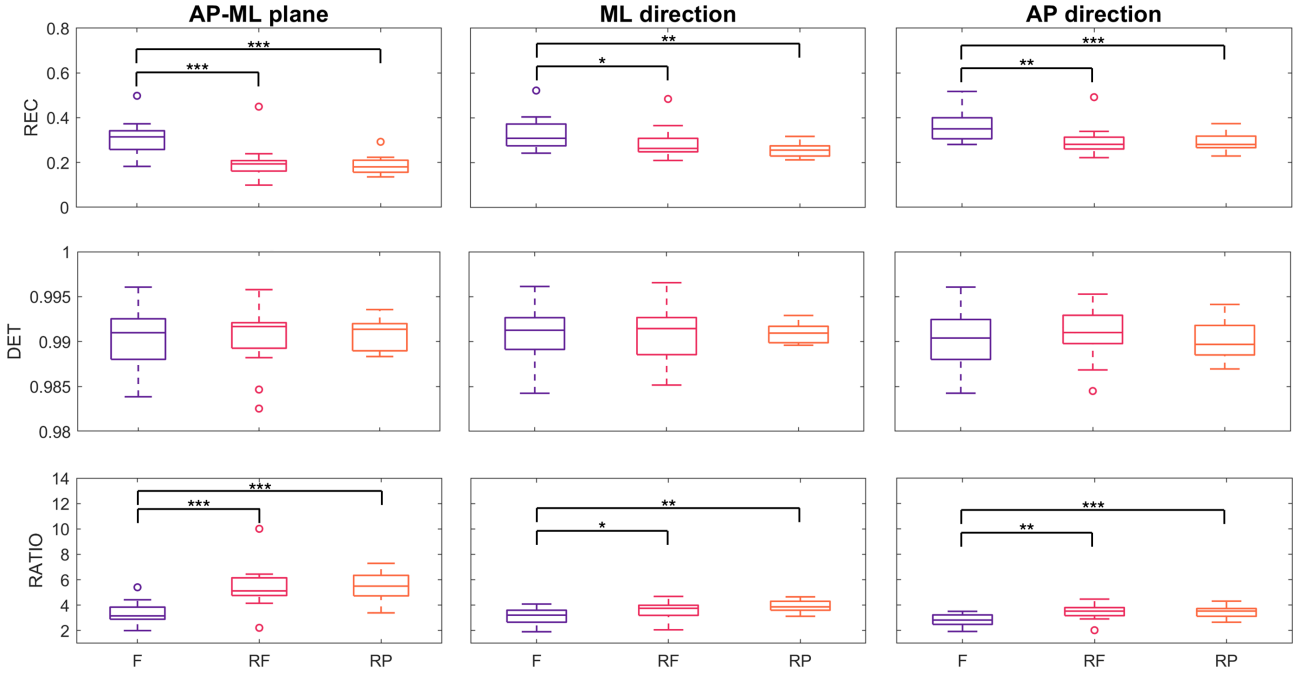
Nonlinear Metrics

An example of the RQA recurrence maps obtained from a subset of the cycles relative to 1 exemplary participant is reported in Figure 6. A consistent pattern emerges across both robot-assisted conditions, marked by a greater density of points along the principal diagonal line in the recurrence maps compared to the Free condition. The Free condition exhibits a more pronounced checkered structure, reflecting the prevalence of recurrent quasi-stationary states.

XSL•FO
RenderX

Figure 6. Sample recurrence maps, relative to 1 exemplary participant, in different trials and for different directions. AP: anteroposterior; ML: mediolateral.



These qualitative and specific observations are supported by the quantitative results shown in Figure 7, which presents boxplots of the RQA-based parameters for all participants. Specifically, the REC is significantly lower in both robot-assisted conditions. REC decreased from 0.31 (SD 0.08) in Free to 0.2 (SD 0.08) in RF (P<.001; r=0.88) and 0.2 (SD 0.04) in RP (P<.001; r=0.88) in the anteroposterior-mediolateral plane; it decreased from 0.33 (SD 0.08) in Free to 0.28 (SD 0.07) in RF (P=.02; r=0.65) and 0.26 (SD 0.03) in RP (P=.007; r=0.75) in the mediolateral direction; it decreased from 0.36 (SD 0.07) in Free to 0.3 (SD 0.06) in RF (P=.009; r=0.75) and 0.26 (SD 0.03) in RP (P<.001; r=0.86) in the anteroposterior direction. On the other hand, determinism remains largely unchanged. Consequently, the ratio between determinism and REC is significantly higher during robotic assistance, reflecting a shift toward more periodic and structured postural control strategies when the cobot is engaged. This ratio increased from 3.41 (SD 0.87) in Free to 5.41 (SD 1.69) in RF (P<.001; r=0.88) and 5.51 (SD 1.11) in RP (P<.001; r=0.88) in the anteroposterior-mediolateral plane; it increased from 3.11 (SD 0.63) in Free to 3.64 (SD 0.72) in RF (P=.02; r=0.6) and 3.92 (SD 0.48) in RP (P=.007; r=0.75) in the mediolateral direction; it increased from 2.82 (SD 0.48) in Free to 3.47 (SD 0.57) in RF (P=.009; r=0.75) and 3.46 (SD 0.45) in RP (P<.001; r=0.86) in the anteroposterior direction. It is worth noting that the determinism values observed here are higher than those reported in [28], which can be attributed to our use of a

XSL•FO
RenderX

lower-dimensional embedding space and different threshold settings in the RQA procedure.

Figure 7. Distribution of recurrence quantification analysis (RQA) parameters, differentiated by experimental conditions. "*," "**," and "***" denote $P<.05$, $P<.01$, and $P<.001$, respectively, as obtained from inferential statistics. AP: anteroposterior; DET: determinism; F: Free; ML: mediolateral; RATIO; REC: recurrence rate; RF: Robot Free; RP: Robot Plane.

Discussion

Principal Findings

The analysis of the COP trajectories shows a greater extent along the anterior-posterior direction in robot-assisted conditions with respect to the Free condition, possibly indicating a higher number of oscillations of the body when the cobot intervenes in the task execution. This could suggest that participants tend to deviate from their postural stability, potentially compromising the overall efficiency and coordination of the kinematic chain during task execution. The absence of an evident difference between COP paths in the RF and RP conditions may indicate that the mode of collaboration with the cobot does not substantially alter the way robotic assistance affects postural stability.

Suggestions resulting from these qualitative observations align with quantitative results from the analysis of traditional COP parameters. Indeed, higher values of all parameters were found in robot-assisted conditions compared to the Free condition, suggesting altered postural dynamics in response to robotic assistance, regardless of the mode of collaboration with the cobot.

Higher mean distance may result from robotic constraints altering postural stability and strategy. Since mean distance is commonly interpreted as an indicator of postural control effectiveness [31], higher values are typically associated with a reduced ability to maintain a stable upright position [15]. Larger COP excursions have also been linked to reduced postural control [32] and balance impairments [33-35].

Higher mean velocity may suggest increased postural control effort and adjustments, likely due to imposed constraints from robotic assistance. Faster COP movements are often interpreted as indicators of increased demand for active postural control [31] or postural instability [32,36], assuming that the mean distance remains constant. However, in our case, the mean distance also increases under collaborative conditions. This combined increase complicates the interpretation; rather than indicating instability alone, it may reflect an active and purposeful postural adaptation to the new collaborative context.

A larger confidence ellipse area usually indicates higher COP exploratory behavior in postural sway, which may represent an adaptive response to the altered task dynamics under robotic assistance. This measure is in some cases associated with reduced balance control [37] and difficulty in maintaining stability during upright standing [38].

A greater sway area reflects increased movement, possibly in response to the higher postural control demands imposed by robot interaction. Since sway area is a hybrid measure capturing both the interaction between postural control activity and stability level [31], larger values are usually interpreted as a sign of decreased stability [39].

Contrary to our initial hypothesis, the analysis revealed no significant differences between the RF and RP conditions across all the parameters. While we expected that constraining the robot's movement might lead to changes in postural dynamics, the results suggest otherwise: the mere presence of robotic support, regardless of the collaboration mode, plays a dominant role in shaping participant responses. Indeed, the assistance provided by the cobot in both conditions may be sufficient to modulate the demands of the task, leading to similar adaptations.

Overall, COP tends to travel more (higher mean velocity and, to a certain extent, sway area) and further (mean distance and

XSL•FO
RenderX

ellipse area) when robotic assistance is provided. In general, larger COP excursions are associated with reduced balance control, indicating a decreased ability to remain in a smaller (and typically more stable) area during task repetitions [13]. This may suggest that the cobot influences task execution, which is particularly relevant given that increased COP excursions are associated with the development of WMSDs [40]. From this perspective, the Free condition appears to allow the most effective postural control and imposes the lowest associated risk, as evidenced by more stable and restricted sway patterns.

These findings might be the result of an alteration of the body schema, an integrated and dynamic internal representation of the body and its surrounding space [41], continuously shaped and updated through sensory and social interactions [42]. Efficient movement in space requires both localizing objects in extrapersonal space and maintaining a constantly updated status of body shape and posture [43]. The body schema reflects how the body interacts with its environment, and it is highly plastic, adapting to novel tools or altered body representations [44]. Here, the cobot holding the object may have challenged this schema, leading to difficulty in incorporating the cobot interaction and thereby potentially explaining the increased postural sway. Indeed, recent works may suggest that interactions with robots and virtual agents can disrupt or extend embodiment, requiring new sensorimotor adaptations [45-50].

Nonlinear results further support this interpretation. A lower REC in robot-assisted conditions may suggest a more variable or exploratory balance strategy, as postural states repeat less frequently. This indicates a shift away from stable, habitual postural control patterns toward more dynamic adjustments, potentially reflecting the fact that the cobot is not yet fully integrated into the participant's body schema. In this context, participants may need to continuously recalibrate their posture in response to the cobot's actions, rather than relying on familiar strategies. This interpretation aligns with the idea that technological artifacts reshape bodily experience and require new sensorimotor adaptations [43,48,51,52]. Notably, REC values are comparable across the 2 robot-assisted conditions, suggesting that the mode of interaction does not further alter the degree of postural control. In other words, the presence of the cobot itself introduces a fundamental shift in balance strategy, but the specifics of the interaction mode may have a limited additional effect on this aspect of postural control.

Comparable determinism values across all conditions indicate that, despite the increased postural sway and lower recurrence observed in the robot-assisted conditions, the postural responses remain structured rather than random. This suggests that participants are still using organized control strategies, even if these strategies are more adaptive and less repetitive. This reflects a balance between flexibility and structure: while the presence of the cobot necessitates ongoing adjustments, participants appear to adopt consistent patterns, rather than reacting in a chaotic or unpredictable manner. This might be related to Black's critique of the "natural interface" assumption [51]: the robot-object system does not immediately integrate as a seamless extension of the body, but does not cause complete instability either. Although the cobot may provide sufficient task stability, its presence is not yet fully integrated into the body schema, requiring continuous movement adjustments while maintaining a coordinated response. However, confirming this interpretation would require long-term longitudinal studies to assess whether such adaptations persist, diminish, or evolve.

Importantly, as observed with conventional COP measures, no significant differences were found between the 2 robot-assisted conditions across all RQA-based parameters, further indicating that the specific mode of parallel collaboration did not substantially affect overall postural outcomes. Thus, RQA findings suggest that interaction with the cobot challenges postural control without introducing randomness in balance control. The presence of the cobot appears to prevent full postural automatization, requiring individuals to engage in ongoing adjustments rather than relying on familiar movement patterns.

These results are also consistent with broader research on tool use, which demonstrates that tools can alter both perceptual and motor processes in healthy individuals as well as those with brain damage [41,43,52,53]. Effective tool use involves more than simple physical manipulation; it requires recognizing the object as a tool, knowing how to interact with it, and understanding the outcomes of its use [54,55]. These processes may be difficult to fully integrate into the body schema, particularly when new dynamics are introduced that the body has not yet adapted to, such as those posed by a cobot.

Overall, our results suggest that robotic assistance affects postural control and may challenge the body schema. However, interpretations in terms of motor learning, tool use, or body schema adaptation remain speculative at this stage. The observed changes in linear and nonlinear metrics indicate postural adjustments, yet it is unclear whether these reflect short-term responses or longer-term learning. Further research is needed to clarify how these adaptations develop over time.

Limitations

Although this study offers meaningful evidence regarding the effects of cobots on human postural control, several limitations should be considered when interpreting the results.

First, the research was conducted in a controlled laboratory setting using a standardized manipulation sequence, a simulated workbench, and a custom tool. The task sequence was carefully designed to closely resemble typical industrial manipulation operations and to capture key aspects of HRC, such as coordination with a robotic partner, repetitive handling, and precise posture adjustments in this context. While lab-based tasks cannot fully replicate the complexity and variability of real industrial scenarios, our design sought to approximate these conditions to ensure relevance to typical HRC environments. Future studies should incorporate diverse object types, task sequences, and interaction dynamics to further strengthen ecological validity and assess robustness across broader industrial contexts.

Second, the participant sample consisted of 14 healthy young adult males, and this limits generalizability to the broader industrial workforce. Different populations may respond differently in HRC contexts: older adults or individuals with musculoskeletal impairments might exhibit greater postural

XSL•FO
RenderX

sway and slower movements, while sex-related differences in strength, flexibility, and neuromuscular coordination could alter movement strategies. These factors suggest that our findings capture only part of the variability present in industrial settings. At the same time, the large effect sizes observed in our analyses indicate that the identified effects are robust and not solely sample dependent. Moreover, when considering a broader population sample, we expect that, even though sway parameters may be affected by anthropometric characteristics, nonlinear indicators would reasonably maintain similar variations. Future research should, however, include participants of different ages, sexes, and health conditions to improve outcomes.

Moreover, the study focused on short-term cobot interactions, leaving open questions about the long-term effects of repeated exposure, which might influence postural stability and increase the risk of developing musculoskeletal disorders. Investigating whether initial adaptations persist, diminish, or intensify over time, by incorporating more extended sessions, is therefore essential to clarify how postural control reacts or adapts to long-term exposure to HRC.

Finally, although RQA measures are computationally robust and have undergone rigorous validation, their novelty makes interpretation complex and context dependent [35]. As noted in the “Discussion” section, attributing the observed alterations in postural dynamics to body schema changes remains hypothetical and requires complementary methods (eg, kinematics, electromyography, and questionnaires on perceived effort) and longitudinal studies to support the evidence and strengthen causal inferences. This more comprehensive approach would reinforce the ergonomic perspective and offer a more precise understanding of both physical and mental demands in HRC scenarios.

Conclusions

This study investigated how HRC influences postural control and musculoskeletal load during dynamic manipulation tasks performed in upright stance. Postural control was evaluated using traditional COP-derived linear metrics and nonlinear RQA indicators. Findings show that interaction with the cobot increases COP excursions and velocity, indicating higher postural demands and reduced stability compared to performing the task alone [56]. These effects likely stem from task-specific challenges, movement constraints imposed by the cobot, and adaptive neuromuscular system responses. RQA analysis revealed lower RECs but stable determinism, suggesting that postural adjustments become more variable yet remain structured, reflecting adaptive rather than random responses. No significant differences were observed between the 2 robot-assisted conditions, implying that the cobot’s presence, rather than its movement constraints, drives these postural changes.

Overall, these findings indicate that HRC tasks may challenge the body schema and require continuous sensorimotor adaptation, potentially influencing both task execution and balance strategies. From an ergonomic perspective, the results highlight that cobotic tasks can affect whole-body postural organization, even when local task execution remains unchanged. This supports the inclusion of postural control and postural dynamics as complementary indicators in ergonomic assessments of HRC, alongside conventional biomechanical measures. Such insights are critical for ergonomic cobot design, emphasizing the importance of offering assistance that supports, rather than disrupts, natural postural control. In industrial contexts, cobots have the potential to enhance safety, productivity, and ergonomics; however, their impact on postural stability must be carefully considered. Increased COP excursions have been linked to a higher risk of musculoskeletal disorders [13]; poorly designed cobot interactions could thus inadvertently increase physical strain. Conversely, when properly integrated, cobots could reduce the physical demands of repetitive tasks, enabling safer and more ergonomic working conditions. Optimizing cobot design and interaction strategies is therefore essential to ensure that cobots complement human capabilities, support natural movement, minimize physical strain, and promote sustainable, safer human-centered work environments.

Funding

This work was partially supported by the INAIL projects BRIC2019-BRISK and BRIC2022-CoRoMan (CUP: F83C22002780001). The activities of MS, SR, and SC were also supported by the Project ECS0000024 Rome Technopole (CUP: F83B22000040006).

Data Availability

The datasets generated and analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

DB, MS, and SC contributed to conceptualization. DB and SR contributed to the development of the methodology. AdN and GC contributed to software development. DB, GC, and MS performed validation. AdN, DB, and SR conducted the formal analysis. AdN, DB, and SR curated the data. AdN and DB wrote the original draft of the manuscript. AdN, DB, GC, MS, SR, and SC reviewed and edited the manuscript. DB performed the visualization. DB and SC supervised the study. MS and SC administered the project and acquired funding.

Prevalence of Work-Related Pain or Discomfort Among Urologists in the State of Florida: Results From the Florida Urologic Society Task Force on Ergonomic Challenges Experienced by Its Members

Abstract

Background: Pain and work-related musculoskeletal disorders are commonly seen in surgeons, significantly impacting quality of life and burnout. A questionnaire-based study was conducted to further investigate the nature and etiology of work-related pain among urologists in the state of Florida.

Objective: This study aimed to quantify the number of urologists who reported work-related musculoskeletal disorders >25% of the time.

Methods: The Florida Urologic Society Task Force developed a survey based on the Nordic Musculoskeletal Questionnaire, with additional input from Cornell's ergonomic studies. The Mayo Clinic Survey Research Center conducted the survey and distributed it to 504 members of the Florida Urologic Society in 2023.

Results: The total response rate was 18.6% (94/504). The primary outcome (number of urologists who reported pain >25% of the time) was 45.3% (34/75). In total, 32.4% (22/68) of the respondents reported pain associated with endoscopic surgery >25% of the time, 40.0% (14/35) reported pain for major open cases, 20.6% (13/63) reported pain for minor open cases, and 22.7% (5/22) reported pain for robotic cases. In total, 68.8% (53/77) of the respondents attributed their work-related pain to uncomfortable operating positions, and 29.9% (23/77) chose to ignore their pain.

Conclusions: In this contemporaneous population of Florida urologic surgeons, almost half of the respondents describe having work-related pain >25% of the time. The data show that major open surgery had the highest rate of pain, followed closely by endoscopic surgery. Over 70% of the urologists in Florida are interested in official ergonomics training, which, if developed, may lead to increased productivity and better emotional, personal, and interpersonal well-being.

KEYWORDS

ergonomics; robotics; laparoscopy; endoscopy; urology; pain

Introduction

In recent years, ergonomics has gained considerable interest due to the increasing conscientiousness for physical and mental well-being [1-4], including in the field of urology. In the era of open pelvic surgery, complaints of work-related musculoskeletal disorders (WRMDs) were very common, present in more than 66% of surgeons [5,6]. Despite the invention of minimally invasive techniques such as laparoscopic or endoscopic surgery, WRMDs are just as common [5]. A study reported that urologists who regularly perform endoscopic procedures are at a 3 times higher risk for developing a chronic musculoskeletal disorder than those who do not [2].

However, even with attempts at improving ergonomics, such as robotic surgery, WRMDs are still present. A survey of robotic surgeons showed that pain is very prevalent, with the neck (73.7%), shoulder (52.6%), and lower back (42.1%) being the

XSL•FO
RenderX

most common areas [1]. An astounding 70% of urologists performing robotic, open, or endoscopic cases have used nonsteroidal anti-inflammatory drugs to cope with musculoskeletal pain while operating [3]. The type of injury likely differs. For example, WRMDs associated with major open surgery may be more related to the trunk and neck, while robotic surgeons have higher hand and/or wrist injuries [1,5,6]. Both open and robotic surgery have seen improvements with respect to ergonomics. Prismatic loupes and passive neck exoskeletons are recent improvements for open surgery that have been shown to decrease pain [7,8]. Robotic consoles continue to improve, such as the da Vinci 5 allowing for straighter back and neck posture and lighter hand controls with a rubber grip to improve finger or wrist discomfort [9].

Robotics and endoscopy are a significant part of many urologists' surgical schedules; however, 80% report no formal ergonomic training in the operating room [3]. This research indicates that there is a high prevalence of work-related pain experienced by surgeons and that minimal ergonomic education has taken place to prevent such problems.

In conjunction with the Florida Urologic Society (FUS), we sent a survey to urologists in the state of Florida to gather more contemporary information regarding the prevalence of work-related pain and discomfort to better understand the role ergonomics plays among Florida urologists.

Methods

Overview

The FUS funded and conducted this study in partnership with the Mayo Clinic Survey Research Center. A survey was developed based on the Nordic Musculoskeletal Questionnaire with additional input from Cornell's ergonomic studies, which is provided in Multimedia Appendix 1. This survey contained 24 multiple choice questions. There are 10 questions used to delineate the etiology, frequency, and treatment of pain. The next 8 questions inquire about the types of surgeries performed and the pain associated with them. A total of 2 questions assess if surgeons received ergonomic training or if they have interest in training. The final 4 questions consist of the surgeons' demographics and years spent in practice. The Mayo Clinic Survey Research Center distributed the survey to members of the FUS consisting of 504 practicing urologists in 2023.

The primary outcome was the number of urologists who reported pain >25% of the time during surgery. Secondary outcomes included demographics and the type of procedure, length of the procedure, cause of discomfort, specific muscles affected, and methods attempted to minimize discomfort. Inclusion criteria included members of the FUS in 2023, and there were no exclusion criteria. Data collection was performed using Research Electronic Data Capture (REDCap; Vanderbilt University) software, and the number of each response out of the total number of responders for each question was recorded. The total number of respondents was identified for each question, and the number of answers for each option was added. Sample size is dependent on response rate.

Ethical Considerations

This study was exempt from institutional review board approval.

Results

Demographics

In total, 18.6% (94/504) of the urologists within the FUS returned the survey. Not all participants completed every question.

Demographic data are presented in Table 1. In total, 46.8% (44/94) of the respondents worked in private practice, 30.9% (n=29) worked at a teaching-based hospital with resident assistance, 9.6% (n=9) worked at a teaching-based hospital without resident assistance, and 12.8% (n=12) worked at a community hospital.

Table . The type of urology practice was selected in the survey, with percentages of each answer provided in the table.

Type of urology practice	Values, n (%)
Private practice	44 (47)
Teaching-based hospital with resident assistance	29 (31)
Community hospital	23 (13)
Teaching-based hospital without resident assistance	9 (9)

In total, 76.6% (72/94) of the respondents completed the question regarding their experience level. Of the 72 respondents, 5.6% (n=4) were residents, 12.5% (n=9) had been in practice less than 5 years, 30.6% (n=22) had been in practice for 6 to 20 years, and 51.3% (n=37) have been practicing for more than 20 years.

In total, 75.5% (71/94) of the respondents completed the question regarding their gender identity, height, and weight. Of the 71 respondents, 84.5% (n=60) were male, 11.2% (n=8) were female, 2.8% (n=2) chose another description, and 1.4% (n=1) chose not to answer. Respondents could also choose their height and weight in a range. The most common height was between 5'9" to 6'0" (n=27, 38.0%) followed by 5'5" to 5'8" (n=25, 35.2%). The most common weight range was 151 to 200 lbs (n=47, 66.2%).

Types of Surgeries Performed: Endoscopic (Question 9)

In total, 79.7% (75/94) of the respondents completed the questions regarding type of surgery performed. Of the 75 respondents, 33.3% (n=25) performed between 1 and 5 endoscopic cases weekly, while 57.3% (n=43) performed >5 weekly.

XSL•FO
RenderX

Types of Surgeries Performed: Open (Question 11 and 13)

In total, 45.3% (34/75) of the respondents performed 1 to 4 major open cases, defined as cases taking more than 3 hours, while 53.3% (n=40) performed 0 weekly, and 1.3% (n=1) performed >4 cases. In total, 66.7% (n=50) of the respondents performed 1 to 4 minor open cases, 14.6% (n=11) performed 0, and 17.3% (n=13) performed >4 cases.

Types of Surgeries Performed: Robotic (Question 15)

In total, 70.7% (53/75) of the respondents performed 0 robotic cases weekly, while 22.7% (n=17) performed 1% to 3%, and 6.7% (n=5) performed >3 robotic cases per week.

Etiology of Pain or Discomfort

In total, 88.3% (83/94) of the respondents completed the question regarding types of WRMDs. Of the 83 respondents, 90.4% (n=75) reported pain at any point in the last week.

The primary outcome was pain or discomfort greater than 25% of the time during surgery. In total, 79.8% (75/94) of the respondents answered questions regarding the frequency of pain depending on the type of surgery. Of the 75 respondents, 45.3% (n=34) reported pain or discomfort greater than 25% of the time during surgery. Years in practice was not a significant predictor of pain, as 53.8% (7/13) of the urologists in practice for 5 years or less reported pain greater than 25% of the time during surgery, while 45.9% (17/37) of the urologists in practice for more than 20 years reported pain greater than 25% of the time during surgery.

In total, 32.8% (22/68) of the urologists who perform endoscopic surgery reported pain or discomfort for at least 25% of the time. In total, 32.0% (8/25) of the urologists who perform less than 5 endoscopic cases per week reported pain, while 32.6% (14/43) who perform greater than 5 cases reported pain. In total, 40.0% (14/35) of the urologists who perform major open surgery reported pain, with 41.8% (14/34) who perform 1 to 4 cases per week reported pain and 0% (0/1) of urologists who perform more than 4 major open cases per week. In total, 20.6% (13/63) of the urologists who perform minor open cases reported pain, with 14.0% (14/50) in those who perform 1 to 4 cases per week and 46.2% (6/13) in those who perform more than 4 cases. In total, 22.7% (5/22) of the urologists who perform robotic cases reported pain or discomfort at least 25% of the time, with 11.8% (2/17) in those who perform 1 to 3 cases per week and 60.0% (3/5) in those who perform more than 3 robotic cases per week.

We then analyzed the cause of discomfort (Table 2). In total, 18.2% (14/77) of the respondents reported no work-related discomfort, while 68.8% (n=53) of the respondents attributed their work-related pain and discomfort to an uncomfortable operating position, 51.9% (n=40) to extensive standing, 35.1% (n=27) to equipment hindrance, 19.5% (n=15) to heavy tools, 15.6% (n=12) to moving patients, and 10.4% (n=8) to another reason not listed on the survey.

Table . The causes of work-related pain, with the percentage of each response detailed in the right-hand column.

Cause of work-related pain	Values, n (%)
No work-related pain/discomfort	14 (18)
Uncomfortable operating position	53 (69)
Extensive standing	40 (52)
Equipment hindrance	27 (35)
Heavy tools	15 (20)
Moving patients	12 (16)
Other	8 (10)

Surgeon-Directed Measures to Reduce Pain or Discomfort

In total, 61.0% (47/77) of the respondents changed positions, 37.7% (n=29) used a chair for seated surgery, 35.1% (n=27) implemented wearing supportive footwear or stockings, and 31.2% (n=24) took microbreaks. Furthermore, 29.9% (n=23) of the respondents chose to ignore their intraoperative discomfort, 37.7% (n=29) managed their pain with over-the-counter medications, 14.3% (n=11) pursued medical attention, 14.3% (n=11) decreased surgical workload, and 10.4% (n=8) took time away from the operating room. In total, 6.49% (n=5) of the respondents chose to change to robotic surgery to attempt to alleviate pain.

The survey also explored the types of neuromusculoskeletal disorders formally diagnosed by the surgeon's medical care team, which revealed that 17.1% (13/76) of the respondents had cervical disc disease, 7.9% (n=6) reported wrist or forearm tendonitis, and 28.9% (n=22) reported back pain secondary to lumbar disc disease. In total, 46.6% (35/75) of the respondents stated that their sleep was affected by their work-related discomfort, 45.3% (n=34) stated that their work-related pain affected their surgical posture, 22.7% (n=17) reported deleterious effects on their mobility, and 21.3% (n=16) reported decreased stamina.

We then studied pursued medical intervention. In total, 35.1% (26/74) of the respondents pursued massage therapy, 27.0% (n=20) required diagnostic studies, 24.3% (n=18) required prescription medications, 20.3% (n=15) required referral to a specialist, 18.9% (n=13) used a brace or support device in the operating room, and 16.2% (n=12) even needed surgical intervention (Table 3).

XSL•FO
RenderX

Finally, 75% (54/72) of respondents have never received formal ergonomic training, and 72% (n=52) would be interested in completing such training.

Table . Methods used to minimize operative discomfort. Respondents could select multiple options.

Methods to minimize operative discomfort	Values, n (%)
Seek medical help	11 (14)
Changing position	47 (61)
Take a break	24 (31)
Go slower	3 (4)
Adjust some aspect of the surgical field	26 (34)
Change height by using step	23 (30)
Use chair for seated surgery	29 (38)
Changing instruments	4 (5)
Switch to robotic surgery	5 (6)
Consider different operative approach	5 (6)
Reduce case load	11 (14)
Footwear or support stockings	27 (35)
Surgical floor mats	16 (21)
Time away from the operating room	8 (10)
Over-the-counter medication	29 (38)
Ignore it	23 (30)
Other	8 (10)

Discussion

Principal Findings

The results of the present survey showed the prevalence of WRMDs in Florida urologists estimated at 45.3%, which is consistent with the literature estimating around 47% to 62% prevalence for urologists, who are at risk due to the high use of minimally invasive surgical modalities such as endoscopy, laparoscopy, and robotics [2]. Our definition of WRMD included those who experienced pain at least 25% of the time during surgery, while comparative studies have less restrictive criteria.

Our survey not only provided more information concerning the prevalence of WRMDs and lack of ergonomic education within the field of urology but also provided valuable details about which types of cases are causing injury, the circumstances during those cases causing discomfort, methods being used to combat this issue, and how these injuries are affecting physician performance. In total, 80% (75/94) of the respondents described having pain in the workplace, primarily due to an uncomfortable operating position or extensive standing.

Over half of the survey respondents reported being in practice for a minimum of 20 years, raising the possibility of selection bias. Further review of this cohort of surgeons revealed that almost half of the respondents performed open surgery weekly, which likely influenced the nature of WRMDs. While the number of years in practice did not influence prevalence of pain, the number of surgeries performed per week, especially for minor open cases and robotics, may influence the prevalence of WRMDs.

An intentional byproduct of robotic surgery was to lessen the ergonomic demand of surgeons. However, WRMDs associated with robotic surgery are still prevalent, but the affected body part may differ. In our study, the prevalence of WRMDs was higher with major open (14/35, 40.0%) versus robotic surgery (5/22, 22.7%)

Our survey found that over 1 in 4 urologists sought medical care for their pain, which contributes substantially to health care costs as the median estimated cost per claim for WRMDs is over US $20,000 [10]. While many urologists attempted to treat their pain with over-the-counter medications or other modalities, almost a third of respondents ignored their pain. Ignoring the pain is an alarming finding, as it often coexists with physician burnout [11].

A significant takeaway is the disparity between infrequency, effectiveness, and substantial interest in ergonomic training. Our study showed that 75% (54/72) of the urologists had no formal training, and 72% (52/72) would be interested in such education. A study evaluating the effectiveness of ergonomic training showed that 100% (32/32) of those who received such instruction found it helpful, 88% (28/32) changed their practice as a result, and 74% (24/32) noticed a decrease in strain after training [1]. This particular study also showed that a small time commitment to ergonomic training can dramatically decrease the incidence of strain and injury from performing robotic procedures by greater than 70% [1]. Because of the effectiveness of ergonomics training, its implementation into practice may

XSL•FO
RenderX

improve the pain and discomfort experienced during urologic surgery. If actual training sessions are not possible, general advice regarding acceptable intraoperative modifications to prevent injury should be practiced more routinely. Some tips include modifying table height to decrease back strain, maintaining a neutral position throughout a procedure, and taking 2-minute pauses every half hour or as needed to move, stretch, and relax during cases and stretching between cases [12-15]. Regarding robotics specifically, it has been associated with surgeon discomfort especially in the neck and trunk [16]. Becoming familiar with the robot's ergonomic settings has been shown to lower the rate of physical symptoms during and after procedures by not allowing greater than 20 degrees of neck flexion, avoiding excess knee flexion, and using the clutch often to restore proper and comfortable posture frequently [15].

There are limitations to this study. Any questionnaire-based study is associated with selection bias, as participants who complete the study may be more likely to have physical ailments or WRMDs. In total, 18.6% (94/504) of the recipients completed the survey, which is near the response rate of similar studies assessing surgical WRMDs [17-19]. Despite the consistent response rate with other studies, the low response rate may not truly represent the burden of WRMDs. A significant number of respondents practiced >20 years, risking the potential of selection bias. This study is also limited by convenience sampling as only urologists from Florida were included and respondents may have been affected by their accessibility to the survey. Another limitation is the inability to account for other confounding variables outside a surgeon's career, such as preexisting conditions or injuries that could contribute to pain. Additionally, many urologists perform several different types of surgeries, but it may be difficult to attribute their pain to a particular type. Our survey could not account for the type of practice a urologist has, as surgeons in an academic setting may have resident substitutes for parts of the surgery.

The goal of this survey was to explore the prevalence and etiology of pain in urologists. With further knowledge about the etiology of urologic surgery–related pain in this contemporary cohort, we hope that changes can be implemented to minimize the pain and improve work-related satisfaction, comfort, and surgeon longevity.

Conclusions

Surgeons are burdened by WRMDs far too frequently. Our survey found that nearly half of the urologists who answered the survey reported pain for more than 25% of the time during surgery, and more than one-fourth have sought medical attention for this pain. In addition, we found a higher rate of pain during surgery for major open surgery compared to robotic surgery. In total, 75% (54/72) of the respondents have received no formal ergonomic training, which could potentially decrease pain, health care costs, and burnout. Although ergonomic changes have continued to be implemented, such as with advanced robotic consoles, work-related pain is still prevalent.

Abstract

Background: Mobile health (mHealth) apps are increasingly integrated into clinical workflows to support decision-making and adherence to best practices. Usability is a critical determinant of adoption, engagement, and long-term use.

Objective: This study aimed to evaluate the usability of the C8 Health platform deployed in the Department of Anesthesiology at MetroHealth in 2024.

Methods: A quality improvement initiative was conducted using the mHealth App Usability Questionnaire (MAUQ). A total of 142 anesthesiology clinicians participated by completing the questionnaire. This study was reported in accordance with the SQUIRE (Standards for Quality Improvement Reporting Excellence) guidelines for quality improvement reporting.

Results: The overall MAUQ scores indicated high usability, with mean scores greater than 5.5 across core items (overall mean MAUQ score 5.73, SD 0.81). These findings suggest strong user satisfaction and positive engagement with the C8 Health platform among anesthesiology clinicians.

Conclusions: The C8 Health platform demonstrated high usability in an anesthesiology setting. These results support its integration as a clinical decision support tool to enhance workflow efficiency and adherence to best practices.

KEYWORDS

C8; mobile health; mHealth; mHealth App Usability Questionnaire; MAUQ; usability; quality initiative; anesthesiology

Introduction

Mobile health (mHealth) technologies have become integral to modern health care, offering “low-cost and high accessibility” solutions that empower clinicians and patients alike and help streamline clinical workflows [1,2]. However, a significant barrier to adoption lies in usability. Poor app design, data entry burden, and frustrating interfaces often cause users to abandon these tools. To address this, the mHealth App Usability Questionnaire (MAUQ) was developed as a validated, reliable instrument tailored specifically for evaluating usability in health care apps, covering ease of use, interface satisfaction, and perceived usefulness [3].

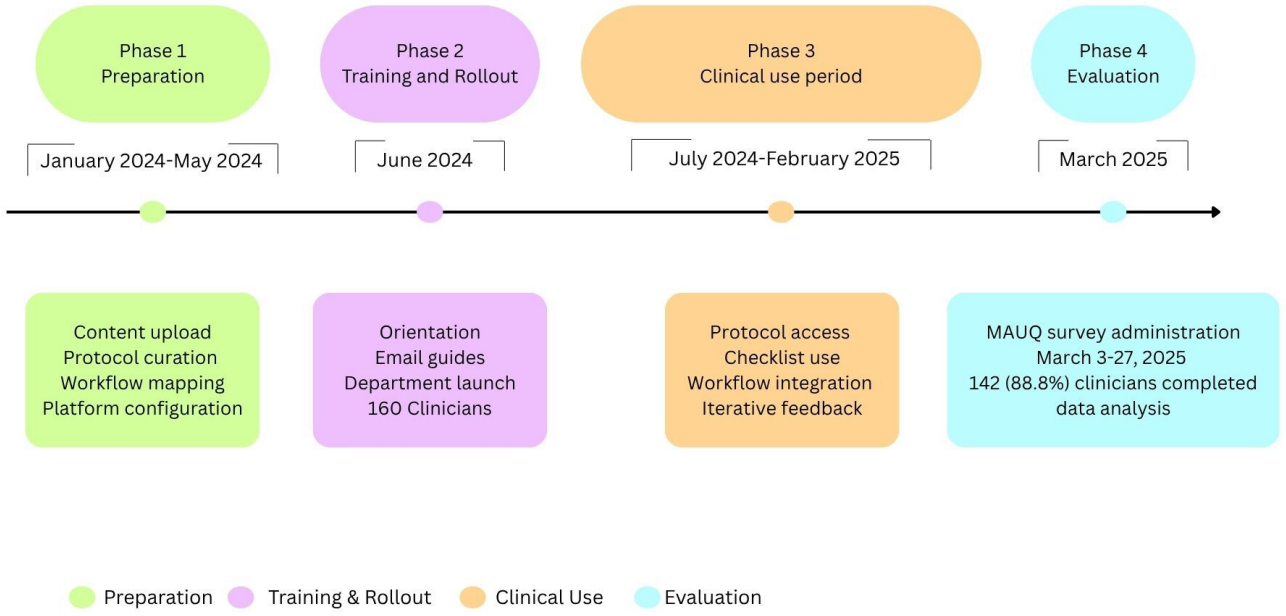
In June 2024, the MetroHealth System introduced C8 Health, an mHealth app designed to help health care institutions implement their best practices effectively through the centralization of clinical protocols, checklists, and workflows for care teams. Though early feedback has been promising [4-6], systematic usability evaluation among end users has not yet been conducted.

This study aimed to fill that gap by assessing C8 Health’s usability among MetroHealth anesthesia clinicians using the MAUQ. Evaluating usability at this stage is critical not only to refine the app’s user interface and functional workflow but also to understand how such tools might support scalable, protocol-driven perioperative care [7]. The results are expected to guide both iterative improvements to C8 Health and inform

XSL•FO
RenderX

frameworks for introducing similar mHealth solutions in hospital settings.

Methods



Study Design and Setting

This was a cross-sectional survey study conducted in the Department of Anesthesiology at the MetroHealth System, a tertiary academic medical center in Cleveland, Ohio, United States. The study evaluated the usability of C8 Health, a mHealth app introduced in June 2024 to support clinical workflow efficiency and adherence to best practices. This study was reported in accordance with the SQUIRE (Standards for Quality Improvement Reporting Excellence) guidelines for quality improvement reporting.

Participants and Recruitment

All anesthesiology clinicians employed at the MetroHealth System during the study period were invited to participate. Inclusion criteria included active clinical practice in the department and familiarity with the C8 Health platform. Participation was voluntary and anonymous. Recruitment was conducted via institutional email invitations, and nonresponders received 2 to 3 reminder emails per week from research faculty to maximize response rates (Figure 1).

Figure 1. Implementation timeline of the C8 Health platform in the Department of Anesthesiology and Pain Management, the MetroHealth System, Cleveland, Ohio, United States. MAUQ: mHealth App Usability Questionnaire.

Data Collection

The survey was administered online using SurveyMonkey (SurveyMonkey Inc) between March 3 and March 27, 2025. Survey responses were deidentified to preserve confidentiality. No personally identifiable information was collected.

Measures

Usability was assessed using the validated MAUQ, which evaluates 3 domains: ease of use, system information arrangement, and usefulness in health care delivery. The questionnaire uses a 7-point Likert scale, with higher scores indicating greater usability. Open-ended questions were also included to capture qualitative feedback regarding functionality, interface design, and overall user experience.

Outcomes

The primary outcome was the overall usability score derived from the MAUQ. Secondary outcomes included subscale scores for usability domains and thematic analysis of open-ended responses to identify strengths and areas for improvement.

Statistical Analysis

Descriptive statistics were used to summarize the survey responses. Continuous variables (eg, MAUQ scores) were reported as means with SDs. Subscale analyses were performed to compare usability domains. Open-ended comments were analyzed thematically to identify recurring usability issues and user recommendations.

Ethical Considerations

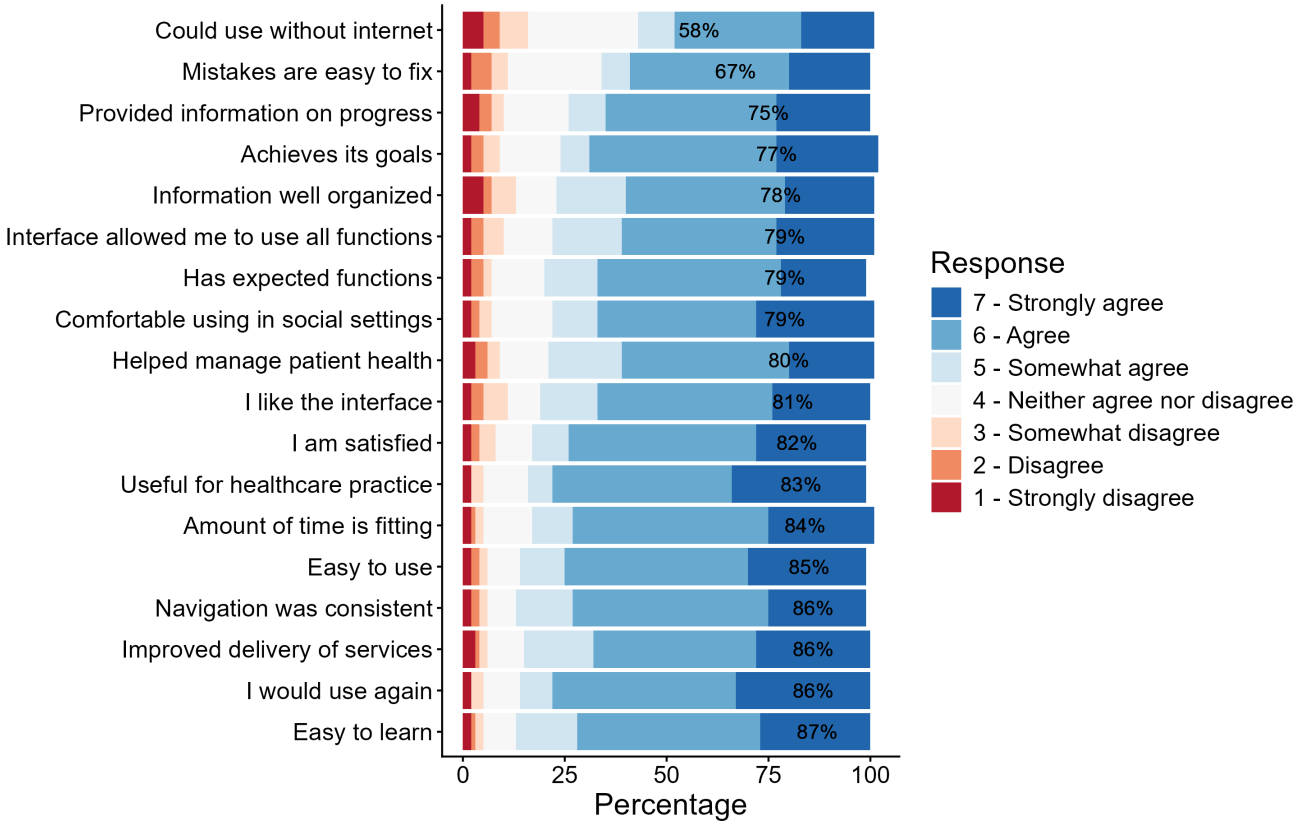
The study received institutional review board exemption (STUDY00000729) from the MetroHealth System, as it was classified as a quality improvement initiative involving minimal risk to participants. As the study was granted an institutional review board exemption, informed consent was waived. All data were handled in accordance with institutional privacy and confidentiality standards, and no compensation was provided to participants.

Results

The survey was distributed to all 160 clinicians, including faculty physicians, residents, and departmental staff, yielding a response rate of 88.8% (n=142).

Overall, results showed high usability ratings. On a 7-point Likert scale, the app received weighted averages above 5.5 for most core items. Clinicians strongly agreed that the app was easy to use (122/142, 86%; mean 5.73), easy to learn (124/142,

XSL•FO
RenderX



87%; mean 5.78), and supported consistent navigation (122/142, 86%; mean 5.70). Additionally, participants (112/142, 79%) valued the design and were able to access all key functions (mean 5.50). Because of the straightforward interface, 84% (119/142) of respondents felt the time required to use the app was appropriate.

Surveyed clinicians also found the information distributed by C8 Health beneficial, as 79% (112/142) of users appreciated the app's serviceability. The app was perceived as valuable in practice, with strong agreement that it improved health care service access (mean 5.66) and supported effective patient health management (mean 5.54, SD).

Although largely positive, the survey highlighted areas for improvement. Offline utility received a weighted average of 4.95, with only 58% (82/142) of users finding this component satisfactory. Additionally, error recovery received a lower average of 5.28 (SD), yet 67% (95/142) of participants felt satisfied with this function.

However, overall satisfaction remained high (mean 5.72), affirming the app's acceptance and perceived benefit in a clinical setting. Respondents strongly agreed that they would use C8 Health again (mean 5.87). These findings (Figure 2) validate the C8 Health app's design and implementation as a useful, user-friendly digital tool for anesthesiology professionals. Ongoing iterative improvements, particularly focused on offline functionality and error handling, are recommended to maximize utility and engagement.

Figure 2. mHealth App Usability Questionnaire survey results with percentages representing the summation of "agree" and "strongly agree" responses.

Discussion

Principal Findings

In this usability study, of the 160 clinicians from the Department of Anesthesiology at the MetroHealth System, 142 (88.8%) completed the MAUQ questionnaire to assess C8 Health, an mHealth app that centralizes clinical protocols and checklists to enhance clinical workflow and adherence to best practices. The MAUQ is a validated tool to assess the usability of the mHealth platform targeted for health care providers. Overall, the scores showed high usability and satisfaction, with weighted averages above 5.5 on a 7-point Likert scale for key aspects such as ease of use, accessibility of functions, design appreciation, and perceived value in practice.

Beyond global usability ratings, individual MAUQ items provide insight into how C8 Health supported clinical practice. A total of 86% (122/142) of respondents agreed or strongly agreed that the platform improved the delivery of health care services, and 83% (118/142) found it useful for their health care practice, reflecting its integration into day-to-day clinical workflow. Notably, 80% (114/142) agreed that it helped them manage patient health, suggesting that clinicians perceived the platform as more than an informational repository but rather as an active support tool in patient care decisions. The high agreement on information organization (111/142, 78%) and availability of expected functions (112/142, 79%) further suggested that clinicians could reliably locate protocols and checklists when needed at the point of care, a key requirement in time-sensitive perioperative environments such as the operating room.

About C8 Health

C8 Health is a platform for the implementation of best practices that centralizes medical knowledge to streamline health care operations and improve patient care. It disseminates essential information such as clinical protocols, policies, procedures, guidelines, checklists, and workflows, giving care teams fast access to standardized, evidence-based resources [7]. Apps such as C8 Health have the potential to offer benefits in health care by improving access to standardized clinical knowledge with the goal of reducing care variability and informing clinical decision-making. By unifying resources and enabling seamless knowledge sharing across departments and organizations, these tools may support more consistent, accurate, and timely care delivery. Whether this translates to direct improvements in patient outcomes, including reductions in medical errors or mortality rates, remains to be established through controlled outcome studies.

Current State of Best Practices Implementation in Health Care

Adherence to established clinical protocols significantly enhances patient outcomes by reducing complications, shortening hospital stays, and lowering health care costs. For instance, following the Enhanced Recovery After Surgery (ERAS) protocol in breast reconstruction has been shown to decrease postoperative complications and reduce hospital length of stay [8]. Similarly, compliance with anesthesia-related ERAS measures, such as multimodal analgesia and opioid-sparing strategies, has been associated with significantly shorter hospital stays in colorectal and gynecologic surgeries [9,10]. Furthermore, the use of ventilators and infection prevention bundles in intensive care unit settings has been shown to decrease mortality and ventilator-associated pneumonia rates when properly implemented [11,12]. Nonadherence to anesthesia guidelines in pain interventions has also been linked to severe complications, emphasizing the risks of deviation [13]. Collectively, these findings reinforce that rigorous protocol compliance in surgical and anesthetic care settings leads to safer patient outcomes, with patients subsequently facing fewer complications and lower out-of-pocket expenses related to preventable hospitalizations or errors.

Current adherence to medical protocols such as the ERAS protocol remains suboptimal despite widespread implementation. A recent large-scale study found that the actual compliance rate with the ERAS protocol was only 32.3%, with a potential compliance rate of 53.2% if patients without postoperative medical issues were included [14]. These findings are consistent with broader literature, which highlights that adherence to medical protocols is often challenged by clinical complexity and organizational factors [15]. Thus, while protocols such as ERAS have proven benefits, real-world adherence is influenced by a complex interplay of patient, health care provider, and system-level factors [14,15].

Systems for implementation of best practices, such as C8 Health, have demonstrated the potential to improve adherence to medical protocols by providing clinicians with timely, evidence-based recommendations and reminders integrated into clinical workflows. Multiple studies indicate that similar interventions are associated with small to moderate improvements in the delivery of guideline-recommended care, with average absolute increases in process adherence of approximately 5.8% and best-case improvements reaching up to 8.5% [16]. Features such as treatment recommendations and automated flagging of best-practice alerts are particularly effective in supporting guideline adherence and quality assurance in patient care [17]. These systems can also enhance diagnostic accuracy, support monitoring, and facilitate preventive screening, all of which contribute to better protocol compliance [17]. Overall, while the extent of improvement varies, systems for implementation of best practices consistently contribute to better adherence to clinical protocols across diverse health care settings, indicating a substantial functional role of apps such as C8 Health in improving patient outcomes [16-18].

From the health care provider's perspective, these digital tools may enhance the experience of delivering care by potentially reducing cognitive burden, supporting confidence in clinical decisions, and encouraging a culture of collaboration and transparency. Features such as natural language search, real-time updates, and integrated authoring tools help clinicians spend less time searching for information and more time focused on patient care. This contributes to reduced burnout and greater job satisfaction, both critical factors in an era marked by workforce shortages and growing demands on health care professionals [19].

Assessing C8 Health

Considering the benefits of apps such as C8 Health to patients, health care providers, and health care institutions, one of the first steps in determining the feasibility of implementing this app is assessing usability. Using the MAUQ, the C8 Health app received a high overall MAUQ score among anesthesiologists at MetroHealth, with most core items receiving >5.5 on a 7-point Likert scale. Overall satisfaction with the app was high, with users agreeing that the app was easy to use with an agreeable interface. Notably, the app was perceived as valuable in practice, as users agreed that it improved health care service access and supported effective patient health management. These positive findings have important future implications: as the app was well perceived by anesthesiologists, broader adoption and integration into clinical workflows are increasingly possible, potentially supporting streamlined communication and increased efficiency, though improvements in patient outcomes remain hypothetical at this stage and require validation through prospective studies with objective outcome measures across health care institutions.

Strengths and Limitations

Strengths of this study include that usability was assessed using the MAUQ, a validated and widely used instrument in mHealth research. The use of this tool increases both the reliability of our measurements and the comparability of findings with those from other studies in the field. The evaluation was conducted solely at a single postimplementation time point. The absence of preimplementation data precludes direct before-and-after comparisons of workflow efficiency, protocol adherence, or platform use, which would have provided stronger causal evidence. Furthermore, although voluntary participation in the questionnaire introduces the possibility of selection bias, this

XSL•FO
RenderX

risk is mitigated by the exceptionally high response rate (142/160, 88.8%), which strengthens confidence in the representativeness of the data.

This study did not collect objective operational or clinical outcome data (eg, protocol adherence rates, time-to-information retrieval, or patient-level outcomes). Consequently, the improvements in workflow efficiency and care quality discussed herein are based on user perception rather than measured performance indicators.

One significant limitation of this study is that the evaluation was conducted at a single center and lacked a control group, both of which may restrict the generalizability of the findings. In addition, limitations of the C8 Health platform itself were identified. These include limited offline functionality, suboptimal error recovery, and a lack of integration with existing electronic health record systems. Such constraints may reduce workflow efficiency and continuity of care in practical settings. However, these issues represent identifiable opportunities for improvement to be addressed in future system development.

Future Directions

In future research, quantifying improvements in patient care and institutional productivity following implementation of the app may assist in valuing the app in the context of outcomes and efficiency metrics. There is also a need for multicenter and longitudinal studies to assess sustained use. Future research should explore the integration of C8 Health with electronic health record systems to create a more comprehensive clinical decision support ecosystem. This integration could enable automated protocol selection based on patient characteristics, streamlined documentation workflows, and enhanced tracking of clinical outcomes. Future studies should also incorporate prospective pre-post designs with baseline data collection before implementation to better isolate the platform's effect on clinical workflow and protocol adherence.

Overall, the strong usability and perceived value of the C8 Health app pave the way for it to become a transformative tool in perioperative care, setting a new standard for technology-driven support in anesthesiology and beyond.

Conclusions

These findings indicate that the C8 platform demonstrates strong perceived usability and holds significant promise for supporting perioperative clinical workflows, as reported by end users. Ongoing development based on user feedback may further improve its effectiveness and extend its applicability to other clinical areas.

Acknowledgments

The authors would like to acknowledge the Department of Anesthesiology at the MetroHealth System for its support in the distribution of the survey and for facilitating clinician participation. The authors thank the clinicians who generously contributed their time and feedback, which made this study possible. The authors further extend their sincere gratitude to Tomer Cramer for his careful review of the manuscript and for his insightful suggestions, which significantly enhanced its quality.

Funding

This project was supported in part by the Clinical and Translational Science Collaborative (CTSC) of Cleveland, which is funded by the National Institutes of Health (NIH), National Center for Advancing Translational Sciences (NCATS), Clinical and Translational Science Award (CTSA) grant UL1TR002548. Abstract

Background: Assessing usability is important given the increasing use of technology in rehabilitation. While wearable robotic exoskeletons (WREs) are commonly incorporated into neurological rehabilitation in both clinical and community settings, there is a need to examine the applicability of different usability instruments in this context. The Assistive Technology Usability Questionnaire for People with Neurological Diseases (NATU Quest) was developed to evaluate the usability of assistive technology in individuals with neurological conditions. However, its reliability and validity have been established only for assistive devices such as wheelchairs and canes, restricting its generalizability.

Objective: This study aimed to cross-culturally adapt a Taiwan Chinese version of the NATU Quest and to preliminarily evaluate its applicability, reliability, and validity for assessing WRE use among patients who had a stroke as an expanding application context.

Methods: Cross-cultural adaptation was achieved through a structured translation from Spanish to Taiwan Chinese, followed by content validation by an expert panel of 10 raters. Following the adaptation process, psychometric testing of the NATU Quest was administered to 20 patients who had a stroke following the completion of a comprehensive course of robot-assisted gait training facilitated by a WRE. The internal consistency of the NATU Quest was evaluated using the Cronbach α coefficient. The reliability of the test-retest procedure was evaluated using the intraclass correlation coefficient (ICC). Convergent validity was ascertained by examining the correlation between the NATU Quest scores and the System Usability Scale (SUS).

Results: The culturally adapted NATU Quest showed acceptable content validity, with item-level content validity index (CVI) values ranging from 0.80 to 1.00 and scale-level CVI values of 0.93 for clarity and 0.97 for relevance. Cronbach α was 0.943, indicating high internal consistency. Of the 20 participants who completed all 6 rehabilitation sessions, 13 participants completed repeat testing. Preliminary test-retest reliability was acceptable (ICC=0.823; P<.001; SE of measurement=0.31). NATU Quest scores were strongly correlated with SUS scores (Spearman ρ=0.818; P<.001), providing preliminary support for convergent validity.

Conclusions: The adapted NATU Quest demonstrated promising preliminary psychometric properties when applied to WRE use among individuals who had a stroke. Further studies with larger sample sizes are warranted to examine additional psychometric properties such as construct validity and responsiveness.

Introduction

Wearable robotic exoskeletons (WREs) have been widely used for robot-assisted gait training (RAGT) to restore walking ability in individuals with neurological or mobility impairments for many years [1]. They offer high-intensity and task-specific training and have demonstrated benefits for stroke, spinal cord injury, Parkinson disease, and cerebral palsy [2-5]. Moreover, WREs are increasingly transitioning beyond clinical and laboratory settings toward widespread adoption in homes, communities, or even industrial settings, reflecting a broader application for home-based rehabilitation and assistive devices [6-8].

While the application of WREs has become increasingly popular in rehabilitation, usability assessment for their effective adoption and clinical integration has not yet been comprehensively addressed. According to the International Organization for Standardization, usability is defined as "the effectiveness, efficiency, and satisfaction with which users achieve specified goals in specific contexts of use" [9]. It is an important feature of an assisted technology in rehabilitation related to user comfort, feedback mechanisms, difficulties in donning and doffing, compliance mismatch, and environmental conditions [10-15]. The World Health Organization also recommends that usability assessment should be the initial step in evaluating any digital health intervention [16]. However, a systematic review by Koumpouros [17] indicated that 64% of studies relied on either custom-developed or nonvalidated instruments to assess the usability of assistive robotic technologies. The lack of a comprehensive psychometric evaluation of these instruments will likely raise doubts about reliability and validity, limiting comparability between studies.

Usability evaluation of WREs requires consideration of the elements that contribute to the interaction between the device and the user. These elements include aspects such as comfort, ease of donning and doffing, individual adaptability, perceived safety, and functional support [17]. However, there is limited research on usability evaluation instruments for WREs. Up to 67% of the measures used for subjective assessment of rehabilitation and assistive robot devices are custom-made and lack validation [17]. Among the standardized measures, two are most commonly used, that is, the System Usability Scale (SUS) [18] and the Quebec User Evaluation of Satisfaction with Assistive Technology (QUEST 2.0) [19,20]. The SUS was originally developed for website usability. Despite its broad application to various products, it focused more on the software design and users' interaction with systems [21] without addressing the physical, task-dependent, and dynamic human-device interactions that are central to rehabilitation robotics [22]. The QUEST 2.0 demonstrates a stronger alignment with our intended focus on device-related usability; however, its inclusion of service-related domains, such as delivery, repairs, and follow-up services, limits its relevance in clinical scenarios where patients who had a stroke predominantly use WREs within hospital-based rehabilitation settings [19]. Recently, an Assistive Technology Usability Questionnaire for People with Neurological Diseases (NATU Quest) was developed and addresses the paucity of assessment tools covering specific domains relating to assistive technology, such as adaptability to user needs, perceived safety, contextual fit, and user experience [23]. These domains may represent a contextually appropriate measure of immediate user-device interaction in WRE-assisted gait training; however, their feasibility remains to be examined.

The NATU Quest is a self-reported questionnaire containing 10 items selected through 2 rounds of a Delphi study based on the opinion of 69 experts. It is scored on a 6-point Likert scale, with item scores ranging from 0 to 5. The total questionnaire score is calculated by summing the scores of valid responses to items 1 to 10 and dividing by the number of valid items, resulting in a final score ranging from 0 to 5, with higher scores indicating greater usability. The initial validation study assessed the usability of conventional assistive tools (eg, wheelchairs and walking aids) in patients with neurological impairments and demonstrated good internal consistency (Cronbach α=0.895), high test-retest reliability (intraclass correlation coefficient [ICC]=0.869), and construct validity (Spearman ρ=0.756 with 8 items of the QUEST 2.0) [23]. In a recent study, Bosch-Barceló et al [24] further applied the NATU Quest on a gamified virtual reality treadmill intervention used in rehabilitation for patients with Parkinson disease, expanding its application to different technology.

Our study had 2-fold goals. First, we would adapt a Taiwan Chinese version of the questionnaire following an established guideline to ensure the cross-culture equivalence of the questionnaire. Second, we examined whether the NATU Quest can be applied in a group of patients undergoing RAGT, a representative example of wearable robotic rehabilitation technology, and will preliminarily evaluate its psychometric properties. We hypothesized that the adapted questionnaire had acceptable reliability and validity. The results could provide pilot evidence to ascertain its suitability for usability assessments of WREs in future studies.

Methods

Cross-Cultural Adaptation

The adaptation of the Spanish version of the 10-item NATU Quest questionnaire was conducted according to the guidelines proposed in the study by Guillemin et al [25] after we obtained the permission from the original authors.

It was first forward translated into Taiwan Chinese by 2 native Taiwan Chinese translators proficient in Spanish without medical backgrounds. The first draft was concluded by a consensus-based expert panel consisting of a rehabilitation physician, an occupational therapist, and one of the translators to review both translations and resolve discrepancies. Back translation of the first draft into Spanish was conducted by an independent native Spanish translator fluent in both Taiwan Chinese and Spanish, who was blinded to the original NATU Quest. The expert panel conducted a second review to compare the back-translated version to the original Spanish NATU Quest and resolve discrepancies to ensure semantic, idiomatic, experiential, and conceptual equivalence. During this process, the panel was assisted by one of the original authors (Maria

XSL•FO
RenderX

Masbernat-Almenara) through personal communication to clarify minor ambiguities. Finally, the content validity index (CVI) of the finalized version was tested by a panel of 10 physical therapists and occupational therapists who are all familiar with the use of WREs. Each item was assessed based on clarity and relevance related to the WREs using a 4-point Likert scale [26]. The results were used to compute 2 indices: item-level content validity index (I-CVI) and scale-level content validity index (S-CVI) according to equations (1) and (2). The minimum threshold of the I-CVI and S-CVI was 0.78 and 0.8, respectively [26].

$$\text{I-CVI}=\frac{\text{Number of rating 3 or 4}}{\text{Total number of experts}} \quad (1)$$

$$\text{S-CVI}=\frac{\sum \text{I-CVI}}{\text{Total number of items}} \quad (2)$$

Study Design and Participants

This was an extended study of a prospective and pilot case-control study aiming at investigating the therapeutic effects of RAGT using a user-initiated powered WRE in patients in the early stages of recovery after stroke [27]. All RAGT sessions used the same WRE, Keeogo Exoskeleton (Wistron Medical Technology; Figure 1). It is an electrically powered robotic device that provides knee power assistance while preserving passive hip motion [28,29]. Participants were patients who had a stroke in the early subacute stage who could maintain basic postural stability and demonstrated sufficient lower-limb motor capacity to safely engage in user-initiated robotic gait training. Individuals with substantial cognitive impairment, severe musculoskeletal or cardiopulmonary conditions, insufficient joint range or muscle tone, or dermatological or vascular problems preventing safe device use were excluded [27]. Given the limited availability of clinically eligible participants for inpatient exoskeleton training, a pragmatic pilot sample was recruited.

Figure 1. A patient who had a stroke undergoing Keeogo exoskeleton robotic gait training.

Ethical Considerations

The study was approved by the institutional review board (IRB) of the Chang Gung Medical Foundation (IRB approval number 202200822B0, 2022) and adhered to the Declaration of Helsinki. Before enrollment, all participants were informed of the study purpose, procedures, and potential risks and benefits, and written informed consent was obtained from each participant. Participants' privacy and confidentiality were protected throughout the study. All research data were deidentified and stored securely, and only authorized members of the research team had access to the study data. No financial compensation was provided to participants.

Study Procedures

Each participant completed 6 sessions of the RAGT (40 minutes per session, 1 session per day, 2 - 3 sessions per week) and was invited to answer the NATU Quest and SUS after the final session (T1). The NATU Quest was repeated within 1 week after the final session (T2) for the evaluation of test-retest reliability [30].

XSL•FO
RenderX

The SUS is a standardized 10-item questionnaire used to assess perceived usability across different technologies. Each item is rated on a 5-point Likert scale, and the total score ranges from 0 to 100, with higher scores indicating higher perceived usability [18]. The SUS has been extensively studied and has demonstrated well-established reliability and validity across diverse technologies [21]. It has also been used for usability assessment in robotic rehabilitation and assistive robotic devices, including upper- and lower-limb exoskeletons, end effectors, and sensor-based systems [31-38]. Therefore, the SUS was used to assess convergent validity and to facilitate comparisons across studies. A validated Chinese version of SUS was used for the current study [39].

Statistical Analysis

Demographic data were analyzed using nonparametric and descriptive statistics for a small sample size. The psychometric properties of the adapted questionnaire were analyzed as follows:

1. The proportion of participants who achieved the lowest or highest possible score was computed. More than 15% of participants having the maximal or minimal score was defined as having a ceiling and floor effect, respectively.
2. The internal reliability of the scale at T1 was evaluated by calculating Cronbach α and Cronbach α if an item was deleted. Values of Cronbach α between 0.70 and 0.80 were considered good internal consistency, whereas values above 0.80 were considered very good [40]. Item-total statistics were computed to evaluate the corrected item-total correlation for each item, with values ≥0.3 considered acceptable and values ≥0.5 indicating strong homogeneity [41].
3. Test-retest reliability was evaluated with an ICC and their 95% CIs for scores obtained at T1 and T2. The ICC estimates were based on a single rating, absolute-agreement, and 2-way mixed-effects model, and interpreted as poor (<0.40), good (0.40 - 0.75), and excellent (>0.75) [42].
4. The SE of measurement (SEM) was calculated to reflect the variability in the scores of individual items in the questionnaire using the following formula, where $SD_{baseline}$ is the SD of the scores from the first measurement (T1) and ICC is the test-retest reliability between the T1 and the second measurement (T2):
   SEM=SDbaseline×1-ICC
   Subsequently, the minimal detectable change (MDC) was calculated to determine the minimum change in score that can be interpreted as a real difference, beyond measurement error, at a 95% confidence level with a *z* score of 1.96.
   MDC=1.96×SEM×2
   MDC was also expressed as a percentage of a parameter's grand mean (MDC%) by dividing the MDC by the mean scores of the NATU Quest at T1. An MDC% of <30% is considered acceptable [43].
1. Convergent validity was tested by computing the Spearman rank correlation coefficient (ρ) between the NATU Quest and SUS scores, and the size of the correlation coefficient was interpreted as being strong (>0.75), moderate (approximately 0.50-0.75), fair (approximately 0.25-0.50), and no relationship (approximately 0.00-0.25) [44].

All statistical analyses were performed using SPSS software (version 26.0; IBM Corp). The level of statistical significance was defined as $P<.05$.

Results

The NATU Quest was translated from the original Spanish version, and there was generally no dispute to form the consensus, except for the Q5 ("Me siento seguro usando/llevando...//...es seguro en su utilización"). Two versions of translation: "I feel that I can use the exoskeleton robot very safely" and "I feel that the exoskeleton robot is safe to use" were consolidated into "I feel safe when wearing the exoskeleton robot." The finalized Taiwan Chinese version of the NATU Quest was submitted to the original author of the NATU Quest for a final approval.

The I-CVI for all the items regarding the clarity and relevance of the adapted version exceeded the threshold of 0.78, while the S-CVI, calculated using the averaging method, was 0.93 for clarity and 0.97 for relevance. Therefore, the adapted version was used for further testing without modifications.

Twenty participants were enrolled in the validation study, most of whom were first-time survivors of ischemic stroke in the early subacute phase following a stroke (Table 1). They completed the 6 RAGT within an average of 20.3 (SD 4.5) days, and no adverse events were reported during the experimental process.

XSL•FO
RenderX

Table . Demographic characteristics of the participants (N=20).

Variables	Results
Age (years), mean (SD)	55.8 (11.4)
Sex, male, n (%)	15 (75)
Educational level, n (%)	
Middle school and below	4 (20)
High school or vocational school	8 (40)
College or above	8 (40)
Stroke-related characteristics	
Affected side, n (%)	
Left	12 (60)
Right	8 (40)
Stroke type, n (%)	
Ischemic	14 (70)
Hemorrhagic	6 (30)
First-time stroke, n (%)	18 (90)
Stroke duration in days, median (IQR)	37 (22 - 62)

The median scores of each item of the NATU Quest ranged from 4 to 5, and the overall scores were 4.4 and 4.1 on the two occasions (Table 2). No participants reported floor scores on the NATU Quest, whereas 2 (10%) participants reported ceiling scores in T1, below the 15% criterion for a ceiling effect. Meanwhile, none reported a ceiling or floor score with the SUS.

Table . Descriptive data and internal consistency measures of the Assistive Technology Usability Questionnaire for People with Neurological Diseases (NATU Quest) and System Usability Scale.

Components	Score, range	Values, median (IQR)	Item-total correlation	Cronbach α (if an item was deleted)
NATU Quest				
Q1. Effectiveness	3-5	5 (4-5)	0.791	0.937
Q2. Comfort	2-5	4 (4-5)	0.785	0.936
Q3. Adaptability or adjustability	2-5	4 (4-5)	0.768	0.936
Q4. Donning or doffing	1-5	4 (4-5)	0.736	0.940
Q5. Perceived safety	3-5	4.5 (4-5)	0.680	0.940
Q6. Functionality	2-5	4 (4-5)	0.804	0.935
Q7. Ergonomics or fit to body	3-5	4 (3.75 - 5)	0.829	0.934
Q8. Ease of use	2-5	4.5 (3.75 - 5)	0.868	0.932
Q9. Ease of learning	2-5	4 (4-5)	0.685	0.940
Q10. Satisfaction (overall)	3-5	5 (4-5)	0.780	0.936

XSL•FO
RenderX

The Cronbach α of the NATU Quest at T1 was 0.943, and the Cronbach α if item deleted was between 0.932 and 0.940 (Table 2), lower than the Cronbach α of the overall scale. The item-total correlations were all above 0.5, with the highest for Q8 (ease of use: 0.868) and the lowest for Q9 (ease of learning: 0.685). This finding suggested that all items contributed to the internal consistency of the scale in this sample.

Thirteen participants completed the NATU Quest on 2 occasions, with a mean interval of 3.5 (SD 1.5) days, ranging from 2 to 6 days. There were no significant differences in demographic characteristics between participants who completed the survey at T2 and those who did not, including age (P=.70), sex (P=.61), stroke duration (P=.23), modified Rankin Scale (P=.59), and SUS scores (P=.88) by the Mann-Whitney U test. The ICC was 0.823 (95% CI 0.533 - 0.942; P<.001), indicating an excellent test-retest reliability. The SEM, MDC, and MDC% were 0.31, 0.86, and 20.1%, respectively. The collective results supported good reliability of the adapted NATU Quest.

The Spearman ρ coefficient between the NATU Quest and SUS scores was 0.818 (P<.001) in all 20 participants, indicating a strong correlation.

Discussion

Principal Findings

We adapted a Taiwan Chinese version of the NATU Quest to facilitate future cross-cultural comparisons in the usability assessment of assistive technology. We also conducted a preliminary evaluation of its psychometric properties in patients who had a stroke using WREs for RAGT, a rapidly evolving field. The results demonstrated acceptable CVI scores, test-retest reliability, and convergent validity when referenced with the SUS. By following the guidelines for the adaptation process, we ensured the contextual clarity of the adapted questionnaire. The reliability and convergent validity of the adapted NATU Quest support its potential use in the usability assessment of WREs. However, the findings should be interpreted with caution because of the modest sample size.

The 10 items of the NATU Quest were derived using the Delphi method, and the original validation study included wheelchairs, walking aids, splints, and treadmills, without specific focus on WREs. Similar to the SUS and QUEST 2.0, it is not a device-specific instrument. However, these validated instruments offer the advantages of requiring fewer resources and enabling comparability across studies [45]. Our results showed a high CVI from 10 therapists who were familiar with this WRE and confirmed the face validity. They generally align with the essential features of the medical device as emphasized by the guidelines established by the International Electrotechnical Commission and the US Food and Drug Administration guidelines [46,47]. However, caution should be exercised, as the use of a generic tool may fail to capture certain risks and usability dimensions specific to WREs [48]. WREs are available in many forms and multiple purposes, such as rehabilitation, assistive mobility, industrial and military use, sports and function, and personal mobility [49]. The WRE we tested, Keeogo, has been used in stroke, multiple sclerosis, and older adults with morbidities [27,50,51]. Its intended use includes not just for rehabilitation but also personal use. We did not attempt to add device-specific items during the adaptation process, as this could compromise the construct validity of the original questionnaire. Therefore, future users should be aware of the potentially limited coverage of certain device-specific concerns, including but not limited to biomechanical misalignment, falls, and soft-tissue pressure–related injuries.

Several psychometric properties tested in this study aligned closely with those reported for the original NATU Quest [23]. The median scores of the participants for Keeogo are between 4.1 and 4.4, around 82% to 88% of the highest scores, implying a generally positive perception of the device. Test-retest reliability (ICC=0.823) also paralleled the previously reported excellent temporal stability [23]. However, up to 10% of the participants reported ceiling scores at T1, and 2 items had median scores of 5, raising concerns regarding ceiling effects and restricted score variability in this specific clinical context. In addition, the internal consistency (Cronbach α=0.943) was higher than that reported in a previous study involving various devices and patients with diverse diagnoses [23]. Although the Cronbach α values if an item was deleted were mostly below 0.94, potential item overlap or redundancy should be examined in future studies with a larger sample size.

A strong correlation between the NATU Quest and SUS scores (Spearman ρ=0.818) supported convergent validity. Both the SUS and QUEST 2.0 have been used to assess the usability of rehabilitation robots [52,53], and QUEST 2.0 demonstrated greater overlap with the components evaluated by the NATU Quest than the SUS (Table 3). However, we selected the SUS over the QUEST 2.0 to test convergent validity because up to 4 items in the QUEST 2.0 were service-related, including service delivery, repairs, and follow-up services, and were therefore not applicable to the present hospital-based inpatient RAGT context. In contrast, the SUS is widely used and may facilitate comparisons across studies. Nonetheless, the convergent validity with respect to the SUS should be interpreted cautiously because of the limited overlap between questionnaire items. Future studies assessing the convergent validity of usability questionnaires for WRE may benefit from considering instruments in addition to, or instead of, the SUS.

[a]NATU Quest: Assistive Technology Usability Questionnaire for People with Neurological Diseases.

[b]SUS: System Usability Scale.

[c]QUEST 2.0: Quebec User Evaluation of Satisfaction with Assistive Technology.

Limitations

This study has several limitations. First, the small sample size and the absence of longitudinal follow-up prevented the evaluation of essential psychometric properties, including construct validity, discriminant validity, and responsiveness. These properties should be examined in future studies before the adapted NATU Quest can be more broadly recommended for WRE usability assessment. Second, the inclusion of only patients who had a stroke receiving a single type of powered lower-limb WRE limited the generalizability of the findings, as WREs are designed for diverse patient populations and clinical applications. Future studies should evaluate the applicability of the NATU Quest across different neurological and musculoskeletal conditions and a broader range of WRE systems. Finally, the NATU Quest was originally developed as a general assistive technology usability instrument and may not fully capture WRE-specific concerns, such as biomechanical alignment, fall-related risks, or soft-tissue pressure–related issues. Given the wide variety of WREs currently available on the market, developing device-specific usability instruments for each system would be time-consuming. Therefore, the NATU Quest may provide a practical general usability measure, although complementary WRE-specific safety and biomechanical assessment items may still be required.

Conclusions

The present study adapted a Taiwan Chinese version of the NATU Quest and preliminarily evaluated its psychometric properties in patients who had a stroke undergoing RAGT with 1 powered lower-limb WRE. The findings provided preliminary evidence supporting its content validity, internal consistency, test-retest reliability, and convergent validity within this specific clinical context. Given that no device-specific instrument is currently available for assessing WRE usability, the NATU Quest may provide a useful general usability measure for patients who had a stroke receiving RAGT with a powered lower-limb WRE. However, given the safety-critical and biomechanical nature of user-device interactions in WREs, the NATU Quest may not fully capture these aspects of usability. Further studies are needed to evaluate its comprehensive psychometric properties, including construct validity, discriminant validity, and responsiveness, before the adapted NATU Quest can be broadly recommended for usability assessment of WREs across different devices, patient populations, and clinical settings.

Acknowledgments

The authors would like to express their sincere gratitude to Dr Maria Masbernat-Almenara from the University of Lleida for authorizing the translation of the original Assistive Technology Usability Questionnaire for People with Neurological Diseases and assisting in the finalization of the adapted questionnaire.

Funding

This work was supported by the Ministry of Science and Technology (MOST; grant MOST 111-WHK-051-0674) and the National Science and Technology Council (NSTC; grant NSTC113-2314-B182A-092-MY2) for study design and execution and by Chang Gung Medical Foundation (grant CMRPG3N0013) for manpower support.

Data Availability

The Taiwan Chinese version of the NATU Quest is available in Multimedia Appendix 1. Due to the involvement of human participants and institutional ethics restrictions, the data are not publicly available outside the journal submission. Additional information may be made available from the corresponding authors upon reasonable request and with approval from the institutional review board.

Authors' Contributions

HWL contributed to the conceptualization and methodology of the study, led the cross-cultural adaptation of the NATU Quest into Taiwan Chinese, conducted content validity index evaluation, performed formal analysis, acquired funding, and critically reviewed and edited the manuscript. YCP contributed to formal analysis and funding acquisition, conducted the test-retest reliability analysis, and provided supervision and critical review of the manuscript. HW was responsible for project administration, data collection, and data handling; conducted the investigation; drafted the original manuscript; and prepared the visualizations. JJH contributed to project administration, validation of the study, and drafting of the original manuscript. HW and JJH contributed equally to this work as first authors. All authors reviewed and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Augmented reality (AR) glasses with waveguide optics and facial recognition may enhance patient identification and clinical workflows. However, their usability among physicians has not yet been evaluated.

Objective: The objective of this study was to assess the usability and acceptability of prototype AR glasses with facial recognition in a simulated outpatient setting.

Methods: In May 2025, 14 urologists from a single institution tested prototype AR glasses developed by Cellid Inc. The device incorporates waveguide-based optical displays, a miniature camera, and deep learning–based facial recognition software. Physicians identified preregistered mock patients, with demographic and clinical data displayed on the right lens. After the trial, participants completed an anonymous questionnaire on usability, comfort, visibility, and self-reported symptoms using 3- or 5-point Likert scales.

Results: Eleven participants (79%; 95% CI 52% - 92%) found the device helpful in performing clinical procedures, and 12 (86%; 95% CI 60% - 96%) believed it improved patient safety. Most participants adapted quickly to wearing the device, and 79% (95% CI 52% - 92%) expressed a willingness to use it in future practice. Four of 13 respondents (31%; 95% CI 13% - 58%) selected “somewhat tired” for eye fatigue, and only 1 participant experienced minor and transient physical symptoms including headache and nausea. Three of 13 respondents (23%; 95% CI 8% - 50%) rated the glasses as slightly heavy, and among the 5 participants who wore prescription glasses, 4 (80%; 95% CI 38% - 96%) reported difficulty wearing the prototype over their glasses. Surrounding-environment visibility and perceived facial recognition responsiveness were generally favorable; however, 8 of 13 respondents (62%; 95% CI 36% - 82%) rated the displayed patient information as slightly difficult to see.

Conclusions: In this pilot study, AR glasses with facial recognition were well accepted by physicians. This technology has demonstrated perceived clinical utility and has the potential to assist medical professionals, though further refinement and larger clinical evaluations are needed.

augmented reality; automated facial recognition; smart glasses; data display; patient care

Introduction

Augmented reality (AR) is a technology that overlays digital content onto the real world in real time, thereby enhancing human perception of reality. AR technologies are advancing rapidly in many fields, and the use of AR in clinical settings is highly anticipated. Previous studies have proposed various clinical applications of AR and virtual reality, such as surgical

XSL•FO
RenderX

navigation and educational uses for medical students and residents [1-5]. The use of wearable devices in clinical settings requires hardware development and application implementation specifically designed for clinical use, which differs from consumer applications.

Patient misidentification is a critical issue in health care settings. Since patient identification errors can lead to serious medical malpractice, medical staff have to exercise the utmost caution when identifying patients. The accuracy of facial recognition technology is rapidly improving, and its application to patient identification shows great promise. By incorporating the latest AR and facial recognition technologies, health care workers will be able to identify patients more easily and accurately than is currently possible.

A previous study reported favorable overall usability of AR glasses equipped with facial recognition functionality among nurses working in an ophthalmic ward [6]. However, no previous studies have investigated the usability of AR glasses equipped with facial recognition functionality among doctors.

The purpose of this study was to evaluate the clinical usability of AR glasses that are equipped with facial recognition technology developed by Cellid Inc and that use a waveguide-based optical system. This evaluation was conducted through a questionnaire survey targeting physicians in a simulated outpatient scenario. The study was not designed to estimate face-matching accuracy or to determine effects on misidentification, patient safety, or clinical workflow.

Methods

Study Design

This study was conducted in May 2025 to evaluate the usability of AR glasses equipped with facial recognition technology in a simulated clinical setting. Urological physicians were invited to wear the AR device and experience its patient identification function using mock patients preregistered in the system. The pilot study used a convenience sample of urologists because urology outpatient practice was the initial formative use case at the investigators' institution. Participants were tasked with identifying preregistered mock patients using the facial recognition capabilities of the AR device.

Recruitment and Participants

A total of 14 physicians, including 9 urology specialists and 5 residents, were recruited from the Department of Urology at the Institute of Science Tokyo. All participants used the AR glasses under standardized conditions using mock patient data.

Device and System Description

The AR glasses used in this study were a see-through type with waveguide optics and weighed 58 g. The device included a miniature camera (Figure 1) mounted on the bridge and required a wired connection to a smartphone (ROG Phone 7, ASUS), weighing 239 g, via a 20 g cable, resulting in a total carry weight of 317 g. Since the prototype AR glasses require external power and do not support wireless data transmission, they must be physically tethered to a smartphone running facial recognition software.

XSL•FO
RenderX

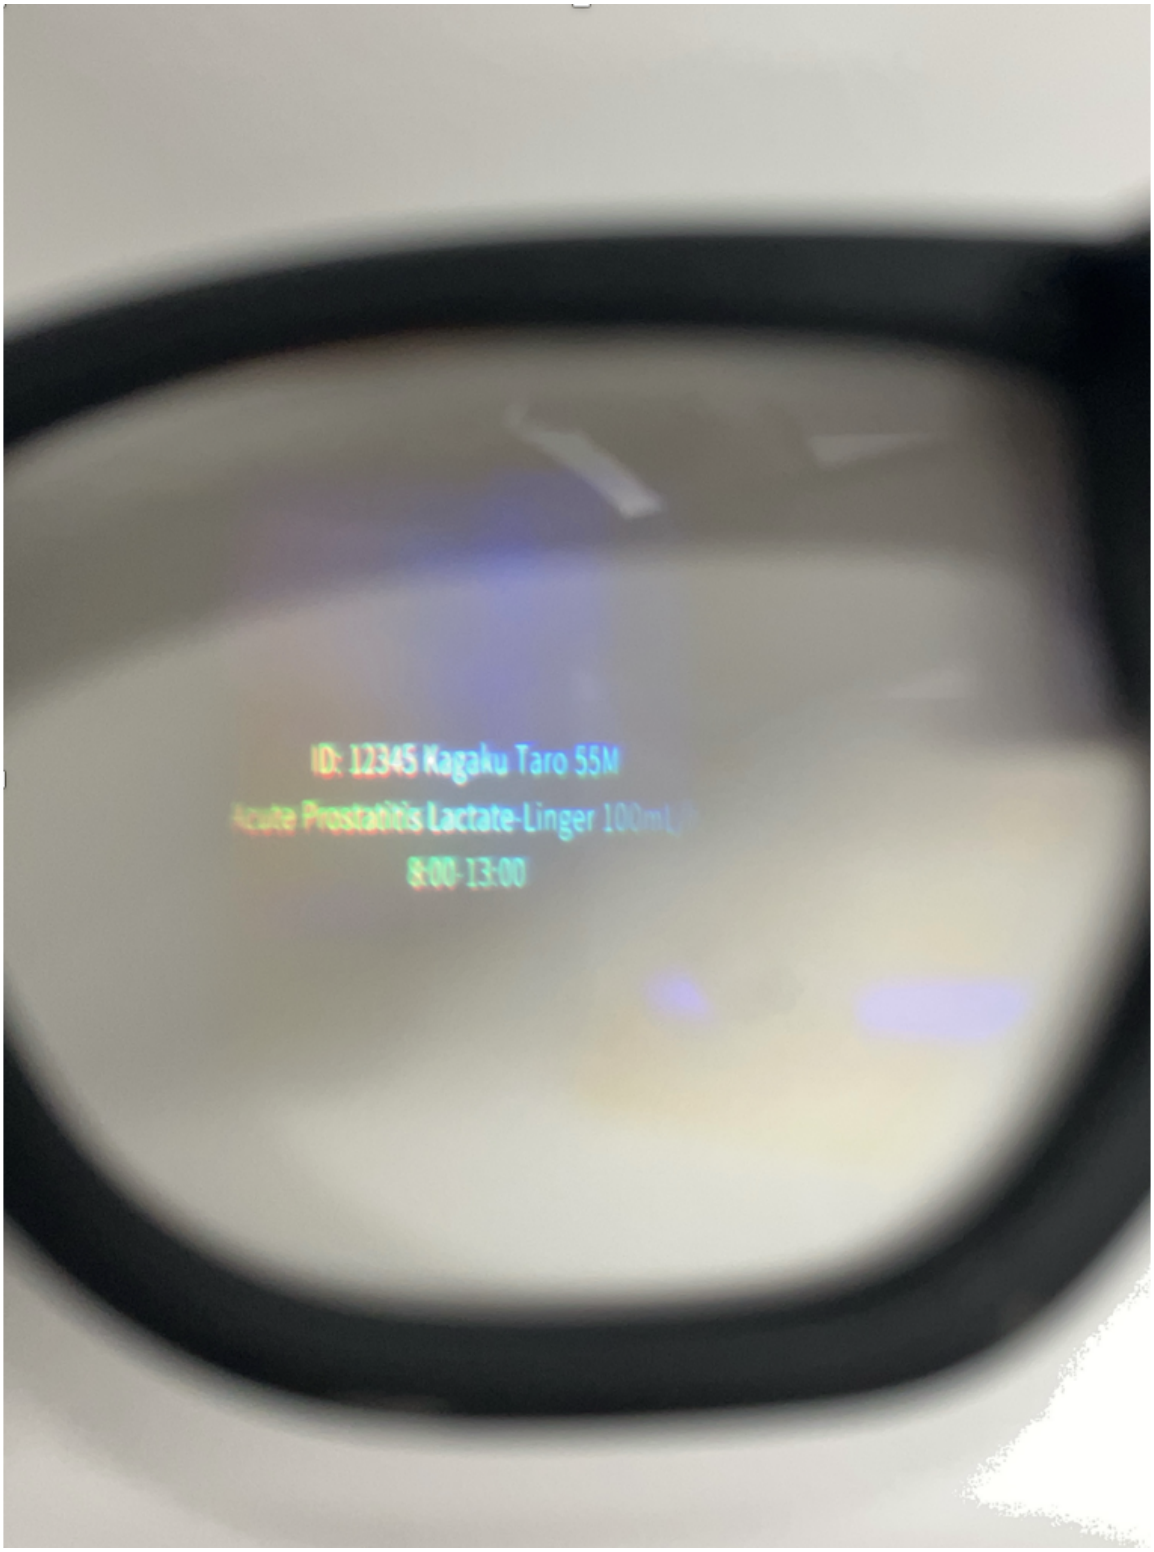

Figure 1. Photograph of a doctor wearing augmented reality glasses. A diffraction grating is installed on the right lens (framed red arrowhead), and a built-in miniature camera is located on the bridge (red arrow).

The facial recognition system was developed by Cellid Inc and used Amazon Rekognition (Amazon Web Services) for deep learning–based image recognition. Upon recognition of a registered face, patient information—including name, age, diagnosis, and allergies—was displayed in real time on the right lens via the waveguide optical system (Figure 2). This design enabled simultaneous visualization of the real-world environment and patient data. During the evaluated task, the display operated as an automatic, 1-way information presentation; direct manipulation of holographic content was not evaluated. Since the pilot study was designed as a user-experience demonstration rather than a technical validation study, recognition attempts, false matches, false rejections, repeated attempts, and software or network failures were not prospectively logged. Consequently, sensitivity, specificity, error rates, recognition success rates, and processing latency cannot be calculated from this study.

XSL•FO
RenderX

Figure 2. Patient information displayed on the augmented reality glasses lens.

Data Collection

After using the AR glasses, participants completed an anonymous questionnaire evaluating the glasses' usability and potential adverse effects. The investigator-developed questionnaire consisted of 15 items and an optional free-text field. The questionnaire was designed to assess the integrated prototype experience rather than facial recognition accuracy alone. Six domains were evaluated: perceived clinical utility (items 1 - 2), adaptation and intended adoption (items 3 - 4 and 10), wearing-related symptoms (items 5 - 9), weight and fit (item 11 and free-text comments), visual usability and task interference (items 12 - 14), and perceived facial recognition responsiveness (item 15). Items 1 - 11 and 15 used 5-category response scales, while items 12 - 14 used 3-category scales. A nonresponse was treated as missing data rather than a scale category. The questionnaire was not psychometrically validated,

XSL•FO
RenderX

and no composite usability score was calculated. The complete questionnaire is provided in Multimedia Appendix 1.

Statistical Analysis

Questionnaire data were analyzed using descriptive statistics. Categorical variables, including responses on usability, comfort, visibility, and adverse effects, are presented as frequencies and percentages. Ordinal variables collected via 3- or 5-point Likert scales are treated as categorical and summarized using counts and percentages for each response category. Continuous variables, such as participants' years of clinical experience, are reported as median and range. For all reported categorical outcomes, post hoc Wilson score 95% CIs were calculated to show sampling uncertainty. No hypothesis testing, subgroup comparisons, or adjustment for multiplicity was performed because of the small exploratory sample.

Ethical Considerations

This study was approved by the institutional review board of the Institute of Science Tokyo (approval number: I2024-070). All participants provided written informed consent prior to participation. This study used mock patient data to avoid the risks associated with handling real patient information, thereby minimizing ethical concerns related to privacy and data protection.

Results

Principal Findings

Fourteen urology specialists or residents with a median of 13 years of experience as physicians (range 3 - 24 years; IQR 3.75-17.75 years) were enrolled in this study. Thirteen (93%) participants were male and 1 (7%) was female. Five (36%) participants wore prescription glasses. All participants used the facial recognition function and completed the anonymous questionnaire. The results of the questionnaire are shown in Table 1.

Domain	Questions	Responses (N=14), n
Adaptation and adoption	Would you recommend the use of AR glasses to other medical professionals?	Not at all, 1 Unlikely, 0 Neutral, 3 Somewhat, 7 Strongly, 3
Weight and fit	What did you think about the weight of the AR glasses?	Very light, 3 Slightly light, 1 Just right, 6 Slightly heavy, 3 Very heavy, 0 No response, 1
Visual usability	How was the visibility of patient information through the AR display?	Very hard to see, 0 Slightly hard to see, 8 Easy to see, 5 No response, 1
Visual usability	How was the visibility of the surrounding environment?	Very hard to see, 0 Slightly hard to see, 3 Easy to see, 10 No response, 1
Task interference	To what extent did you find the AR glasses interfered with clinical tasks?	Very obstructive, 0 Slightly obstructive, 3 Not obstructive, 10 No response, 1
Perceived responsiveness	How did you find the responsiveness of the facial recognition function?	Too slow, 0 Slightly slow, 2 Just right, 10 Slightly fast, 1 Too fast, 0 No response, 1

[a]AR: augmented reality.

Perceived Clinical Utility and Future Adoption

For perceived assistance with clinical procedures, 5 of the 14 participants (36%) rated the device as “slightly helpful,” and 6 (43%) rated it as “helpful.” In total, 11 participants selected “slightly helpful” or “helpful” (79%; Wilson 95% CI 52% - 92%); the remaining 3 selected “neutral.” Similarly, for perceived support of clinical safety, 12 selected “slightly helpful” or “helpful” (86%; 95% CI 60% - 96%), with 3 (21%) selecting “slightly helpful” and 9 (64%) selecting “helpful”; 2 (14%; 95% CI 4% - 39%) selected “neutral.” Eleven of 14 participants expressed willingness to use the glasses in future practice (79%; 95% CI 52% - 92%), and 10 of 14 would recommend the prototype to other professionals (71%; 95% CI 45% - 88%).

Wearability and Adaptation

of the 14 participants, 8 (57%; 95% CI 33% - 79%) reported that no or minimal time was needed to adapt to the glasses, 1 (7%; 95% CI 1% - 30%) selected “neutral,” 4 (29%; 95% CI 12% - 55%) selected “somewhat,” and 1 (7%; 95% CI 1% - 30%) selected “very much.” Among 13 respondents to the weight item, 3 (23%; 95% CI 8% - 50%) rated the glasses as very light, 1 (8%; 95% CI 1% - 33%) as slightly light, 6 (46%; 95% CI 23% - 71%) as just right, and 3 (23%; 95% CI 8% - 50%) as slightly heavy; 1 participant did not answer. In free-text comments, 4 of 5 participants (80%; 95% CI 38% - 96%) using prescription glasses mentioned difficulty wearing the prototype over their prescription glasses.

Visual Usability, Task Interference, and Perceived Responsiveness

Patient information legibility was an important concern. Among 13 respondents, 8 (62%; 95% CI 36% - 82%) rated the displayed patient information as slightly hard to see, while 5 (38%; 95% CI 18% - 65%) rated it as easy to see; 1 participant did not answer. By contrast, 10 of 13 respondents (77%; 95% CI 50% - 92%) rated the surrounding environment as easy to see, and 3 (23%; 95% CI 8% - 50%) rated it as slightly hard to see. Ten of 13 (77%; 95% CI 50% - 92%) considered the device nonobstructive and 3 (23%; 95% CI 8% - 50%) as slightly obstructive. Perceived facial recognition responsiveness was rated as just right by 10 of 13 respondents (77%; 95% CI 50% - 92%), slightly slow by 2 (15%; 95% CI 4% - 42%), and

XSL•FO
RenderX

slightly fast by 1 (8%; 95% CI 1% - 33%); 1 participant did not answer. These ratings do not constitute an objective latency or accuracy assessment.

Self-Reported Symptoms

For eye fatigue, 5 of 13 respondents (38%; 95% CI 18% - 65%) selected "not at all," 2 (15%; 95% CI 4% - 42%) selected "minimal," 2 (15%; 95% CI 4% - 42%) selected "neutral," and 4 (31%; 95% CI 13% - 58%) selected "somewhat tired"; none selected "very tired," and 1 participant did not answer. Mild physical fatigue, headaches, and nausea were reported by a single participant. However, the reported symptoms were confined to the trial period and resolved spontaneously. No participant selected the highest-severity category for physical fatigue, headache, dizziness, or nausea.

Discussion

Principal Results

This study reported generally favorable reactions from doctors to the use of facial recognition–equipped AR glasses in a simulated clinical setting. Most participants considered the AR glasses to be useful both for performing medical procedures and in enhancing clinical safety.

Huang et al [6] reported favorable overall usability of an AR-AI assistant among 15 ophthalmic day-ward nurses, and Lin et al [7] evaluated an intelligent verification tool for ophthalmic surgical information among surgical nurses. To the best of our knowledge, this is the first study to evaluate the usability of AR glasses equipped with facial recognition functionality among physicians.

While no serious self-reported symptoms were observed in association with wearing the AR glasses, it is noteworthy that their use may induce mild symptoms, including eye fatigue, physical fatigue, headache, and nausea. Moreover, the AR glasses used in this study have room for technical improvement. Although the device used waveguide optics that enabled a more compact design compared to other AR display technologies [8] and achieved weight reduction through wired connection to a smartphone, 21% of participants rated it as "slightly heavy." There is also strong anticipation of the development of wireless devices in the future. While this study only evaluated the facial recognition functionality of the AR glasses and limited the display to basic patient information, the device could potentially display a wider range of information, such as CT scans and real-time vital signs, during procedures. This could support doctors not only in outpatient care but also during surgery and other medical interventions. Further research is needed to evaluate the utility of AR glasses equipped with enhanced functions in clinical settings. Furthermore, AR glasses have potential applications for health care professionals beyond physicians. Our previous study [9] demonstrated that when scrub nurses used see-through head-mounted displays, it facilitated their understanding of surgical procedures and improved the efficiency of instrument handling. Additionally, since nurses and medical administrative staff are also involved in patient identification, implementing facial recognition technology could potentially benefit all medical staff. However, facial recognition in this setting should be regarded as an adjunct rather than a replacement for established patient identification procedures. Wristbands, barcodes or QR codes, and confirmation using multiple identifiers have the advantage of being embedded in established workflows. A near-eye system may offer hands-free access to contextual information and reduce the need to look away from the patient, but face matching can be affected by lighting, pose, occlusion, masks, image quality, database composition, demographic performance variation, and the selected decision threshold. A false match may also create automation bias. Therefore, practical clinical use requires a fail-safe system for unrecognized faces, as well as independent confirmation using standard identification methods.

Limitations

This study was limited by a small sample size. Consequently, the 95% CIs for the survey responses are notably wide (eg, 52% - 92% for 11 of 14 participants), which underscores the substantial uncertainty in our point estimates. Although the prototype used a cloud-based facial recognition service, this study did not evaluate the data routing, retention, deletion, access control, or regulatory requirements necessary for clinical deployment. As this was a pilot usability study, precise device use duration, detailed facial data registration procedures, and database size were not recorded. The usability of the AR glasses was assessed subjectively via a questionnaire lacking objective indicators. Similarly, participants' prior experience with AR technologies and familiarity with wearable devices were not recorded, which might have influenced individual adaptation times and usability ratings. Furthermore, the potential risk of cognitive overload associated with processing simultaneous real-world visual inputs and AR-displayed information was not evaluated in this study. Industry provision of the prototype and the participation of a company executive as an author may have introduced expectancy bias despite anonymous responses. Finally, no real patient clinical data were used; the displayed demographic and clinical information was fictitious. Because this study was conducted in a simulated setting rather than actual clinical practice, future research is needed to evaluate the system's acceptability from the patients' perspective.

Conclusions

We found overall favorable responses from doctors regarding the use of AR glasses using waveguide optics with facial recognition functionality in a simulated clinical setting. This technology has the potential to assist medical professionals, providing a safeguard against patient misidentification.

Acknowledgments

Abstract

Background: HIV disproportionately affects men who have sex with men (MSM), transgender individuals, and people who inject drugs, with 70.1% of cases in Pakistan linked to these groups, aggravated by stigma and legal constraints. Mobile health (mHealth) interventions offer the potential to enhance HIV prevention, yet their acceptability remains underexplored.

Objective: This study aimed to assess the feasibility, willingness to use, and preferences for mHealth-based interventions designed to improve HIV knowledge, testing uptake, and risk behavior reduction among MSM, transgender individuals, and people who inject drugs in Pakistan.

Methods: A cross-sectional survey was conducted from February 2025 to May 2025 with 210 participants, including MSM and transgender individuals, recruited through respondent-driven sampling in collaboration with community-based organizations and nongovernmental organizations, while people who inject drugs were recruited from the rehabilitation centers of trusted community-based organizations and nongovernmental organizations, to ensure privacy and reduce safety concerns. Participants completed a self-administered questionnaire covering demographics, HIV knowledge, access to and use of mobile technology, acceptability and preferences for mHealth interventions, and HIV-related risk behaviors.

Results: The majority of participants owned smartphones (161/210, 76.7%) and had daily internet access (115/210, 54.8%), spending an average of 3.41 (SD 3.10) hours online daily. High willingness (182/210, 86.7%) to use a clinic-integrated mHealth app for HIV prevention was reported. Preferred app-delivered features included educational resources (85/210, 40.5%), daily medication reminders (108/210, 51.4%), weekly HIV prevention information (110/210, 52.4%), e-consultation (158/210, 75.2%), and mental health information (134/210, 63.8%). Smartphone ownership (odds ratio 4.14, 95% CI 1.41 - 12.21; *P*=.009) and prior experience with an mHealth app (odds ratio 2.97, 95% CI 1.00 - 8.81; *P*=.05) were significantly associated with willingness to adopt an mHealth app. While 80.5% (169/210) reported some knowledge of HIV, only 17.1% (29/169) rated their knowledge high, and 46.1% (97/210) were unaware of their HIV status. In terms of vulnerability, participants reported that injected drug use (122/210, 58.1%), experiences of violence (87/210, 41.4%), and police detention (128/210, 61%) were prevalent. In terms of risky sexual behaviors, nearly half engaged in transactional sex (104/210, 49.5%) or had multiple partners (101/210, 48.1%), while consistent condom use remained low (90/210, 42.9%).

Conclusions: There is high acceptability and considerable potential for mHealth interventions to enhance HIV prevention efforts among MSM, transgender individuals, and people who inject drugs in Pakistan. Tailored, discreet, and comprehensive mHealth platforms that include educational content, medication reminders, e-consultation, and mental health support are warranted. Addressing criminalization and ensuring user privacy will be crucial for the successful design and implementation of these interventions. Future research should focus on implementation research to assess the real-world uptake of these findings.

KEYWORDS

mobile health; mHealth; mHealth apps; smartphone; mobile phone; HIV; HIV prevention; smartphone apps; health technology; key populations; marginalized communities; digital health

Introduction

Despite remarkable advancements in HIV care and prevention, the acquisition of HIV remains a significant public health issue globally [1]. As of 2023, approximately 39.9 million people were living with HIV worldwide, including 1.3 million who were newly diagnosed, around 0.45 million of these in Southeast Asia [2]. The epidemic still disproportionately impacts key populations: the HIV prevalence was 11 times higher among gay men and other men who have sex with men, 7 times higher among people who inject drugs, and 14 times higher among transgender individuals, in comparison to the general adult population [3]. Discrimination, stigmatization, and punitive laws targeting key populations are costing lives and preventing the world from achieving the agreed global 95-95-95 AIDS target: 95% know their HIV status, 95% diagnosed with HIV are on antiretroviral therapy (ART), and 95% of those on ART are virally suppressed. Structural barriers, including poverty, limited health care access, and legal and human rights challenges, raise the likelihood of HIV infection 35-fold for people who inject drugs, 30-fold for female sex workers, and 14-fold for transgender women compared to adults in the general population [4]. Globally, studies confirm that HIV incidence remains high among sex workers, especially in countries that criminalize sex work compared to their counterparts in countries where sex work is wholly or partially legalized [5].

Mobile health (mHealth), defined as the use of mobile technologies for health services, has emerged as a promising tool for improving global health care access and delivery, improving health outcomes, and promoting preventive health behaviors [1,6]. mHealth, particularly smartphone apps and messaging, holds great promise for HIV prevention, especially when linked to HIV testing and pre-exposure prophylaxis (PrEP). The World Health Organization (WHO) and the Joint United Nations Program on HIV/AIDS have endorsed the integration of mHealth in HIV care strategies due to its reach across low-, middle-, and high-income countries [7]. For example, a study from China found that men who have sex with men who received customized short-message interventions reported significantly lower rates of risky sexual activities like multiple sex partners and condomless anal sex than those who did not receive the intervention [8].

Pakistan, the world's fifth-most populous country, has an estimated 0.33 million people living with HIV. According to the latest data, only 23% of people living with HIV know their HIV status; among them, 74% are on ART [9]. In the absence of recent national viral suppression data, estimates can be drawn from the 2023 Joint United Nations Program on HIV/AIDS report, which indicated that 34,000 individuals on ART have achieved viral suppression [2]. When compared with ART enrollment figures reported by the country's National AIDS Control Program, this suggests an approximate viral load of 63% among people living with HIV on ART in Pakistan [9]. Pakistan continues to face significant funding constraints in its HIV/AIDS response. The reallocation of HIV/AIDS-related resources to address the COVID-19 pandemic has further strained an already under-resourced health system, leading to disruptions in essential services for sexual and gender diverse populations [10]. Notably, in 2025, the HIV/AIDS component implemented by the National AIDS Control Program in collaboration with the United Nations Development Program (UNDP) Pakistan has experienced a reduction exceeding US $4 million [11]. Pakistan is still falling short of achieving the previous 90-90-90 global target set for 2020, and remains far from the current 2025 goals [12,13]. The number of new HIV infections in Pakistan increased from 14,000 in 2010 to 25,000 in 2020 [14]. AIDS-related deaths in Pakistan surged from 1400 in 2010 to 8000 in 2020 [3]. The HIV epidemic in Pakistan has shown evidence of shifting from isolated key populations to spreading into broader sexual networks. In Pakistan, 70.1% of HIV cases belong to key groups: men who have sex with men (22%), people who inject drugs (38.4%), female sex workers (2.2%), and transgender individuals (7.5%) [15]. Legal provisions such as Section 377 of the Pakistan Penal Code further exacerbate stigma and limit access to essential HIV services [16]. A total of 190 million cellular mobile connections were active as early as 2025, equivalent to 75.2% of the total population, and over 45.7% were using the internet [17]. Recent studies in other Asian and low- and middle-income countries have shown strong willingness among men who have sex with men, transgender individuals, and people who inject drugs to engage with mHealth platforms for HIV-related services [1,6,18].

Despite this, data on the feasibility and acceptability of mHealth solutions in Pakistan remain sparse, particularly among the most at-risk communities. A few digital platforms, such as "Sehat Dost" UNDP with support from the Global Fund and "HIV/AIDS Pakistan" by the Association of People Living with HIV, offer HIV information, self-assessment tools, and self-testing kits [19]. However, these apps lack integration, user-centered features, and functionality typical of comprehensive mHealth solutions. To address this, this study explores the willingness, preferences, and feasibility of adopting mHealth-based interventions among men who have sex with men, transgender individuals, and people who inject drugs in Pakistan. It aims to generate evidence for designing effective, user-centered digital tools that have the potential to improve HIV knowledge, increase testing uptake, and reduce high-risk behaviors in marginalized communities.

Methods

Study Design and Setting

A cross-sectional study was conducted from February 2025 to May 2025, using the quantitative survey-based method to assess the willingness, preferences, and feasibility of mHealth interventions for HIV prevention among the key populations in Pakistan, with data collected through collaboration with

XSL•FO
RenderX

community-based organizations (CBOs) and nongovernment organizations (NGOs). The STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guideline (Checklist 1) was followed to conduct this study.

Sample Size

The minimum sample size for estimating the proportion willing to use mHealth was first calculated with the single-proportion formula (95% CI, 5% precision, and anticipated prevalence=50%), giving 384 individuals. Because the accessible sampling frame in our sites was approximately 500 individuals, we applied a finite-population correction [20], resulting in 218 individuals. Anticipating minor design clustering across the 3 key population strata, a design effect of 1.1 was used, yielding approximately 240 individuals. However, the final achieved sample size was limited to 210 due to practical constraints such as limited recruitment time and resource limitations. Furthermore, many individuals from marginalized populations were reluctant to participate because of fears related to stigma, confidentiality, and social consequences. Although the final sample size was slightly lower than the initial target, it does not meaningfully compromise the overall interpretability of our findings. A post hoc power check indicates that with a sample of 210 participants, the study still retains acceptable precision for estimating willingness proportions with approximately ±6% to 7% precision at a 95% CI [21,22].

Definitions of Key Terms

Key Population

Groups who, due to specific higher-risk behaviors, are at increased risk of HIV, irrespective of the epidemic type or local context. Also, they often have legal and social issues related to their behaviors that increase their vulnerability to HIV. According to WHO guidelines, key populations relevant to this study include: (1) men who have sex with men, (2) people who inject drugs, and (3) transgender individuals [23].

Men Who Have Sex With Men

This group encompasses male individuals who engage in sexual activities with other male individuals, regardless of their sexual orientation or identity. The term is used to focus on behavior rather than identity, recognizing that not all men who have sex with men identify as gay or bisexual [24].

People Who Inject Drugs

Individuals who inject psychotropic (or psychoactive) substances for nonmedical purposes through intravenous, intramuscular, subcutaneous, or other injectable routes. People who inject drugs are at heightened risk of HIV due to practices such as sharing contaminated injection equipment. This definition also applies to people who inject other nonmedical substances.

Transgender Individuals

An umbrella term for individuals whose gender identity and expression do not conform to the norms and expectations traditionally associated with the sex assigned to them at birth; it includes people who are transsexual, transgender, or otherwise gender nonconforming. Transgender people may self-identify as transgender, female, male, a transgender woman, or a transgender man [25].

Study Participants and Procedures

Inclusion criteria were (1) being aged 18 years or older; (2) self-identified as men who have sex with men, transgender individuals, or people who inject drugs; (3) resident of Pakistan; and (4) being able to understand Urdu or English.

Other key populations, such as female sex workers and people in prisons, were not included due to legal and ethical considerations. Although multiple groups are criminalized under Section 377, female sex workers in Pakistan are subjected to stronger policies, social stigma, and the absence of secure community-based networks, which create substantial barriers to safe, confidential, and ethical recruitment [16,26]. These factors present significant barriers to safe recruitment and ethical engagement in research contexts involving these groups.

Respondents were recruited using respondent-driven sampling (RDS), which is a network-based sampling method commonly used to recruit the hard-to-reach population, and combined with peer-driven recruitment [27]. Initial respondent-driven sampling participants, also called seed participants, were selected upon recommendations of trusted NGOs and CBOs for men who have sex with men and transgender individuals. We selected a sample of 10 seed participants from each group to ensure diversity. Each seed who completed the interviewer-administered questionnaire received 5 recruitment coupons to invite their peers. In turn, the subsequent participants were also given 5 coupons to recruit more peers. Each coupon card contained a unique RDS number that allowed us to trace the peer recruitment chain and related study information. Coupon management software tracked, distributed, and redeemed coupons during the study, and a standard numbering system was implemented to monitor the recruiter-recruit relationship. Due to ethical and security concerns, people who inject drugs were recruited through convenience sampling from rehabilitation centers and harm reduction centers operated by trusted NGOs and CBOs. The participants were only recruited if they were stable, conscious, and could provide informed consent. This approach was adopted to ensure privacy, reduce participant risk, and allow for more secure and supportive recruitment and data collection. Data collection was conducted in the private room of the NGO or CBO to ensure participants' trust and privacy. Individuals could choose whether to come during the working hours of the NGO or CBO or set an appointment by phone. Individuals who presented with a valid coupon underwent initial eligibility screening. If eligible, an Android tablet was provided to complete the survey questionnaire, which was hosted on Google Forms in a private room. Participants were allowed to self-identify their gender from a list of inclusive options or choose not to disclose, in line with ethical guidelines for gender identity data collection [28]. Each participant completed the questionnaire in approximately 20 minutes, while study staff waited outside to ensure privacy.

Ethical Considerations

The ethical approval for this study was obtained from the research and ethics committee of Riphah Institute of

XSL•FO
RenderX

Pharmaceutical Sciences, Riphah International University (reference: REC-RIPS/RARE/2025/16); all ethical guidelines for research involving human participants were followed. Before participating, all participants were verbally informed about the purpose of the study, the nature of their involvement, potential risks and benefits, and their rights as research participants. Informed written consent was secured from all participants before data collection. Moreover, all the participants were informed that participation in this study was voluntary and that they could withdraw at any time. All participants were assured that their data would remain confidential, and they were informed that their data would be used for publication purposes. Participants were invited to self-identify their gender using inclusive options, with a choice to opt out, ensuring respect for individual autonomy and alignment with ethical standards for gender identity data collection. All the study procedures adopted complied with the Principles of the Declaration of Helsinki, Good Clinical Practices, and the applicable laws and regulations of research involving human subjects in Pakistan. The SAGER (Sex and Gender Equity in Research) guidelines were followed throughout the study and can be found in Checklist 2. Participants received PKR 500 (US $2.77) for study participation and an additional PKR 200 (US $1.11) for each peer successfully recruited to the study, up to a maximum of 5 peers.

Measures

Overview

After reviewing the literature, the questionnaire for this study was adopted from a validated questionnaire used in a similar mHealth study in Malaysia [27]. After carefully reviewing the questionnaire and discussing it with other team members and the principal investigator, we made some modifications. Some questions were removed from the questionnaire, keeping in mind the cultural and ethical standards of the country. The questionnaire was subsequently translated into Urdu, and HIV experts in Pakistan, along with the principal investigator, evaluated its content validity. The main scale achieved a Cronbach α of 0.75, indicating acceptable reliability for a formative exploratory study. The questionnaire used for the study can be found in Multimedia Appendix 1.

Participant Characteristics

We collected participant characteristics: type (men who have sex with men, transgender individuals, or people who inject drugs), sexual orientation, education, employment status, and ethnicity. We did not take provincial and residential information to ensure confidentiality and privacy.

Knowledge About HIV Prevention

In the first section, participants were asked, “Do you know about HIV care and prevention methods?” Those who responded “Yes” to the previous question were asked to rate their HIV knowledge on a scale from 1 (very low) to 5 (very high).

Access to and Frequency of Use of Communication Technology

Participants were asked if they had their own smartphone and daily internet access, and the number of hours spent on the internet each week. Participants’ use of smartphones for various internet-based activities (including social networking, sending or receiving emails, using websites, searching for health-related information, or using health-related apps) was assessed using a 5-point Likert scale (ranging from 1=“never” to 5=“daily”). The participants were then asked if they had used any health-related mHealth apps previously, and a follow-up on their experience using the mHealth app was assessed using the Likert scale (ranging from 1=“very dissatisfied” to 5=“very satisfied.”

Acceptability of mHealth App

Participants were asked about their willingness to use a clinic-integrated mHealth app for HIV prevention, and their willingness to use 5 mHealth-related features: medication reminders, HIV prevention information, e-consultation with the doctor, mental health information, and engagement in a virtual mental health group. The study also evaluated respondents’ preferred frequency (daily, weekly, or monthly) and mode of mHealth delivery (such as phone calls, SMS text messaging, or mobile apps). Participants were asked, “What feature would you consider most important in a clinic-integrated mHealth app for HIV prevention?,” followed by a question: “On a scale of 1 (not at all feasible) to 5 (extremely feasible), how feasible do you think it is to integrate mobile apps into an HIV prevention program?”

Risky Sexual and Drug-Related Behavior

Participants were asked information about their sexual behavior, including recent (past 6 mo) engagement in anal sex, sexual relationships with multiple partners, consistent condom use, and transactional sexual relationships. Additionally, participants were asked about injectable drug use at any point in their lives. Participants were asked if they had ever tested for HIV and their HIV status. Participants were then asked if they had ever been diagnosed with other sexually transmitted infections (STIs), and if they had ever used PrEP or postexposure prophylaxis.

Data Analysis

We calculated the descriptive statistics for categorical variables, such as frequency and percentage, and mean and SD for the continuous variables. Cross-tabulation and chi-square tests were used to measure the association between the categorical variables. Bivariate and multivariate logistic regression analyses were conducted to identify the correlates of mHealth acceptance. Results were reported as odds ratio (OR) with 95% CI. Analyses were performed in SPSS (Statistical Package for the Social Sciences; version 27; IBM Corp) and RStudio (2025.05.0+496), an integrated development environment for R (version 4.5.0; R Foundation for Statistical Computing).

Results

Participants’ Characteristics

A total of 210 participants were included in the study (mean age of 29.55, SD 4.82 y). Of the 210 participants, 83 (39.5%) were people who inject drugs, 72 (34.3%) were transgender individuals, and 55 (26.2%) were men who have sex with men. Regarding sexual orientation, 84 (40%) identified as heterosexual, while 72 (34.3%) identified as homosexual. Most

XSL•FO
RenderX

respondents were college graduates (n=88, 41.9%), while only a few reported having completed higher education (n=25, 11.9%). Employment status showed that half of the participants were unemployed (n=105, 50%), and a large proportion identified themselves as Muslims (n=159, 75.7%; Table 1).

Table . Demographic characteristics of the participants (N=210).

Demographic characteristics	Value, n (%)
Key population	
Men who have sex with men	55 (26.2)
Transgender individuals	72 (34.3)
People who inject drugs	83 (39.5)
Sexual orientation	
Homosexual	72 (34.3)
Heterosexual	84 (40)
Bisexual	53 (25.2)
Education	
Less than high school	53 (25.2)
High school	88 (41.9)
College or associate	44 (21)
Higher education	25 (11.9)
Employment status	
Unemployed	105 (50)
Part-time employed	67 (31.9)
Full-time employed	32 (15.2)
Ethnicity or race	
Muslim	159 (75.7)
Non-Muslim	51 (24.3)
Knowledge about HIV and its transmission	
Yes	169 (80.5)
No	41 (19.5)
HIV knowledge rating	
Low	88 (52.1)
Moderate	54 (31.9)
High	29 (17.1)

Overall, 169 out of 210 (80.5%) participants reported having some knowledge of HIV and its transmission, while 29 out of 210 (17.1%) demonstrated a high level of HIV-related knowledge. Men who have sex with men reported the highest proportion of strong HIV knowledge (23/55, 41.8%), followed by transgender individuals (18/72, 25%) and people who inject drugs (13/83, 15.6%).

Access to and Frequency of Use of Mobile Technology

Of the 210 participants, 161 (76.7%) had smartphones, and 115 (54.8%) had daily access to the internet. The most common activities that participants used the internet on their smartphones for were online social networking apps like Facebook, WhatsApp, or TikTok; on average, they spent 3.41 (SD 3.10) hours per day on them. A total of 77 out of 210 (36.7%) participants used mobile apps several times a week, and 74 out of 210 (35.2%) used them daily. Additionally, 127 out of 210 (60.5%) of the participants stated that they had used an mHealth app, and 94 out of 210 (44.7%) were satisfied with their experience with the mHealth app. A significant association was found between the education levels and previous mHealth app experiences (χ^2_4=24.08; P<.001). Among those who reported using the app (127/210, 60.5%), 40 out of 127 (31.4%) were transgender individuals, 27 out of 127 (21.2%) were men who have sex with men, and 32 out of 127 (25.1%) had a high school level education, suggesting a positive association between education and mHealth app engagement.

Acceptability of the mHealth App

Of the 210 participants, 182 (86.7%) expressed a willingness to use a clinic-integrated mHealth app for HIV prevention (Table 2). More than half (n=108, 51.5%) indicated interest in a daily

XSL•FO
RenderX

medication reminder feature, while 83 (39.5%) reported no interest in this function. Among those interested in medication reminders, 89 of 130 (68.5%) preferred to receive notifications through the app.

Secure messaging with health care providers	28 (13.5)
Appointment reminders	15 (7.5)

Regarding the dissemination of HIV prevention information, 110 out of 210 (52.4%) respondents preferred receiving updates on a weekly basis, followed by 49 out of 210 (23.3%) who favored monthly updates. Among these, 77 out of 180 (42.7%) indicated a preference for receiving such information via the app. Additionally, two-thirds of the participants (158/210, 75.2%) expressed interest in e-consultation services, with preferences split between app-based consultations (75/156, 48.1%) and phone calls (68/156, 43.6%). Furthermore, 134 out of 210 (63.8%) participants showed interest in receiving mental health information, with 73 out of 138 (52.9%) preferring to access this content through the app. Most participants (85/210, 40.5%) indicated that educational resources was the most important feature, followed by information on HIV self-testing (42/210, 20.2%) and secure messaging with health care providers (28/210, 13.5%). Furthermore, a total of 75 out of 210 (35.7%) participants reported moderate feasibility, and 61 out of 210 (29%) reported high feasibility for an mHealth app for HIV prevention.

There was a positive association between smartphone ownership, daily internet access, and interest in mHealth for HIV prevention; 99.1% (114/115) of them were willing to use an mHealth app for HIV prevention. A chi-square test indicated a statistically significant association between smartphone use, daily internet access, and willingness to use an mHealth app (χ^2_2=71.19; P<.001). The likelihood-ratio chi-square test confirmed this association (χ^2_2=63.35; P<.001). The Cramer V was 0.41, indicating a moderately strong association between internet access, smartphone ownership, and willingness to use a clinic-integrated mHealth app.

HIV Testing, Prevention, and Risk Behaviors

Out of 210 participants, 141 (67.1%) participants had been tested for HIV, but only 111 of 208 (52.9%) respondents knew their current HIV status. HIV prevention services uptake was limited, with 105 (50%) reporting no use; PrEP (47/88, 53.4%) was the most common. Self-reported awareness of STI status was moderate, with 92 out of 210 (43.8%) reporting that they knew their previous STI status. Participants reported a substantial level of vulnerability: 87 out of 210 (41.4%) had experienced violence, 128 out of 210 (61%) had been detained by the police, and 122 out of 210 (58.1%) used injectable drugs. Risky sexual behaviors were frequent, 104 out of 210 (49.5%) engaged in transactional sex, and 101 out of 210 (48.1%) reported multiple partners, while consistent condom use remained low (90/210, 42.9%), though slightly higher among men who have sex with men and transgender individuals (Table 3). Cross-tabulation analysis showed differences in patterns across groups. PrEP users reported higher use of a health-related mobile app. When grouped by sexual orientation, bisexual participants reported the highest levels of risky sexual behavior, followed by homosexual participants, while heterosexual participants reported the lowest levels. Participants who used any HIV prevention service tended to report moderately risky sexual behaviors, whereas those who did not use prevention services were more likely to report the highest levels of risk.

Correlates of mHealth App Acceptance

Part-time workers and students were significantly less likely to express a willingness to adopt a clinic-integrated mHealth app for HIV prevention compared to unemployed participants. Specifically, part-time workers had 70% lower odds (OR 0.30, 95% CI 0.12 - 0.77; *P*=.01), and students had 87% lower odds (OR 0.13, 95% CI 0.02 - 0.98; *P*=.047) of being willing to use the app. In contrast, participants who owned a smartphone were over 4 times more likely to be willing to adopt the mHealth app (OR 4.14, 95% CI 1.41 - 12.21; *P*=.009). Moreover, individuals with prior experience using a mHealth app had nearly 3 times greater odds of willingness to adopt the app (OR 2.97, 95% CI 1.00 - 8.81; *P*=.05) compared to those with no prior mHealth exposure (Table 4).

Table . Correlates of mHealth app acceptance.

Discussion

Principal Findings

This study is the first in Pakistan to explore the feasibility and acceptability of mHealth interventions for HIV prevention among key populations, including men who have sex with men, transgender individuals, and people who inject drugs. The findings reveal a significant unmet need for accessible HIV prevention services, evidenced by high-risk behaviors and low engagement with existing methods. However, the widespread use of smartphones and social networking platforms presents a promising avenue for digital health solutions. Participants showed strong interest in a clinic-integrated mHealth app, favoring features like educational content, medication reminders, and e-consultation services.

Our findings identify several key features that prospective users desire in an mHealth intervention for HIV prevention. Specifically, participants expressed strong interest in receiving daily medication reminders, weekly prevention information, access to e-consultation with health care providers, and mental health resources. These preferences align with evidence from India and Nepal, where men who have sex with men and transgender individuals similarly valued medication and appointment reminders, HIV prevention information, and teleconsultation services. In the Nepali study, men who have sex with men also emphasized additional needs such as screening and monitoring illicit drug use, chemsex behavior, and ordering HIV-related supplies, reflecting broader expectations for comprehensive digital support. However, one notable difference is that most participants in Nepal preferred monthly messages and reminders, which contradicts our finding of strong interest in daily reminders and weekly prevention content. Preferences reported in India were more consistent with our results, as participants supported daily medication reminders and weekly HIV prevention information [1,29,30]. In our study, consistent condom use in the past 6 months was reported by 63.6% of men who have sex with men and 62.5% of transgender participants. These rates are considerably higher than those reported in Malaysia, where only 19% of men who have sex with men reported condom use, and moderately higher than in Bangladesh, where 48.6% of men who have sex with men reported consistent use [27,31]. However, these findings were comparable with those of Indonesia, where 76.97% reported protected sex in the past 6 months [32]. Limited access to HIV prevention information, weak social and health care systems, and criminalization of same-sex behaviors and cultural taboos in Muslim-majority settings such as Malaysia, Indonesia, and Bangladesh intensify privacy concerns and restrict access to condoms and prevention strategies. These constraints likely contribute to inconsistent condom use and reduced engagement with HIV prevention programs in these contexts [31,33,34]. mHealth programs have shown promise in improving condom use and mental health. In one example, a self-paced web-based intervention for Chinese men who have sex with men dating app users significantly reduced condomless anal sex and increased participants' use of self-efficacy and positive attitudes towards condoms [35]. More broadly, digital interventions in the settings of low- and middle-income countries have generally been found to enhance sexual and reproductive health knowledge and attitudes, which support safer behavior [36]. Our study found that participants who reported using HIV prevention services such as PrEP were often involved in moderately high-risk activities, and this finding aligns with existing research showing that PrEP use can sometimes be associated with an increase in risky sexual behaviors and the incidence of bacterial STIs [37,38]. This may reflect risk compensation or that individuals with higher baseline risk are more likely to seek PrEP. However, this association is not universal; studies in South-East Asia showed that PrEP use does not always translate into risk compensation, and educational awareness may lead to less involvement in high-risk behavior [39,40]. These findings suggest that integrating HIV prevention, reproductive health information, and risk-reduction counseling into mHealth platforms may strengthen consistent condom use and reduce risky sexual practices.

Also, high rates of violence (41.4%) and police detention (61%) were observed among men who have sex with men and people who inject drugs. Research in the Middle East and North Africa, including countries such as Pakistan, Iran, Lebanon, and Ghana, highlighted a high level of violence, stigma, and discrimination among sexual and gender minorities, with police often implicated in discriminatory practices [41]. These legal and social pressures create significant barriers to accessing care, a finding that is consistent with qualitative research on the lived experiences of people with HIV in Pakistan who face pervasive stigma and structural challenges [13]. Studies from Malaysia and Iran reported that high stigma and criminalization towards men who have sex with men and transgender individuals increased the privacy concerns and limited the open health communication and emphasized mHealth as a discreet option [6,42]. Similarly, a cross-sectional survey conducted among Malaysian men who have sex with men reported that although 74.9% of participants expressed willingness to use a hypothetical HIV prevention app, concerns related to privacy and confidentiality significantly limited acceptability [43]. A Malaysian focus group study among men who have sex with men emphasized that encrypted messages, discreet notifications, and neutral app design are crucial to avoid accidental disclosure of HIV-related content [44].

HIV testing is the first step in reaching those at increased risk of HIV acquisition. Our study found that 63.7% of respondents rarely undergo HIV testing, highlighting the need for frequent screening. This is especially critical in Pakistan, where documented HIV outbreaks have been linked to gaps in testing and prevention among key populations [14]. mHealth could play a vital role in assessing risks and reminding and potentially motivating the marginalized community to be tested regularly through interactive quizzes and tailored push notifications [45,46]. A randomized control trial in Vietnam showed that mHealth improved knowledge and PrEP adherence through interactive quizzes and tailored push notifications [47]. As such, innovative technology can accelerate engagement in HIV prevention strategies and facilitate the PrEP uptake and HIV self-testing, especially in areas where these services are underused [48]. Our results highlight that there is considerable interest in specific mHealth strategies, such as receiving

XSL•FO
RenderX

information related to HIV prevention, e-consultation, medication reminders, and mental health information. Given the lack of public dialogue and stigma, it is not surprising that the Pakistani marginalized population, like their counterparts [49,50], particularly China [51], Vietnam [52], and Malaysia [27], expressed interest. Our study reported low to moderate HIV knowledge, and most of the participants were unaware of their HIV status and STIs, which is confirmed by another study that reported a lack of awareness and low literacy rate among people living with HIV [53], highlighting the need for effective interventions to boost awareness and education. Several studies have reported that mHealth interventions can be helpful in enhancing HIV awareness and education, such as studies from India, Nepal, and Malaysia, demonstrated greater improvement in HIV knowledge awareness, HIV testing, PrEP uptake, and behavioral outcomes among marginalized communities [18,54,55]. Similarly, a cohort study in Indonesia showed that a mobile app increased HIV knowledge from 20% to 60% among men who have sex with men, from 22% to 57% among transgender individuals, and from 49% to 74% among people who inject drugs. Additionally, HIV testing uptake rose by 31% among men who have sex with men, 49% among transgender individuals, and 26% among people who inject drugs [50]. Our study found high feasibility for a clinic-integrated mHealth app that aligns with a systematic review that found that mHealth was both feasible and acceptable in reducing HIV incidence and enhancing care engagement in gay, bisexual, and other men who have sex with men communities [56]. 60.5% of the respondents reported that they had used clinic-integrated mHealth, and some of them had experienced using the smartphone for searching health-related information, which reflects the digital revolution that is especially explosive in Asia, and the fast-paced growth of technology and use within the community [27]. However, it is crucial to contextualize these findings regarding people who inject drugs, as our sample was recruited from rehabilitation centers. Among people who inject drugs in rehabilitation and treatment programs, mHealth interventions show high feasibility and willingness, with around 97% owning mobile phones and strong engagement in text-based HIV prevention and adherence support [57]. In contrast, people who inject drugs outside treatment face major barriers, including low phone ownership, unstable housing, device loss or sale, and limited literacy, reducing mHealth uptake [58]. For example, in Tanzania, only 32% of people who inject drugs owned phones, and just 6.4% had smartphones [59]. Evidence from Malaysia similarly shows higher mobile phone and retention among people who inject drugs in harm reduction programs compared to those outside care [60]. These findings indicate that mHealth works well for stabilized people who inject drugs in treatment but requires tailored strategies to reach broader community populations. Rapid advancements in mobile technology and app development are creating new opportunities to incorporate mHealth into existing HIV prevention services in the region. A mHealth-based app could serve as an additional tool to assist marginalized communities with HIV prevention or care needs between clinic visits, guiding them to needed services, potentially enhancing clinical care, and supporting them through screening and recommendations, and providing different modes of accessing information and prevention commodities. However, the high willingness to use reported in our study may not always translate into sustained use. Studies showed that real-world factors such as the affordability of mobile data, variable digital literacy, especially among marginalized populations, strongly impact users' ability to navigate and benefit from these apps, with digital health literacy often requiring skills beyond general health literacy [61,62]. Mistrust of technology-based health services, rooted in historical health care disparities and concerns about privacy, further reduces long-term acceptability and use [63]. Addressing these barriers through community health worker support, culturally sensitive design, and policies promoting digital literacy and affordable connectivity is critical to translating initial interest into sustained mHealth app use.

Limitations

Despite valuable insights, this study has several limitations. First, the sample size was limited to 210 participants due to resource constraints and challenges in accessing the hard-to-reach population. A larger, more diverse sample, especially including men who have sex with men and people who inject drugs from underdeveloped areas, could improve generalizability. Moreover, interpretation of the regression analysis should be approached with caution, as several predictors, including students, HIV knowledge, and prior mHealth experience, showed wide confidence intervals likely due to small subgroup sizes. Second, key populations like sex workers and prisoners were excluded due to legal and ethical constraints, notably the criminalization of sex work under Islamic and national laws. Third, reliance on self-reported data for HIV or STI status, sexual behavior, and drug use may introduce social desirability bias, especially given the criminalization of same-sex behavior and drug abuse under Section 377 [16] and the Narcotic Control Act [64]. While self-administered, anonymous questionnaires helped reduce this bias, future studies could ensure privacy using branching logic and adaptive questioning. Fourth, because RDS weights were not applied, estimates for men who have sex with men and transgender participants reflect sample characteristics rather than population-level estimates. This may limit generalizability and affect direct comparability with the convenience sample of people who inject drugs. Furthermore, recruiting people who inject drugs via convenience sampling from rehabilitation centers may overestimate mHealth feasibility compared to the broader, nontreated populations like people who inject drugs, who likely face greater structural and digital access barriers. Findings should therefore be interpreted with these sampling differences in mind. Finally, while participants expressed a high willingness to use mHealth, stated interest may not always translate to actual usage. Future implementation studies are needed to assess real-world uptake. Although this study focused on HIV-negative individuals, mHealth also shows potential for people living with HIV, particularly in supporting ART adherence and care management [6,26,65]. Future qualitative studies involving both people living with HIV and health care providers are recommended.

Practical Implications

Overview

This study offers important implications for public health programs and digital health policy in Pakistan. High smartphone ownership (76.7%) and internet access (54.8%) among the key population support the early development of the pilot mHealth intervention, with potential funding support from international donors. However, high willingness to use may not always lead to actual use, and long-term engagement may be affected by mobile data costs, varying digital literacy, and mistrust of technology-based health services [61,62]. Digital platforms offer scalable, resilient health care delivery, crucial during disruptions like those faced by HIV-positive individuals during the COVID-19 pandemic [66,67].

Short-Term Goals

A pilot study should be implemented to test the actual feasibility, usability, and retention in use of mHealth interventions. Given widespread digital engagement, tailored interventions such as apps or SMS text messaging–based systems with multilingual options (eg, Urdu and Punjabi) and gamified education can serve as cost-effective, discreet platforms for HIV education, medication reminders, e-consultation, and mental health resources. Considering the high rate of depressive symptoms (61.4%) and injectable drug use (58.1%), Ahmed et al [13] measured health-related quality of life among people living with HIV and also reported that 63.1% of participants were highly depressed or anxious. Apps should also ensure anonymity, encrypted interfaces, and offline accessibility, especially in a legally restrictive environment where same-sex behavior and drug use are criminalized. Low rates of HIV testing and limited knowledge (16.9%) highlight the need for mHealth tools to promote self-testing, PrEP education, and risk assessment. Push notifications and app-based tools may encourage testing and PrEP uptake, especially among high-risk groups.

Long-Term Goals

After the pilot stage and successful implementation of mHealth among the key population, the focus must shift toward integrating people living with HIV and other correlated programs, such as tuberculosis. This requires training health care providers to integrate these tools into ART centers and national prevention strategies. Retention in care remains a major challenge in Pakistan, especially among mobile communities who are at high risk of being lost to follow-up [68]. The app should be connected with the national database, and services like ART medication delivery through an anonymous way should be incorporated to facilitate these groups and engage them in care. To address structural barriers like violence (41.4%) and police detention (61.6%), mHealth interventions should be supported by community-based organizations that can offer legal and economic assistance. Such an app could incorporate a one-touch emergency support button connecting users to a trusted CBO focal person, a brief and low-literacy legal rights guide in Urdu, a directory of verified safe spaces such as partner clinics or drop-in centers, and secure in-app messaging for confidential safety or rights-related advice [69,70].

Conclusions

This study aimed to assess the feasibility, willingness, and preferences for mHealth interventions among men who have sex with men, transgender individuals, and people who inject drugs in Pakistan. Our findings demonstrate high acceptability and readiness to engage with a future mHealth solution tailored to their needs. Such platforms, yet to be developed, could overcome key barriers, including stigma, low HIV knowledge, and irregular testing, by offering discreet, accessible, and user-centered services. These should include features like HIV education, medication reminders, e-consultation, and mental health support. Policymakers, in collaboration with CBOs, should develop encrypted, culturally sensitive platforms with e-consultation and mental health support aimed at enhancing reach and mitigating HIV risk. Future research, including qualitative studies, is needed to optimize app design for these populations and people living with HIV.

Acknowledgments

The author would like to thank all the participants who participated in the design, data collection, data analysis, manuscript writing, and completion of this survey. The authors affirmed that the study adhered to SAGER (Sex and Gender Equity in Research) guidelines, and sex and gender considerations were integrated into the study design, data collection, analysis, and reporting. The authors acknowledged the use of the artificial intelligence–powered tools ChatGPT (OpenAI) and Grammarly to refine and enhance the manuscript's readability. After refinement and readability enhancement, 2 reviewers thoroughly reviewed the manuscript to ensure accuracy and scholarly rigor.

Funding

No external financial support or grants were received from any public, commercial, or not-for-profit entities for the research, authorship, or publication of this article. However, the authors are thankful to the University of California, San Diego, for providing the article processing fee.

Authors' Contributions

All authors contributed to the review and approval of the final manuscript. FR led all aspects of the study, including conceptualizing the research, designing the questionnaire, collecting and analyzing the data, and writing the manuscript. AA contributed to conceptual development and questionnaire design. The first draft of the questionnaire and manuscripts was shared with AA, who provided feedback. FR addressed all comments and revisions before sharing with other authors. The other authors (MWS, MR, FA, MMU, and AS) reviewed the draft version, provided their feedback and recommendations, and FR addressed their comments through revision. The process continued until all authors reached consensus on the final version.

Abstract

Background: Sleep is essential for overall health and well-being, but assessing sleep architecture is often costly and time-consuming, relying primarily on polysomnography (PSG). While wrist-worn wearables offer alternatives, they face limitations regarding user compliance, such as battery charging and physical discomfort. Nearable devices address these burdens, but they regularly lack rigorous validation, especially in real-world settings.

Objective: This study evaluates the accuracy and reliability of the Withings Sleep Analyzer (WSA), a contactless sleep monitoring device, compared to PSG in a home setting using a large and diverse cohort of healthy individuals.

Methods: A total of 117 healthy volunteers (69 women; mean 39.9, SD 11.4 years), prospectively recruited from the general population, underwent home-based PSG and simultaneous WSA recording. The study was conducted under free-living conditions, without constraints on substance intake, prebedtime activity, or forced sleep schedules. The main outcomes were the device's performance in sleep-wake distinction and sleep stage identification using accuracy, kappa, sensitivity, specificity, and the mean absolute error of sleep measures on the entire population and demographic, clinical, and environmental subgroups.

Results: WSA demonstrates high sensitivity (93%, 95% CI 92%-94%) for sleep detection and moderate sensitivity (73%, 95% CI 69%-77%) for wakefulness, achieving an overall accuracy of 87% (95% CI 86%-87%) for sleep-wake distinction. The device showed consistent performance across various demographic subgroups, including different age, BMI, mattress, and sleep arrangements (with or without bed partner) categories. Challenges were noted in accurately classifying specific sleep stages, particularly in distinguishing between light and deep sleep, with a mean accuracy of 63% (95% CI 62%-65%) and a Cohen κ of 0.49 (95% CI 0.47-0.51). The WSA tended to overestimate total sleep time (20 min, 95% CI 10 min to 31 min) and light sleep (1 h 21 min, 95% CI 1 h 8 min to 1 h 36 min) while underestimating rapid eye movement (−15 min, 95% CI −23 min to −8 min) and deep sleep (−46 min, 95% CI −59 min to −34 min) durations. Disagreements between expert reviewers were mirrored in part by the WSA's misclassifications. Participants reported altered perceived sleep quality during the night with the PSG, suggesting discomfort during sleep.

Conclusions: Being contactless and placed under the mattress, the WSA offers a promising approach to long-term sleep monitoring in natural home environments. It shows competitive performance in sleep-wake and sleep stage identification compared to other consumer devices. Progress in wearable and nearable devices is necessary to enhance their accuracy to better support the monitoring of populations with impaired sleep, although limited by an imperfect gold standard. This work also emphasizes the importance of using large, diverse, and challenging datasets, as well as the need for a standardized methodology for accurate sleep stage classification.

Introduction

Sleep is an essential component of human health and plays an important role in daily functioning and overall well-being [1]. Poor sleep quality can significantly impact multiple aspects of life, including physical health, social interactions, and emotional regulation [2,3]. Moreover, poor sleep quality can diminish alertness and cognitive function, increasing the risk of accidents. Furthermore, inadequate sleep has been linked to numerous health issues, such as metabolic disorders, cardiovascular disease, neurocognitive impairments, and mental health challenges [4]. In severe cases, poor sleep quality can lead to critical outcomes, including an increased risk of suicide [5]. Despite the recognized importance of sleep, sleep-related difficulties remain common in the general population [6]. Approximately 30% of adults experience at least one symptom of nocturnal insomnia on a chronic basis [6], over 15% report sleepiness that affects daily activities [7], and more than 10% experience obstructive sleep apnea [8].

Polysomnography (PSG), considered the gold standard for identifying the micro and macro sleep architecture, records a variety of signals (electroencephalogram [EEG], electrooculogram [EOG], electromyogram [EMG], electrocardiogram [ECG], pulse oximetry, air flow, and breathing effort [9]). As the hypnogram helps physicians identify abnormal sleep patterns, quantify sleep fragmentation, and analyze sleep stage distribution, it supports the diagnosis of various sleep disorders, such as sleep-related breathing disorders, narcolepsy, hypersomnia, and disturbing sleep-related behaviors [10].

PSG has limitations. It often involves extensive setup time and significant costs, making it less feasible for routine monitoring [11]. It is scored manually, which is a labor-intensive process that can lead to long waiting times and has been shown to be prone to human error [12]. Additionally, since it is typically conducted over just a few nights, it fails to capture the full picture of an individual's circadian rhythm and night-to-night variability [13,14]. In most cases, PSG is conducted in a sleep lab with numerous sensors that can disrupt natural sleep patterns [15]. For all these reasons, PSG results in data that may not accurately represent a person's typical sleep in their own home [16].

Ambulatory PSG attempts to address these limitations. Lab studies support its accuracy [17-19]. However, in an uncontrolled home setting, sleep metrics may differ; for example, total sleep time (TST) can increase, potentially due to the absence of lab-induced constraints on waking time [20].

The need for more accessible and cost-effective solutions for multinight sleep monitoring remains, driven by the desire to enhance our understanding of sleep quality and facilitate the identification of potential sleep disorders [14,21]. Home-based sleep monitoring devices can enable continuous tracking in the comfort of one's own home, while providing data that reflect real-life conditions more accurately than laboratory-based examinations [22]. This can provide a more realistic picture of an individual's sleep patterns and helps to address the limitations of traditional sleep studies [23].

To address the challenges of cost and complexity in multinight assessments, wearable sleep devices are commonly used to detect sleep and wake states. These devices increasingly combine actigraphy, which tracks body movements [16], with photoplethysmography (PPG) sensors to increase the accuracy of sleep measures estimation [23]. These devices still show two limitations. First, they struggle to accurately differentiate between wakefulness and sleep when individuals remain still while awake [24]. Second, wearable devices require users to maintain proper charging and wearing, leading to frequent data loss and inconsistent performance [25]. In contrast, nearables, which are not in direct contact with the individual, eliminate the need for charging or wearing a device. Nearables for measuring sleep are typically positioned under the mattress or at the bedside and require minimal intervention after setup.

Withings Sleep Analyzer (WSA) is a nearable device designed to provide a noninvasive alternative for monitoring sleep stages over consecutive nights. Despite the proliferation of wearable and nearable sleep-tracking devices, there is a notable lack of rigorous evaluation of the algorithms, leading to concerns about data accuracy and reliability [26,27]. To date, the WSA performance to detect apnea has been evaluated in laboratory conditions [28-32], for which it is European Conformity (Conformité Européenne) marked and Food and Drug Administration–cleared. In addition, it has been assessed for nocturnal sleep periods detection [33] and cardiorespiratory monitoring [34]. However, validation of its sleep stage detection algorithm remains limited. This study, therefore, aims to assess the WSA sleep stage identification algorithm in a real-world home setting in a cohort of 117 healthy adult participants.

There are several important methodological issues addressed in this work. Existing research in sleep-tracking technologies highlights several persistent problems and limitations. Many studies, such as those on the WatchPAT [35] and Somnofy [36] devices, suggest potential utility but often lack comprehensive validation across diverse populations and real-world settings. Evaluations of consumer-grade devices, like those conducted by Chinoy et al [37] and Kainec et al [38], are frequently limited by small sample sizes and strict exclusion criteria (young individuals with controlled caffeine, alcohol, screen time, and sleep regularity), which limit the generalizability of their findings. These studies typically occur in controlled environments, such as sleep labs, which do not accurately reflect regular user conditions at home.

Moreover, the assessment of device accuracy in these studies is often complicated by two distinct factors. First, the absence of synchronized epoch-by-epoch data in some reports limits performance evaluation to night-scale sleep measures, such as TST, precluding the calculation of detailed classification metrics (eg, accuracy, sensitivity, and specificity). Second, the practice of using lights-off and lights-on times to define the temporal analysis window, which excludes all data outside this interval, impairs the reliability of the computed error for metrics like sleep onset latency. This method indeed assumes observable in-bed time is equivalent to the intention to initiate sleep, which cannot be passively identified in free-living conditions [39].

XSL•FO
RenderX

Recent publications emphasize the importance of assessing these devices under everyday conditions, aligning with our work (eg, [40]). Other research emphasizes the need for standardized evaluation protocols and methodological consistency across studies, reinforcing the approach taken in our research [41-43]. These studies collectively highlight the critical need for standardized and rigorous evaluation methods in sleep monitoring technology. Benchmarking efforts of devices are also being addressed, as recent studies manifest [37,38,44-47].

Our study contributes to the growing literature on sleep tracking by assessing the WSA's performance in a home setting, on a large and diverse sample of healthy individuals, in free-living conditions, that is, without constraints about substance intake, activity before bed, or forced sleeping period, providing insights into the device's accuracy and reliability in real-world conditions. The primary goal is to evaluate WSA's performance using classification metrics and mean absolute error (MAE) on standard sleep metrics [48]. Additionally, we compare performance across subgroups based on demographic and clinical characteristics, such as sex, age, BMI, bed partner presence, mattress type, but also Pittsburgh Sleep Quality Index (PSQI) score [49], mattress, and thickness.

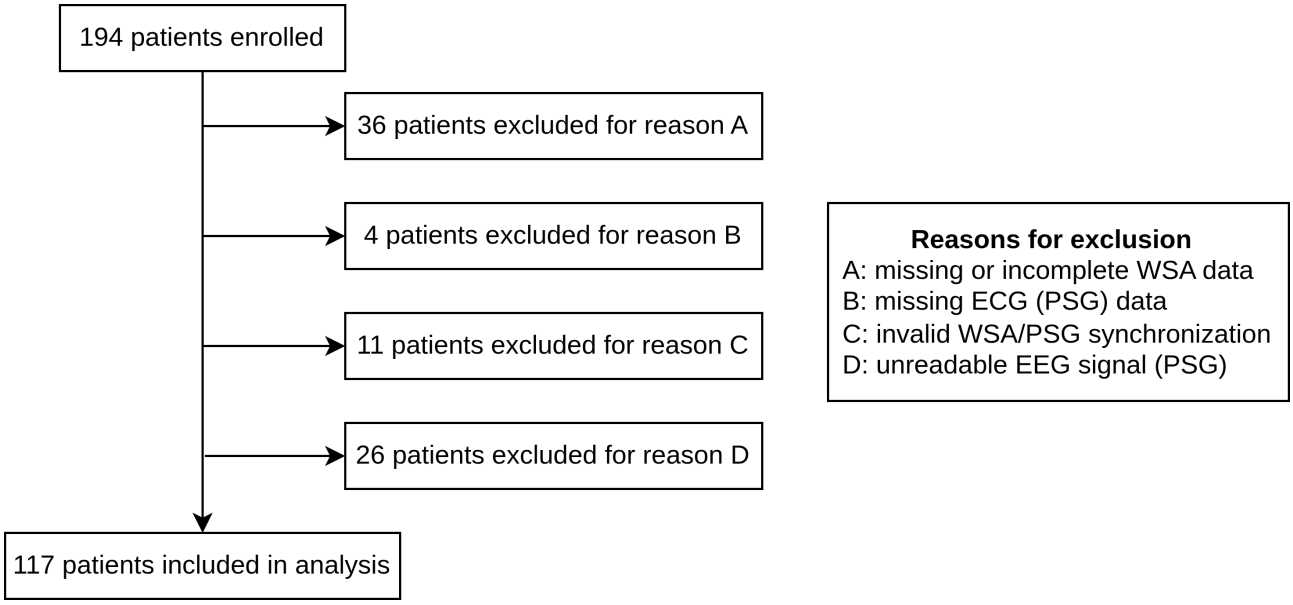
By addressing these gaps, our study enhances the understanding of WSA's capabilities and contributes to the development of more reliable and user-friendly sleep-tracking devices.

Methods

Ethical Considerations

Data were collected during a clinical study approved by the French Institutional Review Board (approval number: 2018-A03129-46) and conducted by Withings from 2020 to 2022. The inclusion process for the study was conducted prospectively by a third party, a general-purpose survey company owning listings of self-declared individuals from the general population. Participants were contacted based on the inclusion and exclusion criteria. In particular, the contacted persons had to have no preexisting medical conditions that would necessitate a PSG examination, and inclusion criteria aimed to ensure a balanced distribution of BMI within each age group. The cohort consisted of a consecutive series of 194 volunteers who provided informed consent. To guarantee data privacy, a unique, randomized anonymization code was assigned to each participant (used for both WSA and PSG data correspondence). Withings only had access to these pseudonymized datasets and never had access to direct identifiers. No compensation from Withings was provided to the participants.

Dataset



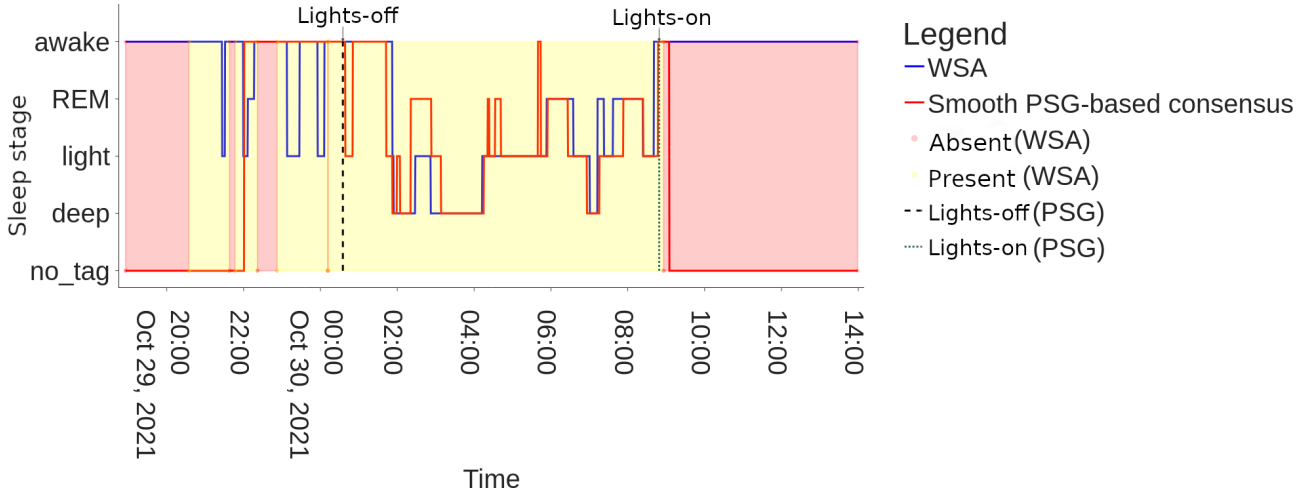
Participants

A total of 194 participants slept for the first night at home with WSA and the CID-LXe portable PSG (CIDELEC), both installed by a technician the evening before the recording. The night after that, the participants slept at home with the WSA, without the PSG. Each participant was asked to answer once to the PSQI questionnaire upon enrollment. After each night, participants were asked to complete a survey addressing the following: their sleep quality for that night, a comparison of that night's sleep quality to their usual sleep, whether they took sleeping pills, and any sleep disturbances related to the sensors.

As illustrated in the flowchart (Figure 1), several sources of data loss have led to the inclusion of 117 participants in this analysis. This trial was notably affected by data collection issues due to a dedicated firmware meant to collect high-frequency sensor data (reason for exclusion A). Unlike the commercial version which transmits aggregated data, the devices in this study were programmed to upload raw, high-frequency sensor signals, which introduced connectivity issues detailed in the Limitations section. We performed Little's missing completely at random (MCAR) test, which did not reject the null hypothesis of MCAR data due to reasons A, C, and D (P>.05). While a statistically significant result was observed for reason B (P=.04), this subgroup comprised only 4 participants and was therefore unlikely to represent a source of systematic bias (see Section A of Multimedia Appendix 1 for detailed results).

XSL•FO
RenderX

Figure 1. Study inclusions flowchart. ECG: electrocardiogram; EEG: electroencephalogram; PSG: polysomnography; WSA: Withings Sleep Analyzer.



Procedure and Study Design

WSA sampled the raw data from the pressure sensors at 250 Hz and preprocessed data from the microphone at 8 Hz. The reference device was CID-LXe PSG (CIDELEC) that recorded the following signals: 3 EEG, 1 ECG, 2 EOG, 1 submental EMG, and ambient light. Based on experience from past investigations, the digital oximeter and the nasal cannula are among the most sleep-disruptive sensors during PSG, even in a home setting. To minimize this sleep disruption and obtain the most natural possible sleep, PSG was therefore done at home with only EEG, EMG, ECG, and ambient light sensors. As sleep stage annotations from expert reviewers are based on EEG and light sensors only [50], the gold standard reference quality is not affected by the removal of the oximeter and the nasal cannula.

Data Processing

WSA is designed to identify sleep stages over 6-minute windows. As a result, this analysis focuses on evaluating WSA's performance in detecting stages longer than 6 minutes. It should be kept in mind that sleep stages shorter than this are ignored by the device in this study. In addition, WSA does not distinguish stages N1 and N2, so for the aim of comparison, the consensus sleep stages N1 and N2 obtained from the PSG were combined into the "light" category. Rapid eye movement (REM) and awake stages of the WSA and the consensus are directly comparable, and N3 is compared with the stage "deep sleep" from the WSA. The resulting stages are illustrated in Figure 2.

Figure 2. Example of hypnogram (participant 20211029_1) showing WSA sleep stages and the reference (PSG consensus). PSG: polysomnography; REM: rapid eye movement (sleep stage); WSA: Withings Sleep Analyzer.

Two independent certified sleep technologists annotated the PSG signals in 30-second epochs, classifying sleep stages as N1, N2, N3, REM, and awake, following the American Academy of Sleep Medicine (AASM) scoring manual [48]. A third professional reviewed the 2 initial readings and established a consensus for reference data. Sleep stage comparisons were performed over windows of 30 seconds. To evaluate WSA's performance in detecting sleep stages longer than 6 minutes, consensus data were smoothed by selecting for each 6-minute window the stage with the highest occurrence of 30-second epochs. For more details about the procedure, please refer to Section A of Multimedia Appendix 1.

XSL•FO
RenderX

In addition to standard sleep quality measures calculated over the night, such as TST and the duration of each stage, evaluating stage classification required synchronizing epoch-by-epoch data from both devices over time. Synchronization of the clocks of the devices was obtained by maximizing the correlation of the breathing signals of the two devices [51]. To verify the robustness of our breathing-based synchronization, we assessed the impact of temporal shifts (up to ±90 seconds) on classification performance [39,52]. This sensitivity analysis revealed negligible variations, with the SD for sensitivity and specificity across all sleep stages remaining below 0.005. Details of the procedure can be found in Section A of Multimedia Appendix 1.

An example hypnogram is presented in Figure 2, showing the smoothed, PSG-based consensus in red and WSA sleep stages in blue. WSA indicates bed absence/presence, marked respectively by a red and yellow background, information which is absent from the PSG data. The consensus annotations use instead the events lights-on/off detected by the ambient light sensor of the PSG as proxies for bed-in and bed-out events. For further information on challenges arising from using lights-off/on timestamps as proxies for bed presence, please refer to Section A of Multimedia Appendix 1.

Performance Evaluation Metrics and Tools

Standard sleep quality measures used for this analysis and based on the AASM scoring manual [48] are the following: total sleep time, time spent in each sleep stage (TIREM, TILight, TIDeep, and TIWake), proportion of the time spent in each sleep stage compared to total sleep time (PIREM, PILight, PIDeep, and PIWake), and number of episodes in each sleep stage (NEREM, NELight, NEDeep, and NEWake) [50]. Each of these measures has been computed by each device (PSG and WSA) and then compared using the MAE and a Bland-Altman analysis, described in Section B of Multimedia Appendix 1.

Epoch-by-epoch agreement is assessed using standard classification metrics. Subgroup analyses were conducted to determine whether WSA performance is affected by demographic, clinical, and environmental factors. Details regarding the evaluation metrics and subgroup analyses are available in Sections B and C of Multimedia Appendix 1.

To compare the median MAE between different groups (categories of a given metadata as listed in Table S3 in Multimedia Appendix 1), a Kruskal-Wallis test has been performed on the MAE obtained on all the metadata described in Table S3 in Multimedia Appendix 1 for each of the following sleep quality measures (TST, TIREM, TILight, TIDeep, PIREM, PILight, and PIDeep) and for the number of episodes in each sleep stage.

To compare the MAE variance between different groups, a Brown-Forsythe test has been performed on the same data for the same sleep quality measures. The Holm-Bonferroni correction is used after both statistical tests to address the issue of multiple comparisons.

Results

Patient Characteristics

Demographic and clinical data are summarized in Table 1 for the population included in the analyses.

Characteristics	Values
No	71 (61)

[a]Skin type is based on the reduced Fitzpatrick scale.

[b]Arterial hypertension, atrial fibrillation, or myocardial infarction.

[c]Parkinson, stroke, adenoma, manic-depression, or epilepsy.

[d]Hemolytic anemia due to glutathione reductase deficiency, ulcer, sleeve, or diverticula.

[e]Diabetes, hypothyroidism, dyslipidemia, or obesity/overweight.

[f]Depression, insomnia, or anxiety.

[g]PSQI: Pittsburgh Sleep Quality Index.

[h]PSG: polysomnography.

A total of 117, mostly healthy, participants were included in the analysis. The cohort comprised 59% (n=69) women and 41% (n=48) men, with a mean age of 39.9 (SD 11.4) years, ranging from 19 to 69 years. The average BMI was 23.9 (SD 3.3) kg/m².

The average sleep quality in this population is considered mildly impaired, with a mean PSQI score of 6 out of 21. The SD of 2.9 highlights significant variability.

The most common mattress types were foam (n=41, 35%), spring (n=29, 25%), and latex (n=24, 21%). Around 55% (n=64) of participants reported having a bed partner. Sensor disturbances were reported by 46 (39%) participants due to the PSG device, while no disturbances were reported regarding the WSA nearable.

Sleep Stages Classification

Figure 3 presents the confusion matrix containing the epochs across all nights, and Table 2 gathers sleep stages classification results on the whole dataset.

Figure 3. Sleep stage classification confusion matrix (N=117). (Left) Raw confusion matrix displaying total epoch counts for WSA sleep stage detection versus PSG ground truth. (Right) Row-normalized confusion matrix (expressed in percentages) illustrating the classification sensitivity and misclassification rates for each true sleep stage. PSG: polysomnography; REM: rapid eye movement (sleep stage); WSA: Withings Sleep Analyzer.

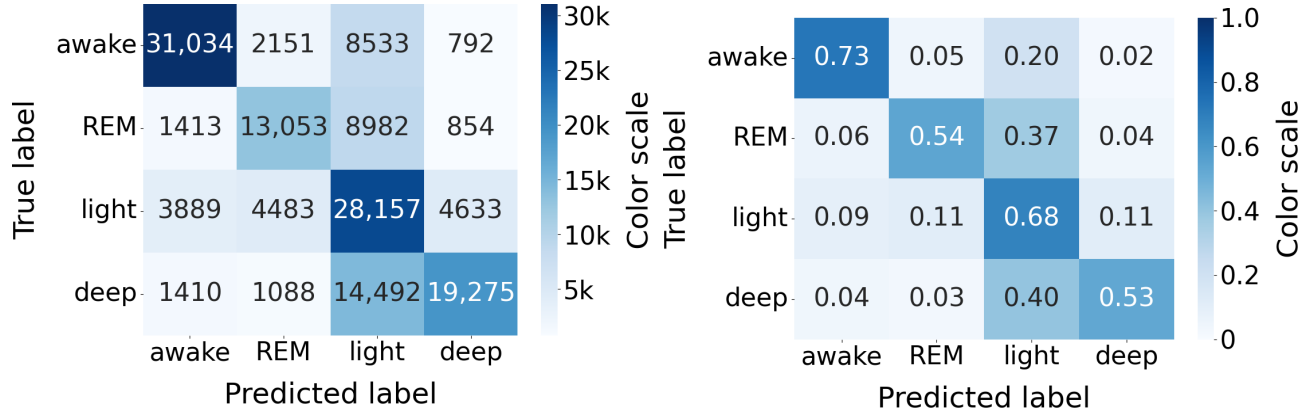

Table . Summary of sleep stage classification results over nights (N=117) (computed as the averages of all nights).

Mean of results per night	Sleep stages								Sleep-wake			
	Kappa	Accuracy	Se[a] REM[b]	Se light	Se deep	Sp[c] REM	Sp light	Sp deep	Kappa	Accuracy	Se sleep	Sp sleep
Mean	0.49	0.63	0.53	0.68	0.56	0.93	0.69	0.94	0.65	0.87	0.93	0.73
95% CI	0.47-0.51	0.62-0.65	0.48-0.57	0.65-0.71	0.51-0.60	0.92-0.94	0.67-0.71	0.93-0.95	0.62-0.69	0.86-0.89	0.92-0.94	0.69-0.77
SD	0.12	0.09	0.24	0.16	0.25	0.05	0.11	0.06	0.19	0.07	0.06	0.22

[a]Se: sensitivity.

[b]REM: rapid eye movement (sleep stage).

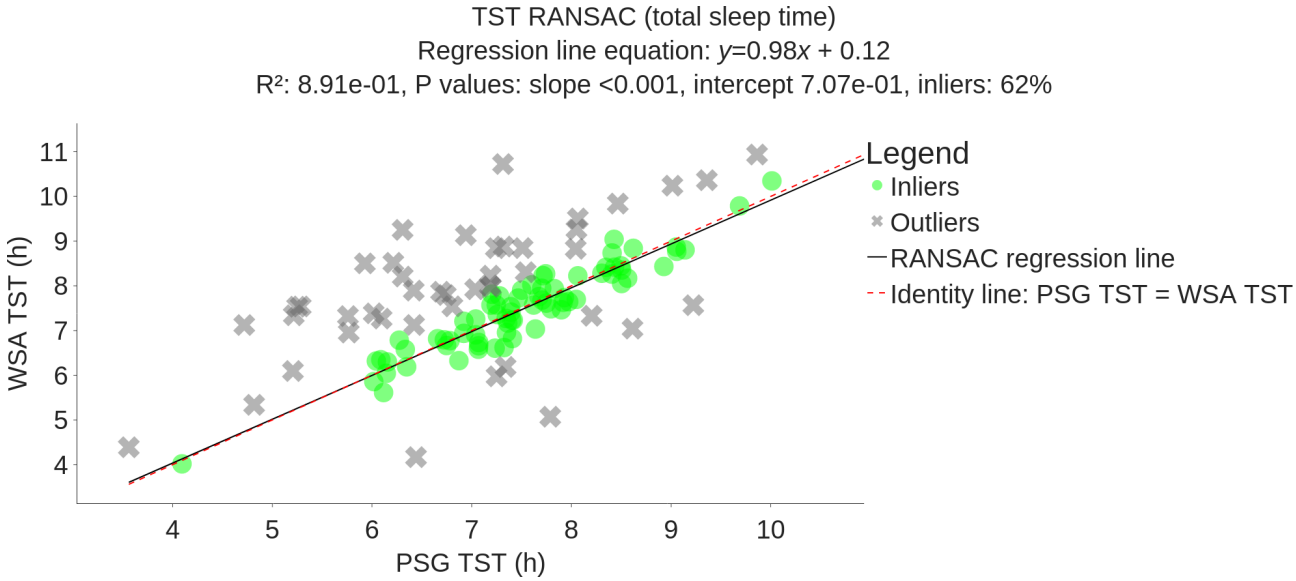
[c]Sp: specificity.

Sensitivity and Specificity

The WSA sensitivity for detecting sleep was 93% (95% CI 92%-94%; N=117), meaning it correctly identifies when a person is asleep 93% of the time. The mean specificity was 73% (95% CI 69%-77%), indicating it accurately detects when a person is awake 73% of the time.

XSL•FO
RenderX

The performance in accurately classifying each individual sleep stage against the other three is more variable, with sensitivities of 53% (95% CI 48%-57%), 68% (95% CI 65%-71%), 56% (95% CI 51%-60%), and 73% (95% CI 69%-77%) for REM, light sleep, deep sleep, and wake stage, respectively. The corresponding specificities were 93% (95% CI 92%-94%), 69% (95% CI 67%-71%), 94% (95% CI 93%-95%), and 93% (95% CI 92%-94%), respectively.



Cohen κ and Accuracy

Please note that, contrary to sensitivity and specificity, Cohen κ and accuracy depend on the relative sizes (prevalences) of each class. In this study's dataset, the WSA mean Cohen κ was 0.65 (95% CI 62%-69%) for distinguishing between sleep and wake stages, and 0.49 (95% CI 47%-51%) for differentiating among the 4 stages (N=117). WSA accuracy to distinguish between sleep and wake was 87% (95% CI 86%-89%). The mean accuracy for the 4 stages was 63% (95% CI 62%-65%).

Assessment of Sleep Quantity Measures

Figure 4 shows the TST estimated by the WSA versus the PSG. The slope of the linear regression is 0.98 (P<.001) and the R^2 value is 0.89, with 38% of outliers, indicating a moderate linear relationship with PSG.

Figure 4. RANSAC regression plot between WSA and PSG total sleep time (black line) compared to the identity line (red dashed line) on 117 participants (R^2=0.89, slope P value P < .001, inliers: 62%). PSG: polysomnography; RANSAC: random sample consensus algorithm; TST: total sleep time; WSA: Withings Sleep Analyzer.

WSA deep sleep was not correlated to time spent in deep sleep (slope estimate of 0.05, P=.7, Figure S4 in Multimedia Appendix 1). The WSA estimates of light sleep and REM were moderately correlated with PSG values, with respective slopes of the regression lines of 0.4 (P<.001, Figure S5 in Multimedia Appendix 1) and 0.65 (P<.001, Figure S6 in Multimedia Appendix 1).

Precision of the WSA estimates is measured with the MAE. The MAE values of total sleep time (equal to the MAE of wake duration because the sum of TST and wake duration is the recording time), REM duration, light sleep duration, and deep sleep duration are 44 min, 35 min, 1 h 33 min, and 1 h 4 min, respectively, with average PSG values of 7 h 15 min (3 h 03 min for awake duration), 1 h 43 min, 2 h 57 min, and 2 h 35 min, respectively. Corresponding 95% CIs are reported in Table 3. The average number of episodes in each sleep stage and the average number of stage changes can be found in Table 4. The WSA tends to underestimate the number of episodes for each sleep stage and is less sensitive to transitions between epochs.

XSL•FO
RenderX

Table . Summary of Bland-Altman results obtained on sleep-related metrics between WSA[a] and PSG[b] estimations (N=117).

Sleep quality measures	PSG value, mean (SD)	MAE[c] (95% CI)	Bias, WSA – PSG (95% CI)
TST[d]	7 h 15 min (1 h 14 min)	44 min (36 min to 52 min)	20 min (10 min to 31 min)
TIREM[e]	1 h 43 min (45 min)	35 min (30 min to 40 min)	–15 min (–23 min to –8 min)
TILight[f]	2 h 57 min (1 h 12 min)	1 h 32 min (1 h 21 min to 1 h 44 min)	1 h 21 min (1 h 8 min to 1 h 36 min)
TIDeep[g]	2 h 35 min (54 min)	1 h 4 min (55 min to 1 h 13 min)	–46 min (–59 min to –34 min)
TIWake[h]	3 h 3 min (1 h 19 min)	44 min (36 min to 52 min)	–20 min (–31 min to –10 min)
PIREM[i]	17% (8.8%)	5.7% (4.9% to 6.5%)	–2.4% (–3.6% to –1.1%)

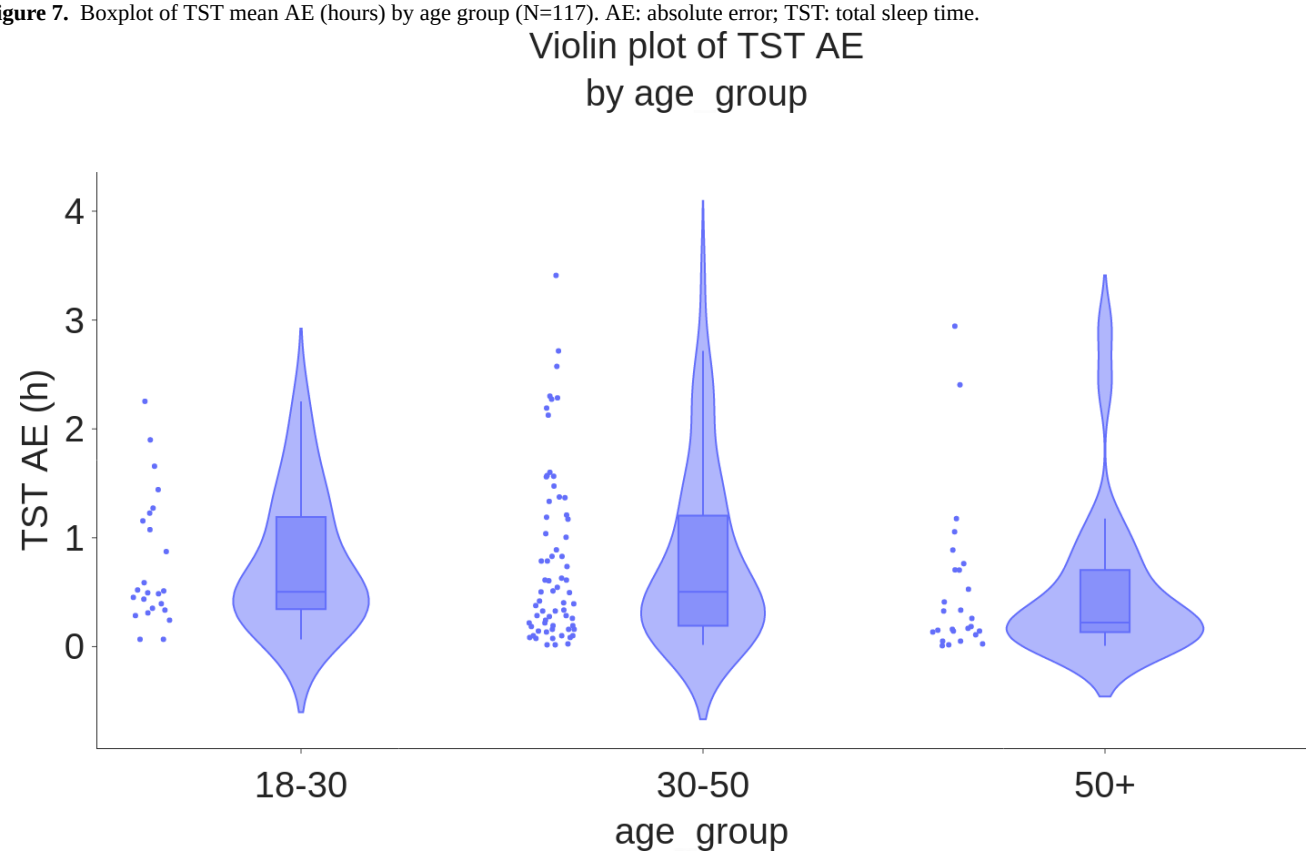
The Bland-Altman plots are presented in Figures 5 and 6. Biases are summarized in Table 3.

Figure 5. Bland-Altman plot comparing WSA and PSG estimation of total sleep time and time in REM on 117 participants. LOA: limits of agreement; PSG: polysomnography; REM: rapid eye movement (sleep stage); TIREM: time spent in rapid eye movement sleep stage; TST: total sleep time; WSA: Withings Sleep Analyzer.

XSL•FO
RenderX

Figure 6. Bland-Altman plot comparing WSA and PSG estimation of time in deep and time in light (N=117). LOA: limits of agreement; PSG: polysomnography; TIDeep: time spent in deep sleep stage; TILight: time spent in light sleep stage; WSA: Withings Sleep Analyzer.

In Figure 5, the Bland-Altman plot for TST does not reveal any proportional bias with the duration of the night. The mean error is 20 minutes. The wide limits of agreement show that there is a substantial amount of variability between PSG and WSA. By contrast, the average error in REM, light, and deep sleep durations depends on the duration of the phase, therefore exhibiting proportional bias. Light sleep is *on average* overestimated for any duration, deep sleep is *on average* underestimated for any duration, and REM is *on average* underestimated for short durations and overestimated for long durations.



The mean error (bias) in light sleep duration is important, with 1 h 21 min. Biases in REM and deep sleep are −15 min and −46 min, respectively. The mean error in TST is therefore 20 min.

Subgroup Analyses

No significant differences were found in the median or variance of the error across most groups for all the quantitative sleep variables of Table 3. This includes comparisons based on gender, BMI categories, age groups, sleeping arrangements, PSQI scores, self-reported sleep quality, mattress thickness, and night awakenings. However, significant differences in median total sleep time and wakefulness proportion were observed within the PSQI sleep duration component subgroup. Median MAE of TST is respectively 21 min and 1 h 11 min for good and bad sleep duration subgroups, and median MAE of wakefulness proportion is respectively 3% and 12% for good and bad sleep duration subgroups (N=117). This finding suggests that distinguishing sleep from wake is a harder task for the WSA when the participant has subjective short sleep duration (<6 h), highlighting an area for further investigation. For a comprehensive overview of the statistical tests and detailed results, please refer to Multimedia Appendix 2.

As an illustration, Figures 7-9 show the boxplots of TST MAE of WSA compared to PSG, stratified by age groups, BMI ranges, and whether the participant was alone in bed. They suggest that the WSA performance did not depend on these factors. Boxplots for TST MAE for the other subgroups can be found in Section D of Multimedia Appendix 1.

RenderX

Agreement Between Reviewers

Each 30-second epoch of the PSG data was independently annotated by two reviewers. The mean κ value for sleep stage determination between reviewers before reaching consensus is 0.71 (SD 0.11), closely aligning with literature findings (κ=0.76 in [53]), while it is 0.81 (SD 0.17) for sleep-wake classification.

In the analysis of reviewer agreement on sleep stage classifications, the primary disagreements occur between light and deep stages, as well as between light sleep and awake/REM stages (Figure 10). This indicates that even expert reviewers, considered the gold standard, face challenges in accurately distinguishing these stages due to their inherent similarities and subtle physiological differences. This inherent difficulty in distinguishing light, deep, awake, and REM sleep stages by human experts is reflected in WSA, which was trained on PSG data labeled using a similar protocol. It is likely that the imprecision of the gold standard is passed on to the device.

Figure 10. Sleep stage classification confusion matrix between the first two reviewers' annotations (N=117). REM: rapid eye movement (sleep stage).

Discrepancies in Performance: Epochs With Reviewers' Agreement vs Disagreement

Given the discrepancies encountered in PSG annotation among reviewers, it is pertinent to investigate whether the WSA performed better on epochs where reviewers reached consensus compared to those where disagreements were present. To perform this analysis, the dataset was divided into two groups of epochs: those where reviewers reached agreement and those where disagreements occurred. Separate performance analyses were then conducted on these two complementary groups.

Results are summarized in Table 5. In the "agreement" column (resp. "disagreement" column), only epochs where both reviewers agreed (resp. disagreed) were included, while epochs with disagreement (resp. agreement) were excluded. Figure 11 shows the confusion matrices obtained for both sets.

Figure 11. Sleep stage classification confusion matrices (N=117) on sets with agreement (left) and disagreement (right); WSA sleep stage detection vs PSG ground truth. PSG: polysomnography; REM: rapid eye movement (sleep stage); WSA: Withings Sleep Analyzer.

We used a *z* test for proportions to test for differences between sensitivity, specificity, accuracy, and kappa. All the results are statistically significant, with WSA performing better on epochs where the two reviewers agreed. The progression is particularly significant for the sensitivity in deep sleep, reaching 0.56, compared to 0.37 when the reviewers disagreed, as in the latter case, WSA predominantly classified deep sleep stages as light sleep. The specificity for light sleep was also starkly improved from 0.52 to 0.72. As a result, the Cohen κ is almost double when reviewers agreed (0.64 vs 0.33 for S/W classification, and 0.52 vs 0.27 for 4-stage classification).

Sleep Quality With vs Without PSG

Since this analysis does not involve the WSA or the PSG data, but only the participants' answers to the questionnaires, it was

XSL•FO
RenderX

conducted on the 186 participants for whom reported sleep quality data were available. Results are given in Table 6.

Table . Comparison of reported sleep quality and sensor disturbance with and without PSG[a] (n=186). In both cases, the participant used a WSA[b] and two ScanWatch devices.

Qualitative sleep quality measures	First night with PSG	Second night without PSG
Sleep quality, n (%)		
Very poor	10 (5.4)	3 (1.6)
Poor	65 (34.9)	32 (17.2)
Quite good	75 (40.3)	71 (38.2)
Good	32 (17.2)	58 (31.2)
Very good	4 (2.2)	22 (11.8)
Sleep quality compared to usual sleep quality, n (%)		
Much worse	28 (15.1)	6 (3.2)
Worse	69 (37.1)	32 (17.2)
Same	77 (41.4)	111 (59.7)
Better	10 (5.4)	31 (16.7)
Much better	2 (1.1)	6 (3.2)
Sensor disturbance		
Device that caused sleep disturbances	PSG	WSA
Yes, n (%)	77 (41.4)	0 (0)
No, n (%)	109 (58.6)	0 (0)

[a]PSG: polysomnography.

[b]WSA: Withings Sleep Analyzer.

Despite the removal of the nasal cannula and the blood oximeter from our home PSG test, the sleep test was associated with significant discomfort in 41% (77/186) of the participants during the night of the PSG home test, compared to 0% (0/186) in the subsequent night with the WSA only. Fifty-two percent (97/186) (resp. 20%, 38/186) of the participants reported a degraded sleep quality on the night of the PSG (resp. without the PSG).

Figure 12 illustrates the changes in sleep quality among participants over 2 consecutive nights. Participants generally experienced better sleep without the PSG sensors. Notable improvements were observed in 52% (97/186) of cases, with transitions from fairly good to good (26/186, 14%), and from poor to fairly good (31/186, 17%), good (12/186, 6%), or very good (10/186, 5%). Additionally, some participants reported significant improvements from very poor to very good sleep, and others from poor to fairly good. These improvements may be influenced by several factors, including the removal of PSG sensors, which can be intrusive and uncomfortable, potentially disrupting sleep. Furthermore, the awareness of being recorded might alter participants' sleep behavior, either positively or negatively. The use of unfamiliar devices could also play a role, as participants may initially experience discomfort or anxiety, which diminishes over time. External conditions such as noise and room temperature, which were not controlled in this study, could also significantly impact sleep quality. Therefore, while the data suggest improvements, it is crucial to consider these potential confounding factors when interpreting the results.

XSL•FO
RenderX

Figure 12. Comparison of reported sleep quality with and without PSG (N=186). Green: improved; yellow: identical; red: deteriorated; black: first night with PSG; grey: second night without PSG. In both cases, the participant used a WSA and two ScanWatch devices. PSG: polysomnography; WSA: Withings Sleep Analyzer.

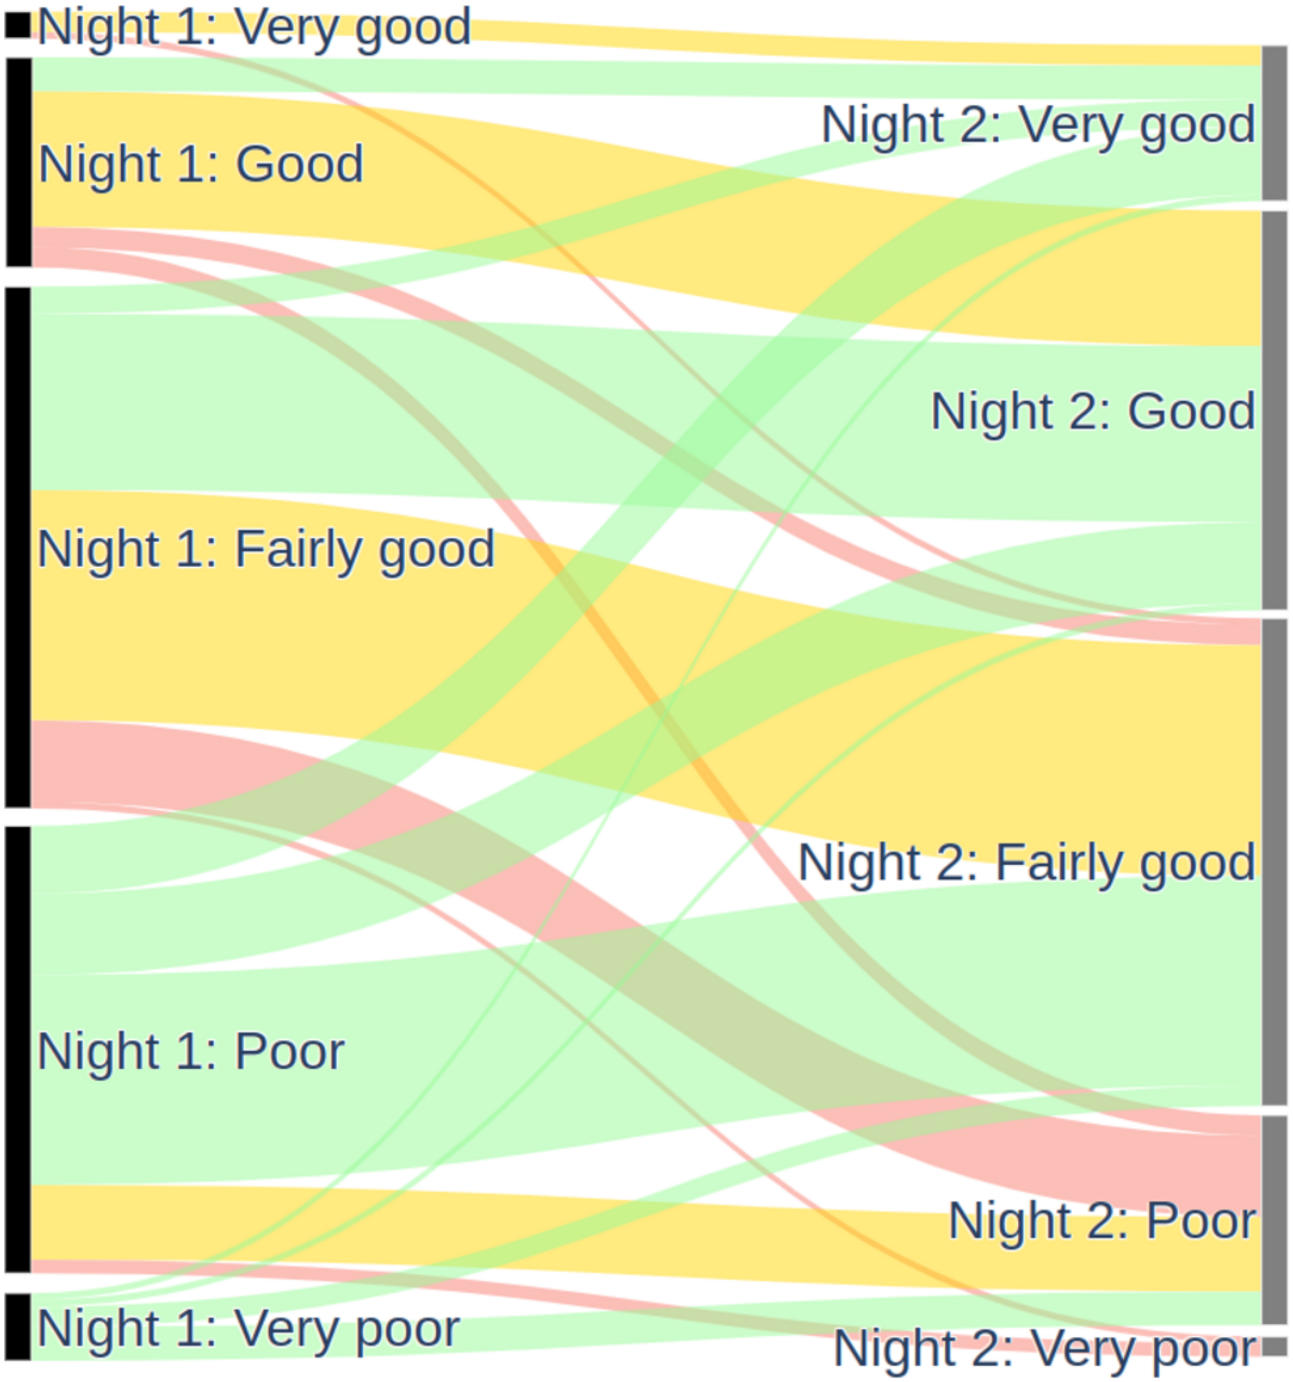

Table 6 highlights that participants slept as well with WSA as they typically do. On the second night, 59.7% (111/186) of participants reported the same sleep quality, 16.7% (31/186) reported better sleep, and 3.2% (6/186) reported much better sleep compared to their usual experience. This suggests that Withings sleep monitoring devices do not negatively impact sleep quality and may even enhance it for some users.

Discussion

Main Findings

The evaluation of the WSA for sleep stage detection in a cohort of 117 participants in a home setting revealed several key insights. The device demonstrated a high sensitivity of 93% for detecting sleep, underscoring its strong capability to accurately identify sleep periods. However, the specificity was moderate at 73%. The duration of the recording before actual sleep onset and after wake-up significantly affects observed performance of wake detection, with shorter periods inflating specificity, accuracy, and Cohen κ. This occurs due to a shortening of quiet wake periods hard to distinguish from sleep (reading or screen time in bed, for instance), leading to fewer false positives while true negatives remain relatively constant. Conversely, overly long (eg, 24-hour) recordings, dominated by easily identifiable diurnal wakefulness, also tend to inflate specificity. In both cases, the performance of the evaluated device is overestimated.

XSL•FO
RenderX

The most clinically relevant and challenging scenario for performance evaluation involves analyzing data encompassing the entire in-bed period, including calm wakefulness before sleep onset and after awakening. While AASM guidelines suggest using lights-off and lights-on as proxies for night boundaries, this approach truncates crucial pre– and post–sleep wake data, therefore introducing a bias in TST and classification performance endpoints. To mitigate this, we used all available PSG annotations, irrespective of lights-off and lights-on times, to provide a more comprehensive and unbiased assessment of performance across the full in-bed duration.

The classification of sleep stages (into wake, REM, light, and deep phases) is more challenging. The confusion matrix (Figure 3) shows that 40% of deep sleep phases, 37% of REM sleep, and 20% of wake phases were misclassified as light sleep by the WSA. As a result, the corresponding sensitivities were rather low (0.56, 0.53, and 0.73, respectively). Thirty-two percent of light sleep stages were misclassified, in similar proportions, into REM, deep sleep, and wake. In consequence, (1) the REM and deep sleep total durations were underestimated (by approximately 30% and 15%), while light sleep duration was overestimated by almost 48% (biases in Table 3), and (2) the specificities for wake, REM, and deep sleep are very high (0.93, 0.94, and 0.94, respectively), while the specificity for light sleep is moderate (0.69).

We showed that these misclassifications of WSA mirror the disagreements between PSG reviewers, who mainly disagree on light versus all the other sleep stages (Figure 11). WSA classification was indeed significantly better on epochs where reviewers agreed (79% of the epochs) than on epochs where they disagreed. WSA's sleep stage classification uses an algorithm trained by supervised learning on PSG data annotated by technician experts, so it is expected that WSA performance is limited by the interreader variability.

Consistent with existing validation studies [33,44], we also report accuracy and Cohen κ. We caution that these performance metrics are strongly dependent on the prevalence of the classes (here, wake, sleep, REM, deep, and light), which creates difficulties in comparing results between studies. In particular, for sleep studies, two factors modify the prevalence of the classes significantly. First, there is no standardized definition of the beginning of the night. Second, the choice of the reference device has some importance, causing more or less sleep disturbances.

With these caveats in mind, the WSA achieved an overall accuracy of 87% for sleep-wake distinction, which is promising for a contactless home monitoring device. Despite this, the accuracy for classifying specific sleep stages was moderate, with REM sleep at 53%, light sleep at 68%, and deep sleep at 56%. The overall accuracy for sleep stage classification was 63%, with a Cohen κ of 0.49.

Notably, the WSA's performance was consistent across various demographic subgroups, including different age and BMI categories. Importantly for a device under the mattress, there was no difference between individuals who slept alone and those with a bed partner, nor between different types or thicknesses of mattresses. Other groups analyzed included sex, PSQI scores, self-reported sleep quality, and whether individuals woke up during the night, all of which also showed no significant differences in MAE, except for wake proportion by subjective sleep duration group. This consistency suggests the device may be useful for a wide range of participants.

Comparison With Previous Research

Differences in Studies' Protocols

To contextualize our findings, we used published validation studies of other consumer sleep trackers. We advise interpreting these comparisons with caution, as study protocols vary significantly (eg, in-lab vs at-home settings, population characteristics, and data handling procedures). We compare our results on WSA with influential studies that have contributed to the understanding of consumer sleep-tracking technology. Studies [29], [37], and [33], respectively, evaluated 7, 5, and 6 consumer devices against PSG, mainly wearable devices, revealing significant variability in their accuracy for sleep stage detection. Studies [33,54-60] compared a total of 8 contact-free devices and 1 wearable against PSG. These studies provide a valuable context for evaluating our device's performance, illustrating both the advancements and challenges in the field of consumer sleep technology. All the data used for this comparison can be found in Multimedia Appendix 3.

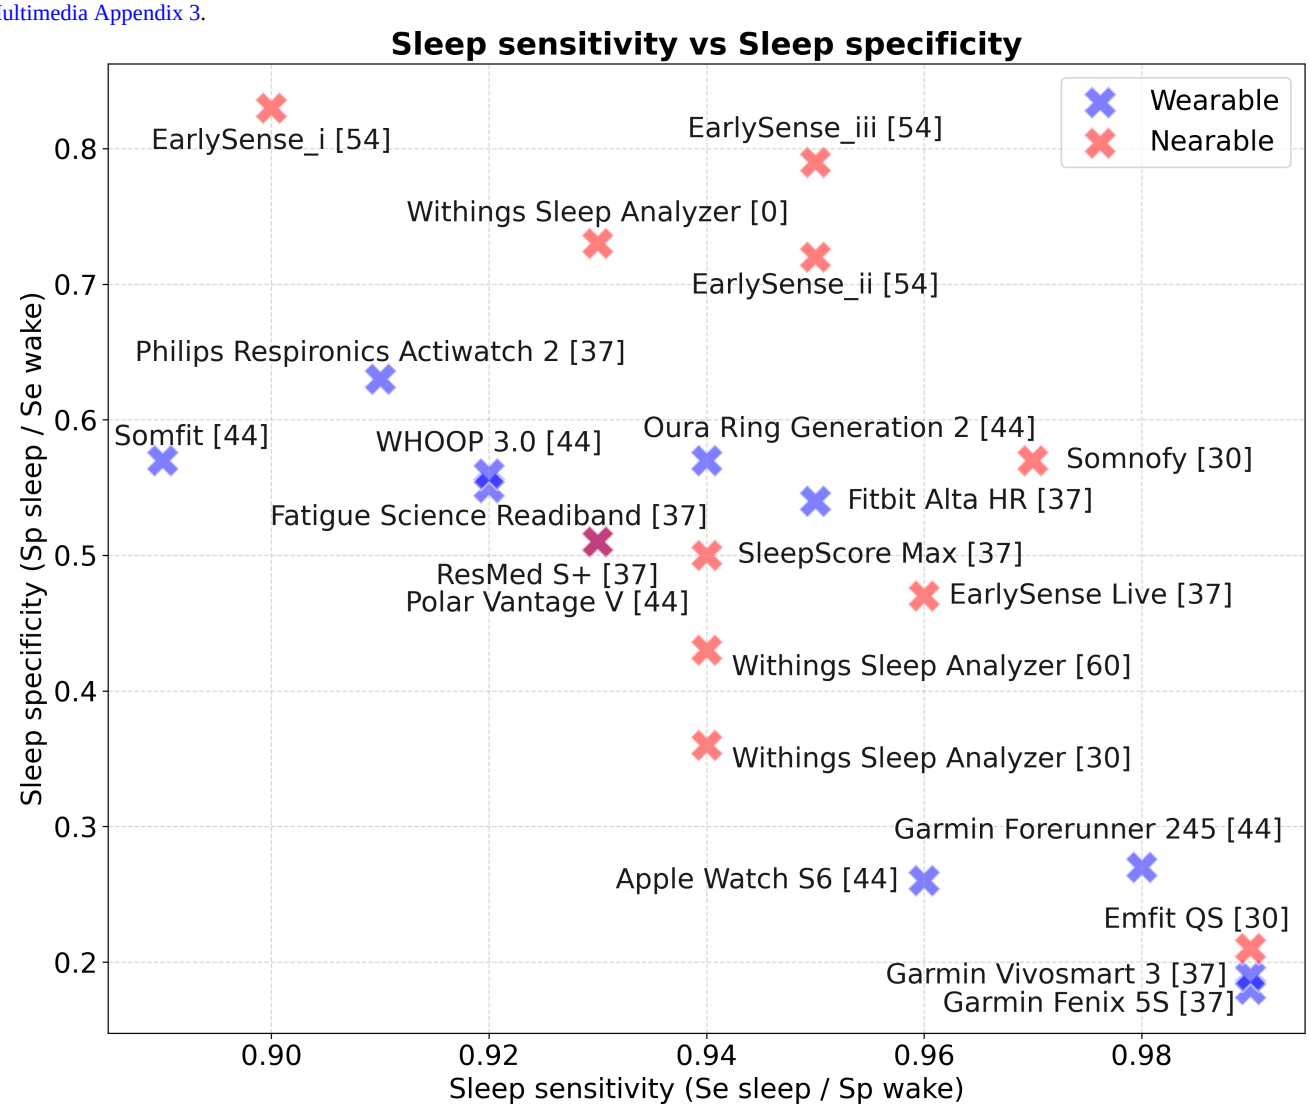
We compared the performance metrics reported by other studies on their respective datasets to the performance we obtained on our dataset, without reproducing their results or running their device algorithms on our data. When a result was not explicitly provided in the study report, we calculated it from the confusion matrix if it was available.

Consistent with recent validations [39], our study population encompasses a diverse range of cofactors of sleep quality, presenting a wide range of age and BMI, as was the case in only 2 of the 11 studies used for the comparison [55,59]. Four studies [37,38,44,58] included only young adults, and one study focused on older adults [33].

The conditions of our study are not controlled since participants stayed at home, as in only one other study [54] but on a much smaller scale (n=20). Our dataset is therefore richer regarding important environmental cofactors of sleep quality, including sleeping arrangements (alone or with a partner), mattress types, ambient temperature, lighting and sound, prebedtime activities (eg, no restriction on caffeine or alcohol consumption, on screen time, no forced sleep regularity), and activities during time in bed (eg, no forced turning off of the lights).

In addition, some studies use strict exclusion criteria also after data collection [38] to ensure data quality and reliability, such as excluding individual nights with a total recording time of less than 7 hours and 50 minutes [37].

Thus, our real-world home setting captures the natural variability in sleep patterns and environmental factors. While this enhances the generalizability of our results, reflecting typical user experiences, it also presents a less favorable scenario for the device, posing additional challenges for accurate sleep stage detection and analysis (for instance, activities in bed like reading or screen time can be confounded by the device as sleep).



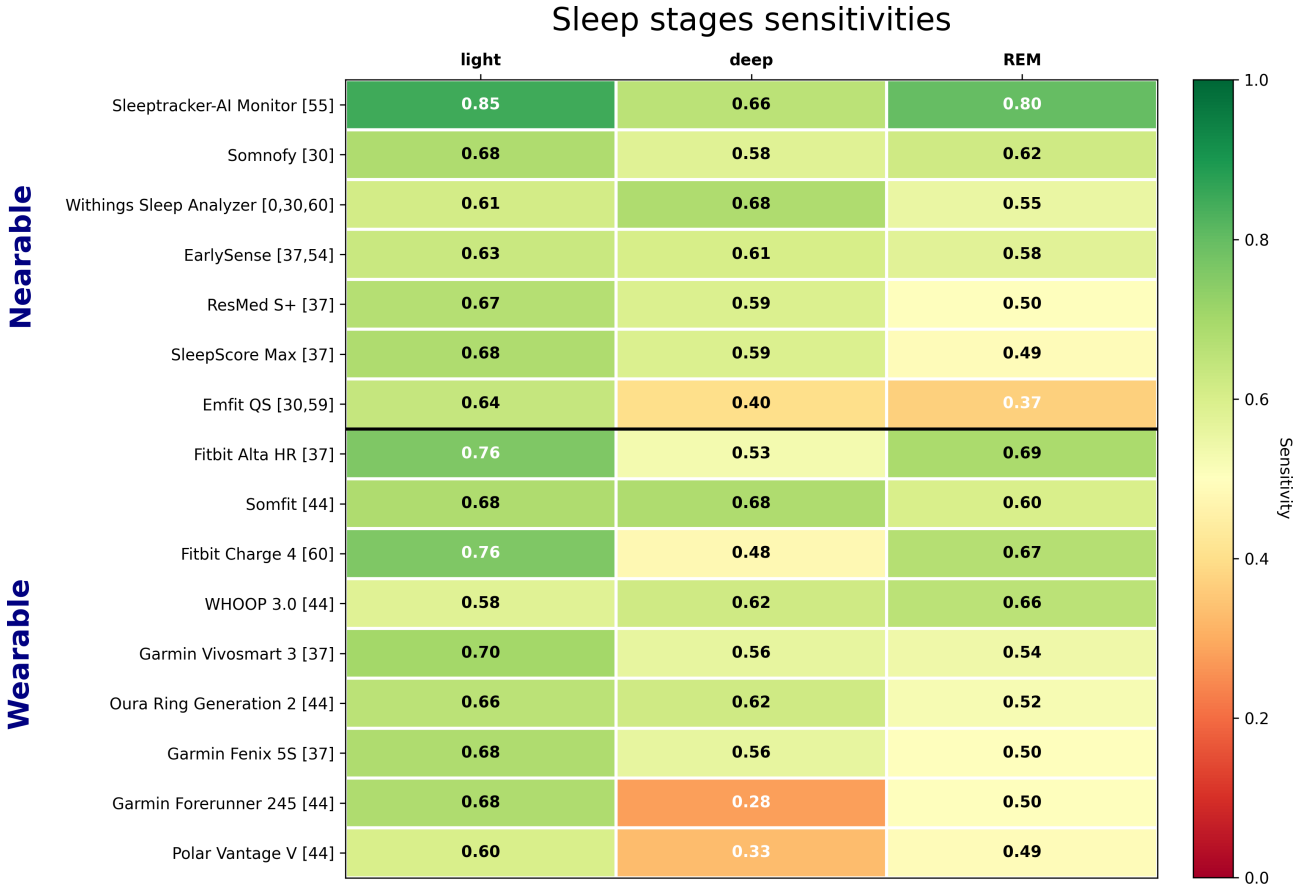
XSL•FO
RenderX

Consequently, our findings provide a more realistic evaluation of the device's performance in everyday conditions.

Sleep-Wake Classification

The choice of a sleep monitoring device requires being informed about the trade-off between sleep and wake identification. This is illustrated in Figure 13. Devices with high sleep sensitivity (≥0.98) exhibit low specificity (<0.30), as observed with the Garmin Forerunner 245, Emfit QS [33], Garmin Vivosmart 3, and Garmin Fenix S5. Conversely, devices achieving higher specificity (≥0.70), such as the EarlySense [54] and WSA, tend to show slightly lower sensitivity (0.90 - 0.95).

Figure 13. Overview of sleep-wake reported sensitivities from varying validation studies. Indication [0] denotes this study. Note: Direct comparison is limited by differences in study protocols and populations [33,37,44,54,60]. The exact data points corresponding to the figure are fully detailed in Multimedia Appendix 3.



As explained above, the proportion of wake stages in the dataset before and after sleep onset can significantly impact the sleep/wake endpoints. These studies vary in the proportions of wake epochs, which refer to the total time spent awake divided by the total recording duration of the entire dataset. Specifically, these proportions ranged from 8% to 14% in [37], 15% in [54], ranged from 20% to 33% in [44], and from 34% to 42% in [33], compared to 30% in our dataset. This information was unfortunately not available for most of the studies evaluating nearable devices [55-60]. Lower proportions of wake data can inflate overall accuracies and kappas if sleep epoch classification dominates, as noted in [61]. In datasets with a low proportion of wake epochs, overall accuracy and kappa can be misleadingly high due to the dominance of sleep epoch classification, which is better classified than wake epochs as indicated in the previous paragraph.

Sleep Stages Classification

The trade-off observed in sleep-wake classification is even more pronounced in sleep stage analysis, where no single device consistently outperforms the others across all stages (Figure 14). The range of sensitivities is particularly large for REM, from 0.37 to 0.80, and quite large for deep sleep (0.28 to 0.68), even after excluding wearables (0.40 to 0.68). The sensitivities for light sleep detection are more homogeneous, with 12 sensitivities between 0.6 and 0.7. The WSA is in the top tier of devices for deep sleep classification, but midrange for light sleep and REM.

XSL•FO
RenderX

Figure 14. Overview of sleep stage sensitivities from varying validation studies. Indication [0] denotes this study. Note: Direct comparison is limited by differences in study protocols and populations [33,37,44,54,55,59,60].

The confusion matrices show that, for all devices, the highest proportion of misclassification for each stage is wrong light sleep detection, which can be explained by the inherent difficulty in distinguishing light from the other sleep stages by human experts, as shown in the Results section.

Device Comparison Conclusion

This analysis highlights the necessity of considering a comprehensive set of metrics to accurately evaluate the capabilities of each device. Relying on isolated overall metrics such as accuracy or kappa is insufficient to provide a fair assessment [62,63]. Every device exhibits relative strengths and weaknesses, and no single device clearly outperforms the others across all tasks. The WSA specifically demonstrates robust performance in sleep-wake distinction, while the precise identification of individual sleep stages remains a more challenging task.

Methodological Aspects and Strengths of the Study

The rapid adoption of new sleep technologies in consumer and clinical settings demands rigorous performance evaluation [64]. To improve the reliability and comparability of sleep research, we describe our methodology in detail and with transparency, an approach that is supported by recent guidelines advocating for uniform analysis pipelines [41,42,44]. Our study was designed to resolve methodological issues frequently found in the literature.

The study's strength lies first in its diverse sample of over 100 participants, who are for the most part healthy and with diverse demographic characteristics. Additionally, the inclusion of relevant factors that may negatively impact the device's performance, like the presence of a bed partner and variations in mattress type and thickness, further enriches the dataset, allowing for a comprehensive evaluation of the device's robustness across different real-life conditions in a healthy population. This allowed us to conduct meaningful subgroup analyses.

A second strength of the study is the method of PSG analysis. Unlike [44,55-58], which opted for a single reviewer, or two reviewers without consensus as in [37], our study is aligned with [33,38] by implementing a double review process with adjudication by a third reviewer in case of disagreement. This consensus methodology is preferable since it enhances the reliability of the sleep stage classification. In particular, we have shown that reviewers often err by misclassifying light sleep stages, a finding consistent with previous research reporting that the interrater reliabilities for light and deep stages were moderate [61]. A reliable assessment of devices' performance in sleep stage classification therefore requires a strong methodology to establish the ground truth.

Third, with a view to limit the participants' discomfort, we chose to perform PSG at home with a limited number of sensors, without the nasal cannula and oximeter. This setup reduces the sleep disturbances typically associated with lab-based PSG, allowing for a more natural assessment of sleep patterns. This limited set of sensors is sufficient for the evaluation of TST and sleep stage classification, with the trade-off that sleep onset,

XSL•FO
RenderX

time in bed, and wakefulness after sleep onset cannot be assessed. Yet, significant sleep disturbances were reported by the participant during the PSG test, underscoring the challenges of completely undisturbed monitoring even in home environments. Despite this, the study offers a realistic evaluation of the WSA's capabilities under typical sleeping conditions.

Fourth, we aimed to give a comprehensive report of the device's performance. Collecting epoch-by-epoch data enables a granular examination of sleep patterns, the consistency of measurement errors over time, and thus enables an accurate assessment of the reliability and utility of sleep monitoring devices in real-world settings. We emphasized the need for such comprehensive reporting and the elements of the protocol that may bias the performance estimates. Thus, transparency requires a presentation of the results including all the performance endpoints, each presenting a different facet of the device's performance [41-43].

In conclusion, given these methodological strengths, our study provides valuable insights into the WSA sleep stage algorithm's performance in real-world settings.

Limitations and Future Work

Despite our efforts for a solid methodology, the study faced several challenges.

Challenges in Defining Bedtime and Wake Time in Sleep Studies

A first challenge is created by the lack of a standardized definition of the start time and end time of a sleep study. As per AASM guidelines [50], bedtime and wake time are defined as the "lights-off" and "lights-on," respectively. This is not adapted to studies in real-world settings, where participants often go to bed and engage in activities before attempting to fall asleep. In everyday life, individuals may not turn off the lights immediately upon going to bed, nor do they always intend to sleep right away. Similarly, in the morning, people may not turn on the lights immediately upon awakening, and their actual wake time may not coincide with the "lights-on" reference. This discrepancy is compounded by the lack of a position sensor, which makes it difficult to accurately determine when a person intends to sleep. In other studies [37], start and end times of sleep are determined by the participants themselves, as suggested in standard sleep diaries [65], but the precision of this method is poor.

This lack of standardization is detrimental to the assessment of nearable and wearable devices intended to be used in home settings. Errors in sleep estimation, where wakefulness is mistakenly classified as sleep, are more frequent at the beginning and end of the night. The reason is that many devices, including the WSA, rely heavily on movement detection to distinguish wake from sleep. Thus, wake periods when the participant is immobile and calm in bed, such as when reading or scrolling with a low heart rate, are frequently mistaken as sleep by the device.

Additionally, the practice of activating the PSG immediately before sleep and deactivating it early prevents the gathering of comprehensive data on a participant's sleep habits. This includes behaviors such as spending extended periods in bed without the intention to sleep. To address this limitation, future studies could extend the duration of PSG recordings to capture activities that occur between the time a person gets into bed and falls asleep, as well as between waking and getting out of bed. This approach would provide a more complete picture of sleep behaviors and enable a thorough evaluation of sleep stage classification algorithms in real-world settings.

Challenges in Data Collection From a Nearable

A second challenge in studies with connected devices is data loss. Our study is no exception since nearly 19% of the data were lost, primarily due to the wireless transfer by WSA of a large amount of raw sensor data (250 samples per second). Note that this high rate is not representative of the intended use of the device, which, in its commercial version, only transfers processed data at a low frequency. To mitigate the risk of data loss, Wi-Fi routers paired with the WSA were installed at the participant's home. The routers experienced occasional connectivity problems. Data loss was further exacerbated by issues such as accidental unplugging of the device and improper reconnection without calibration. These technical challenges underscore the difficulties of gathering high-quality, high-frequency data in uncontrolled settings.

Another factor impacted the accuracy of sleep stage classification; despite receiving instructions from a technician, participants with large beds did not always sleep above the sensor but on the other side of the bed. In such cases, the WSA is not operated optimally, which may have restricted its performance.

Future Work

To validate the utility of longitudinal passive data collection, it is essential to demonstrate that errors in sleep quality measures are consistent over time for a given user.

In addition, our study population only includes healthy participants. There is no data on the performance of the device in special populations that might benefit the most from a longitudinal follow-up.

Looking ahead, the contactless devices hold significant potential for a wide range of research and clinical applications [14,64,66-70]. Their capability to monitor sleep in natural environments [68] underscores their versatility and relevance in advancing our understanding of sleep health and its implications.

Conclusions

In this study, we aimed to (1) assess the performance of a contactless device for sleep stage identification against the gold standard PSG, (2) benchmark it against other comparable devices, and (3) better understand the limitations of such devices. Our paper contributes to those, while also laying out important methodological issues.

This study contributes to the growing body of evidence supporting the utility of nearables for longitudinal sleep monitoring. The WSA's contactless, undermattress design facilitates unobtrusive data collection in free-living conditions

XSL•FO
RenderX

and demonstrates sleep-wake detection performance comparable to established consumer devices. While precise sleep stage classification remains a technical challenge, our results highlight the importance of testing on large, diverse, challenging datasets to capture real-world variability. This research underscores the need for standardized performance assessment methodologies to enable reliable comparisons across devices and studies, offering insights for future device design and guidance for utilization, advancing the goal of improved sleep monitoring for the general population [71].

Acknowledgments

We would like to acknowledge Paul Edouard and Sébastien Ducrot, both employees of Withings, for their crucial support and technical expertise in the offline run of the algorithm. We are also grateful to two anonymous reviewers and the journal editor for their suggestions and comments, which contributed to improving this manuscript. We declare the use of generative AI in the writing process; according to the GAIDeT taxonomy (2025), proofreading was delegated to the Gemini Pro 2.5 tool under full human supervision.

Funding

This study received funding from Withings.

Data Availability

The dataset analyzed during this study is not publicly available due to concerns for privacy, ethical, and legal reasons, but queries for data access can be directed to the corresponding author at privacy@withings.com.

Abstract

Background: Instructional documents are crucial for safely operating medical devices. However, few studies have explicitly considered designing instructions for health care professionals (HCPs). Psychological research suggests that advanced learners with prior expertise in a domain are better able to generalize their existing knowledge to new areas compared to those with little prior expertise, resulting in different informational needs.

Objective: We aimed to understand how HCPs learn from and use their existing expertise when interacting with instructions for use to familiarize themselves with a novel medical device. This would allow us to explore how instructional documents could be designed to better accommodate HCPs' needs as experienced learners with prior knowledge in the domain.

Methods: We conducted our studies centered around a novel liver support system, the HepatiCan and its current instructions for use. We conducted 3 user studies, first using semistructured interviews and think-aloud protocols to understand HCPs' expectations for the process of setting up the HepatiCan and how training for the use of medical devices typically takes place. We followed this up with an observational study to understand HCPs' actual experience in practice and corresponding instructional design needs.

Results: Our results showed that HCPs' prior expertise allowed them to prioritize key areas for attention, but also led them to make assumptions and potentially skim and miss important information. Visual representations and communication were preferred, as well as designs that supported memorization, as this was an essential function of using instruction manuals.

Conclusions: Developers must be aware of what is considered "common" and potentially ignored knowledge within a specific domain in order to clearly emphasize important, safety-relevant information. We also recommend developers focus on using images with attached appendices where possible. This allows advanced users to process information more efficiently without compromising the needs of less familiar users for greater instructional details.

Introduction

Medical devices play a crucial role in the care and treatment of patients. Ensuring the safety and usability of such devices is therefore essential [1], particularly in mitigating human errors. Human errors account for nearly 70% of all errors leading to preventable adverse medical events [2], such as patient injury or death [3].

One of the primary contributors to medical error is a lack of consideration for human factors and, consequently, poor design that fails to account for user needs [4-6]. Human factors, as defined by the Association for the Advancement of Medical Instrumentation, is "the application of knowledge about human capabilities (physical, sensory, emotional, and intellectual) and limitations, to the design and development of tools, devices, systems, environments, and organizations" [7]. Developing a strong knowledge of users' needs and capabilities is therefore essential to appropriately cater for and support users in engaging in safe practices, particularly in the context of a medical device.

XSL•FO
RenderX

A key resource for ensuring the usability of a medical device is its accompanying documentation and manuals, that is, instructions for use (IFU). In this paper, the term IFU is broadly used to encompass any document containing information or guidelines that could inform users about how a task or procedure should be executed under normal conditions [8]. This includes standard operating procedures and commercial user manuals. As the functionality of novel medical technologies increases, however, so too does the complexity of user operation and the likelihood of errors during initial setup [9]. IFUs therefore serve as an essential tool for supporting user learning with novel medical devices and should be subject to the same level of rigor and assessment for usability, user comprehension, and learning, as any other component of the system [10]. Indeed, there have been recent demands for greater transparency and clarification for how safety standards and evaluations should be implemented during the development of a novel medical device [11,12]. Our study adds to the growing collection of studies that address these calls to present detailed usability evaluations across a range of medical devices [5,13-16].

IFUs typically communicate information via both text-based and visual representations. Within the field of instructional design, cognitive load theory is commonly applied to help designers explain which types of media and forms of communication may be most beneficial for different types of users in information comprehension and processing [17-19]. Cognitive load theory suggests that individuals' internal cognitive resources, such as working memory, are finite, and tasks such as learning and processing information place demands, or "cognitive loads," on these resources [18,20]. Higher cognitive loads can limit an individual's capacity to attend to important information and are thus more likely to result in lower task performance [21].

The extent to which cognitive load is induced in an individual depends on external factors, such as the design of interaction materials, as well as individual factors, such as an individual's prior knowledge. This is why it is important to study health care professionals (HCPs) and evaluate their needs in instructional design as distinct from that of layman groups or patients, as HCPs differ significantly in prior domain experience and related medical device knowledge. Previous research suggests that individuals with prior domain experience perform better using procedural, action-oriented, and concise instructions (eg, image only), but worse when using highly detailed, explanatory instructions that are more useful for novices. This phenomenon is known as the "expertise reversal" effect [18,22], and has been observed across many domains and task types ranging from literary interpretation to accounting [18,23,24]. In addition, experienced individuals can encounter negative knowledge transfer [25]. This means they may struggle to disengage from well-established routines and adapt to new knowledge, such as differences in interface designs between similar products [26,27]. Previous research has considered the role of prior knowledge in patients' use of medical devices [28] and the impact of cognitive workload on HCPs' preferences for receiving patient feedback [29]. However, there remains a lack of insight into how HCPs themselves navigate unfamiliar medical devices, especially how their extensive training and prior expertise shape their instructional design preferences.

Our study aims to address the issue of evaluating instructional design principles for HCPs [4,30-32]. First, medical device developers often encounter challenges in accessing the perspectives of HCPs during development [33], so it is important for research to provide a clear and practical description of HCPs' needs. Second, despite the importance of designing devices suited to user needs, there is little advice currently available in regulatory guidelines about specific considerations that are relevant for different user groups (eg, designing for patients or nonmedical staff, compared to trained HCPs) [7,8]. While existing literature has highlighted the importance of supporting HCPs' training and understanding the challenges these individuals face when navigating complex technologies [34,35], there has been little consideration for the specific characteristics of HCPs which differentiate their needs from other user groups in human factors.

The goal of our research is therefore to investigate how challenges of learning and knowledge transfer may reflect in HCPs' behaviors in an applied learning setting, and to consider the types of designs which may help to mitigate these issues based on users' feedback and performance (ie, accuracy or errors made) when following instructions. In the context of medical devices, errors or issues in performance could lead to delays in patient treatment or potentially harmful impacts to patients during treatment [9]. Our research aim is therefore to understand how HCPs learn from, and use their existing expertise when interacting with IFUs to familiarize themselves with a novel medical device.

To address this issue, we use a human-centered approach following the guidelines of the International Electrotechnical Commission [8] to conduct a series of usability studies involving interviews, think-aloud protocols, and observations of HCPs interacting with the IFU for a novel medical device known as the HepatiCan. By conducting these studies, we contribute further insight into the information processing needs of HCPs as experienced learners, how such needs manifest in terms of user behaviors, and provide implications for designing instructions for HCPs.

Methods

Case Study: The HepatiCan

HepatiCan is an extracorporeal liver support system that uses cell therapy to treat patients with liver failure. It serves to temporarily replace the functions of the liver, allowing patients' livers to repair and regenerate. HepatiCan consists of 3 circuits of tubing that are used to circulate blood for treatment. As part of this assembly, sections of circuitry tubing must be connected together using Luer connections and installed into the device's workstation.

HepatiCan served as an ideal case study for our research purposes because it shares many common features with existing extracorporeal medical devices, such as dialysis machines and apheresis machines, so there was room for an expert in extracorporeal treatment to generalize their knowledge in

XSL•FO
RenderX

assembling HepatiCan; and because, as a device still within early developmental stages at the time of the study, there were no existing users whose experience would have otherwise confounded our exploration of "novice" interactions with the IFU. Our paper focuses exclusively on the instructions for assembly for HepatiCan, as this is the first stage of device use before active operation.

Though our focus on the HepatiCan as a case study necessarily means that our sample and corresponding findings are oriented on the experiences of practitioners in extracorporeal treatment, we have striven in this paper to present the needs and patterns that may be applicable to HCPs of varying backgrounds, rather than focusing on specific comments or details which may only be applicable to HepatiCan or the field of extracorporeal treatment.

Study Design

Part of the original study design aimed to evaluate the usability of the HepatiCan, but in this paper, we present only the information related to the current research aims regarding HCPs' prior knowledge and instructional needs. The overall study consisted of 2 separate phases, each designed to address a specific research goal. We applied a qualitative descriptive design to capture users' self-reported experiences in general medical device training as well as their reactions and interactions with the IFU provided in our study, as well as a pragmatic research paradigm to generate actionable insights and recommendations for designers. The first phase consisted of a semistructured interview to understand how HCPs use IFUs in their current workflows and as part of their learning. This helped to contextualize the role of IFUs for HCPs within their wider responsibilities. In the second phase, participants engaged directly with the HepatiCan IFU through a think-aloud and observational study. The think-aloud study had participants read and react to both the IFU document and videos of the IFU procedures carried out by a developer, capturing participants' perceptions of "work-as-imagined" (WAI) based on simply reading the IFU [36,37]. The observational study had participants interact directly with the HepatiCan and attempt assembly themselves while following the IFU. This allowed us to capture participants' real-world experiences of following the IFU, or "work-as-done" (WAD) [36,37]. While the arrangement for participants to read through the IFU before interacting with the HepatiCan mirrored how training interventions take place for practitioners, as reflected in the interviews, the goal of this study was not to examine how practitioners respond to training for a novel medical device, but instead the challenges they face in interpreting the IFU specifically. As such, study procedures were designed to place exclusive focus on how participants react to and interact with the IFU.

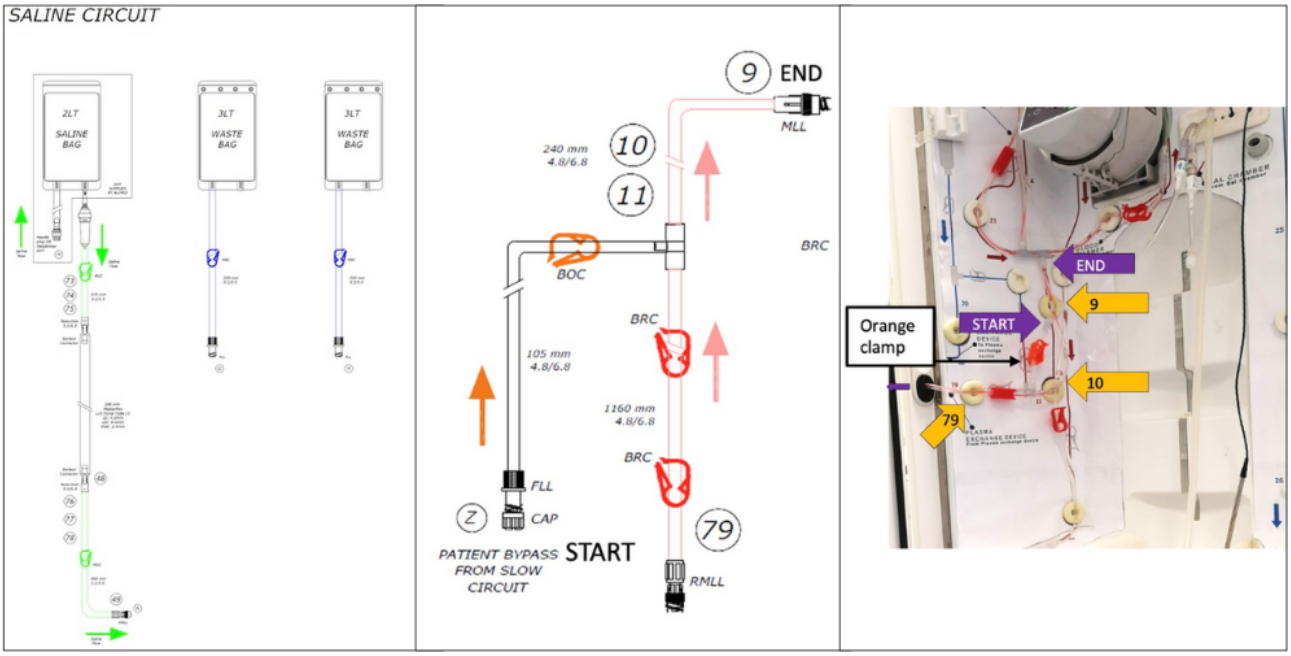
Participants

Participants were recruited to this study via invitation from the HepatiCan project leader, as they knew relevant experts with transferable knowledge. Participants had to fulfill 2 criteria to be considered eligible. First, as we were interested in studying "experienced" learners, it was necessary to recruit individuals with existing expertise in areas that were relevant or highly generalizable to the knowledge required in the assembly of HepatiCan's device components. We therefore looked for participants who had experience in related types of extracorporeal treatment (eg, dialysis), experience or knowledge in hepatology, and/or experience in similar types of extracorporeal systems and medical devices (eg, apheresis machines). This was essential, as HepatiCan is both an extracorporeal device and one that provides hepatological treatments, and thus, in implementation, is intended to be operated by practitioners who work with extracorporeal devices (such as apheresis machines) and those working in hepatological treatments. However, as this is a novel medical device, there are currently no existing user groups. Second, it was essential for us to recruit participants without any prior knowledge or familiarity with the process of assembling the HepatiCan to more accurately replicate the authentic experience of a target user encountering and following the IFU as they would in a real-world context.

In total, 6 participants were invited to take part in the research, though only 3 participants took part in all 3 user studies (Table 1). This limited number was due to the challenges of recruiting participants in the corresponding specialism who had availability during the scheduled timeframe for conducting the study. For the observational study, we required participants to travel to the researcher's location to engage with HepatiCan, which was a unique prototype and could not be readily transported. Participants were compensated for their time and travel expenses.

XSL•FO
RenderX

Table . Participants' backgrounds and participation across all 3 user studies.



Participant ID	Study participation	Background and experience
P1	• Think-aloud • Observation	PhD graduate in cryobiology
P2	• Interview • Think-aloud	Training consultant for apheresis machines
P3	• Interview • Think-aloud • Observation	Researcher and clinical consultant specializing in hepatology and nephrology
P4	• Interview • Think-aloud • Observation	Perfusion specialist and clinical operations manager
P5	• Interview • Think-aloud	Perfusion specialist and clinical research manager
P6	• Observation	Clinical apheresis consultant and researcher

These practical considerations limited the outreach and participant sample of our study, which is a common challenge in health care–centered human factors research. However, our use of qualitative methods ensured that we were able to gather rich information and insights from each participant, and our careful recruitment criteria ensured that our findings reflected the experiences of participants who could be considered knowledgeable learners for the context in question.

Materials

Our study focused on the IFU for the assembly of the HepatiCan, which was used in both the think-aloud and observational study. This document contained a combination of text and labeled images, with instructions divided across the 3 main circuits of the HepatiCan. Three different types of images were used overall—full circuit diagrams (Figure 1A), circuit section diagrams (Figure 1B), and annotated photos (Figure 1C). Full circuit diagrams depicted labeled engineer schematics of the entirety of HepatiCan's tubing and inner circuitry. The circuit section diagrams consisted of segments from the full circuit diagram, but zoomed in to show only the relevant circuit section and were presented at the beginning of the corresponding instructions for assembling a particular section. The circuit section diagrams were accompanied by annotated photos of the particular circuit section when assembled to show how the circuit should appear when correctly installed, initially with unmarked colored arrows to denote positions of components or tubing holders. Photos were also used to supplement text instructions to show a consecutive series of steps within a relevant procedure (eg, to demonstrate how 2 locking Luers should be connected).

Figure 1. Example of a full circuit diagram schematic (left), a circuit section diagram (right), and an annotated photo for a circuit section.

XSL•FO
RenderX

For the think-aloud, participants were additionally shown video clips of a HepatiCan developer conducting the procedures outlined on the IFU. The videos were silent with the text from the IFUs overlayed as subtitles showing one of the developers assembling the corresponding section. Each clip corresponded to one section of the IFU. There were 4 videos in total, each video corresponding to sections of the IFU relating to assembly of 4 distinct sections of the HepatiCan. The total length of the videos was 12 minutes and 18 seconds. Participants viewed around 10 - 30 seconds of the video at a time, representing each step on the IFU.

For the observational study, participants were invited to the laboratory and were asked to assemble the HepatiCan according to the IFU. The materials given to participants included (1) an empty HepatiCan workstation, with the component tubing required for assembly packed in a separate box and labeled as they would be once the device is in clinical use; (2) a printed, color copy of the IFU on single-sided loose pages; and (3) 3 printed and laminated quick reference guides, each on one side of A4, containing the full tubing circuit diagrams for the workstation.

Data Collection

Both the semistructured interview and think-aloud study were conducted in a single session online using Microsoft Teams. During the interview, the first author used an interview guide to discuss participants' main priorities when learning from IFUs, their perceptions of how their prior expertise informs their approach to navigating a novel medical device, and how IFUs are generally used during work or training. These discussions were focused on participants' own experiences and did not involve the HepatiCan or its related documents at this stage. Interviews took around 30 minutes to complete.

Following the interview, participants conducted the think-aloud study. In this study, participants read through the IFU and watched step-by-step video clips of the described assembly process carried out by a HepatiCan developer. Participants verbalized their feedback on the IFU and how well the writing conveyed and aligned with their expectations when watching the video. Feedback on the presentation and layout of the IFU was then implemented following the think-aloud study to improve usability in preparation for the second phase. The think-aloud study took around 1.5 - 2 hours to complete.

The observational study was then conducted 2 to 3 weeks after the think-aloud study. Participants were presented with a physical copy of the IFU and were asked to follow the instructions to assemble the HepatiCan device in person. The study was overseen by the first and second authors; 2 developers, 1 in-person and 1 online, were also present throughout the observation. Participants were asked to follow the IFU as they would naturally and were free to ask questions to one of the developers present if they felt it necessary. The in-person developer was told to answer questions and help if asked by the participants, but otherwise not to explicitly intervene except if there was a risk of serious harm or damage. They were also told to identify instances of errors to the researcher (but not to the participant) so that any mistakes which were not noticed or explicitly addressed by the participant could be identified. This was because direct intervention and corrections from developers may otherwise mask the issues and challenges users experience due to instructions from the IFU. The first author observed and recorded participants' performance in the assembly. Performance was evaluated based on the time taken to complete the assembly procedure, as well as challenges encountered by users, such as errors, hesitation, confusion, and whether they interacted in unexpected ways with the system or required intervention from the developer. The average completion time for the assembly task was around 2 hours across all 4 participants.

Following the observation, the first author conducted a 15-minute follow-up interview exploring (1) overall use experience; (2) preferences and positive interactions with the IFU; (3) challenges and negative interactions with the IFU; (4) use of quick reference materials; (5) addressing key user needs of learnability, ensuring accuracy, and preserving sterility; and (6) suggestions for improvements in the IFU.

Analysis

In the first phase of the study, the interview transcripts were generated automatically from Microsoft Teams recordings and were manually corrected by the first author. The interview transcripts were then analyzed using inductive thematic analysis to ensure that the themes identified were reflective of participants' responses [38]. Descriptive codes were initially generated to provide an overview of the transcript data related to the research aims. These codes were then grouped based on relatedness and summarized by higher-level themes.

For the second phase of the study (ie, the think-aloud and observational studies), a spreadsheet was used with columns to represent each section of the IFU evaluated, and each column represented an individual participant's feedback and queries for each of the respective IFU sections. For the observation, notes were documented and classified using predefined categories to highlight challenges users encountered with using the IFU during assembly. The categories included comments or behaviors related to (1) how participants used and interacted with the IFU; (2) the assembly procedures and how participants conducted each stage of assembly; (3) participants' experience physically interacting with the hardware, that is, tubing or the workstation itself; (4) errors made by participants while conducting the task (defined as any deviations from the IFU procedures and including errors which were later corrected by the user themselves or the developer); (5) any comments verbalized during the task; and (6) questions and clarifications directed to developers during the assembly process. The follow-up interview was recorded using the first author's phone and manually transcribed.

During analysis of the data collected in the second phase, descriptive codes informed by the literature were used with a specific focus on topics relevant to the current research aims. This included (1) comments evaluating information appropriateness and relevance to their specific expertise level; (2) comments assessing the advantages and drawbacks of different types of information and presentation formats (eg, visual and text-based); and (3) observed interaction behaviors with the IFU which correspond either to participants' own descriptions and reported issues with the IFU, or are in line with

XSL•FO
RenderX

previous literature documenting challenges experienced users face with specific types of IFUs [17,22].

Our findings are validated through methodological triangulation [39], as different research methods used to explore the same research aim reveal corresponding evidence to support our conclusions. However, there were also instances where participants' think-aloud reflections and imagined assessment of the IFU differed from their observed behavior and reflections after real-world interactions with the IFU. We report these differences in the "Results" section. In cases of discrepancies, we prioritize recommendations for instructional design based on participants' observed behaviors rather than their initial think-aloud reactions. This is because individuals' ability to successfully carry out the necessary procedures had greater implications for risk assessment and patient safety in practice compared to their self-reported perceptions and preferences to specific aspects of the IFU materials.

Ethical Considerations

The University College London Interaction Centre Research Ethics Committee approved both studies under project number UCLIC/1819/006/BlandfordProgramme-Ethics. The interview and think-aloud activity in Study 1 was conducted and recorded online using Microsoft Teams, which meets the standards of the General Data Protection Regulation and is managed by University College London. Recordings and transcripts were initially stored on OneDrive before being transferred to an encrypted USB drive. All participants were informed of the multistage nature of the study in the information sheet and consent form prior to participation and were given the option to partake in whichever stage they were available for. Participants were paid £35 (US $47.19) for participating in the online study (interview and think-aloud), and £65 (US $87.65) for the in-person session, as well as compensation for travel costs. Transcripts were pseudonymized, and all transcripts and data were stored in an encrypted USB drive.

Results

Overview

In the following section, we summarize and report the main findings related to how HCPs use their existing knowledge when interacting with IFUs, and what their corresponding needs may be. We divide the results into 2 sections. The first section reports findings from the semistructured interview study, providing the background and context for understanding how HCPs use IFUs for medical devices in their typical work context. The second section combines results from the think-aloud study and observation. This highlights the key themes identified in how participants initially reacted to the IFU document, both when reading and when applying the document in practice.

Interview Study

IFUs as Initial Learning Tools to Be Discarded With Expertise

The IFU was an essential part of the users' initial learning process when interacting with a novel medical device. Participants described how IFUs were useful for developing their early conceptual understanding of the device and helping to fill in any gaps in their existing knowledge, such as unfamiliar components within the system. P4 and P5 emphasized that an initial read-through of the IFU was an important part of the process before instructions were implemented and followed in practice.

> *The operator's manual is a fundamental tool because you need to go through the operator's manual before you even start dealing with a new device. [...] Typically when we train on the first time [...] you should have the operator's manual next to you, which you read before, and then you just follow the manual again in practical terms.* [P5]

Three participants mentioned that the main desired outcome of using the IFU was to achieve a point of familiarization where they no longer needed to use the IFU for assembly or operation. Participants emphasized that this level of expertise was achieved either through intentional practice using the IFU or through a natural result of repetitions over the course of engaging in well-established work routines.

> *I have the trainee go through it again and again and again, so that it [...] becomes muscle memory.* [P4]

> *These people are doing the treatments day in, day out. [...] They're doing it frequently, that's the key [to memorisation]. If you only do it twice a year, you forget.* [P3]

Users Generalize Previous Knowledge to Anticipate Potential Problems

As the IFU provides a preview into the medical device system, use of the IFU allows users to efficiently integrate novel information into their existing knowledge about similar types of devices. When asked, all interviewed participants demonstrated extensive expertise and were able to identify several common patterns across extracorporeal systems, including similar components, terminologies, and procedures. These common features allowed participants to identify areas where previous knowledge from one system could be applied to another unfamiliar system with shared features.

> *The knowledge base I gained from [named extracorporeal system] I think is transferable to multiple devices. So the principles are generally the same.* [P4]

Notably, participants' prior experience with similar systems allowed them to anticipate and monitor for commonly occurring problems. This enabled them to formulate generalized assumptions across devices based on shared features and to efficiently prioritize attention toward specific components, assembly procedures, or common errors, even if they have not used a device previously.

> *If it's a peristaltic pump or if it's a centrifugal pump, then you expect different things from it. And I think it's important because you are pre-emptively looking for potential weaknesses or potential sources of error when you encounter the device for the first time.* [P5]

XSL•FO
RenderX

Beyond the problem of patient safety, consolidated knowledge and familiarity when using a new medical device were also essential because participants often had to fend against external stressors in the environment that were likely to otherwise disrupt their performance or concentration. These stressors included issues such as tension, time pressure, and distractions from colleagues and patients, which may lead users to forget key information that may contribute to errors.

The likelihood of distractions, paired with poor or misleading design choices, can therefore mean that users are liable to make mistakes if they are not consolidated enough in their knowledge.

> *You have the pressure of having it ready for the therapy. You have different timings that come into play with transplants.* [P4]

Consolidation of knowledge is important, as decisions made based on the design of the device may be vulnerable to assumptions, and users are therefore liable to make mistakes.

> *So you might think 'OK, [a tubing line] comes from the patient, go to the first point, then the second point, then the third point, fourth point, and then the dialysis [...] but that's not how it works. You actually have to put the line through the blood pump first [...] There is a clue [...] but if somebody's forgotten about that, the line basically looks the same. So it is possible to put it in the wrong way round.* [P3]

Focus on Task Completion May Cause Some Users to Ignore IFUs Completely

Though the utility of the IFU and the information it delivers is widely acknowledged, P2 and P4 both noted, based on their experience observing other HCPs in training, that some users may omit the IFU entirely in favor of working directly on the device. This was largely seen as undesirable, with the use of the IFU generally viewed as an essential tool for reducing the likelihood of user errors.

> *Some people don't like to follow instructions and [...] they'll do it [set up] in an illogical order [...] As long as it's taught properly [...] they generally don't make mistakes.* [P2]

To counter the tendency to omit the IFU at the beginning of training, P4 described how they would develop information delivered in short form to reduce the perceived time and attention required to use the IFU properly, and encourage further engagement from users.

> *What I've noticed when I've given training is people tend not to read operator's manuals and so we created a quick reference guide, so it's an easy to follow, 'do this then do this, then do this.'* [P4]

Summary of Interview Findings

Overall, participants' accounts emphasize that the IFU was an essential tool for initial learning. The IFU supported users in having a clear conceptual understanding of the medical device and to avoid errors particularly during the stages of assembly and operation. However, the role of the IFU was also seen to be supplementary, one that should ultimately be discarded due to convenience and the demands of the work environment. As a result of these external influences, HCPs aimed to consolidate their knowledge enough to be able to perform device operations and assembly correctly without reference to the manual. In practice, a potential issue associated with this is that individuals may ignore the IFU from the outset in order to accelerate this learning process and to try and familiarize themselves directly with the device without supplementary support. This may be because participants ultimately build up a general knowledge of similar devices, which allows them to anticipate problems.

Think-Aloud and Observational Studies

Detailed Information Is Initially Useful, but Counterproductive in Practice

Participants' opinions on the level of detail required for useful instructions shifted from the think-aloud study and the observational study. One recurring example where this debate occurred in the IFU was during a protocol that outlined the assembly process for 2 Luer connections. Luers were connecting points that resembled turn screws, which had to be placed together and turned in a certain direction to ensure that the tubing was securely connected to prevent leakage. Participants described this to be a standard procedure for the assembly of extracorporeal devices, but acknowledged that individuals lacking in expertise may not be familiar with the terms or the process of connecting 2 together. The IFU features an extensive description of how to connect Luers together at each step where Luer connection is required.

During the think-aloud study, participants were generally appreciative of the details and explanatory information incorporated in the Luer protocols, despite their existing familiarity with the steps. P2 and P4 also felt that the details provided were beneficial for minimizing confusion and errors for less experienced individuals than themselves.

> *This is all very obvious for me. I have experience with transducers [...] So it's actually really well-written.[...] For me it's obvious, but for somebody that's not used to pumps or for somebody who's not used to this pump...* [P4]

We did note, however, that P1, who had less practical experience with extracorporeal medical devices, had more difficulty interpreting the text during the think-aloud. He was able to clarify the meaning upon watching the video resources.

> *It's the first part that I'm struggling to visualise what's going on... [...] I don't know. Is it too much writing? [After seeing video] It doesn't seem as complicated as [the text] is making it out to be. I think the fact that it's so wordy so closely might make it seem more complicated than it is.* [P1]

During the observational study, however, feedback on the same Luer connection protocols was mainly negative, with the consensus being that such protocols were unnecessary due to the assumed experience of the target users. P6 found that the articulation of the text often did not clearly correspond to how he would have performed the connection protocol according to his own expertise, and that this would cause him to restart

XSL•FO
RenderX

connection processes in order to check that his interpretations aligned with his experience. When reflecting on the importance of these instructional texts, he stated:

> *A perfusionist [...] does not need to be told 'how to connect a luer lock' [...] Yes, it does need to be there if you pulled somebody off the street and said 'follow this' [...] but you shouldn't need to tell a healthcare professional.* [P6]

Three participants reflected during the observation that the most important information to convey to a reader was the fact that there was only one possible direction that the Luers could turn for a successful connection. In most cases, participants' expertise allowed them to deduce this fact despite this information not being clearly emphasized.

Participants suggested that one way of mitigating this issue was to collate potentially extraneous information to be collected in a separate section of the document (eg, a form of glossary) so that users who wanted the extra information could refer back through the document. Participants emphasized, however, that references to different sections of the document should be clearly identified with page numbers and section numbers so that the information could be easily found.

> *And if you reference other sections of the of the manual [...] I need to know right now where is it? I cannot spend time trying to find it, or going through page by page.* [P5]

HCPs May Prioritize Their Own Routines Over Information in IFUs

During our interviews, participants described how HCPs may neglect to follow IFUs during training, despite the importance of the document. We similarly identified this phenomenon during our own observations. During this part of the study, we found that participants may choose not to follow the IFU to prioritize their own specific routines or familiarity with procedures in related devices.

We noted this again in the Luer connection process, which all participants reported to be familiar with prior to the study. Due to the complexity and the perception that the details of the protocol were unnecessary, we found that users, when performing the outlined Luer connection steps in the IFU, often preferred to carry out the procedures based on their own experience, rather than cross-referencing or double-checking with the IFU. Often, users would prefer to deviate from the IFU or even skip large sections of the IFU. P1, P3, and P6 were often seen carrying out the actions instructed in the IFU (eg, "connect the pressure transducer"), completing the action, only then to find more detailed information about the action that they had just performed and how it should be performed. Often, participants would simply assume that the information in the IFU is redundant or repetitive without using further close scrutiny and skim or even skip sections of the IFU to search for the next step. This process of skimming or skipping occasionally resulted in errors and other relevant steps being skipped as well.

In addition to the above behavior, P3 engaged in additional practices that were not mentioned in the IFU—namely, closing all the clamps on the circuitry tubing once they were assembled. Though this did not have a negative impact on the overall assembly process or the outcome of the assembly or operation of the device, it was nevertheless considered a deviation from the IFU as this was not recommended within the text. When asked about this in the interview, P3 clarified that this practice was encouraged in their specific institution when working with similar extracorporeal devices such as dialysis machines. They carried such practices over and applied them to HepatiCan based on their own judgment of appropriateness and relevance, rather than the information conveyed in the IFU.

> *It's to do with the dialysis equipment, so I'm very scared of air getting into the system. [...] We always make sure that the clamps are closed initially. The manufacturer may not do that, but we would normally clamp everything [...].* [P3]

Images Alone Are Sufficient for Conveying Key Information

Visual representations played a key role in supporting user understanding, both in the think-aloud and in the observation. During the think-aloud, all participants reported using the circuit section diagrams and photos to help them get a sense of the appearance and layout of HepatiCan. However, different images appeared to serve different purposes. Generally, participants described using the circuit section diagrams and their labels for understanding the system flow and identifying specific components and connections. Participants would also refer to the full circuit diagram to understand the relative position of the circuit section they were currently reading about. Photos were frequently used for understanding the relative positions, orientation, state, and appearance of components.

> *I tend to use the line diagrams for referring to the specific component, and the photos I would say are to back up what I'm thinking. So I look at the diagrams – 'that makes sense', and then I look at the photos to see how it's applied.* [P4]

Images played a similar role in practice as participants performed the assembly task in the observational study. Participants were observed frequently setting pages with the relevant section images aside to reference while handling and orienting tubing. Participants often tried to physically manipulate the tubing, using the marked numbers on tubing sections and components and attempting to match them to position numbers marked on the HepatiCan workstation. This behavior aligned with the procedures participants reported mentally visualizing in the assembly procedure in the semistructured interview, when they were just reading the IFU. Participants would frequently switch between reference images and the real-world equipment, such as the tubing circuits and the workstation.

> *Well, I pull the tubing out, identify which end was which end based on the schematic [i.e., circuit section diagram], then I looked at the photo, and identified which end was which end on the Workstation, then I looked at the Workstation, and got started because I knew that was the start point.* [P1]

XSL•FO
RenderX

This study also highlighted the importance of the tubing map on the interior of the HepatiCan workstation wall, which was often used in conjunction with the photos and circuit diagrams. Three participants were also observed relying primarily on the images in the IFU during assembly and only referring to the text to double-check the procedural instructions once components were in place. P6 even suggested creating an instruction manual that was predominantly image-based and using less text, stating that this would improve clarity and reduce the ambiguity of text-based instructions.

> *I found [the wall-map] to actually be quite helpful. But it was obvious, having studied first of all the picture in the [IFU], and then going to it.* [P3]

> *Using that [IFU], I would like to see more detailed pictures and fewer words. It always makes life easier if there are pictures there showing exactly where something should be connected. Then you can remove a lot of the sentences that start creating ambiguity.* [P6]

Indeed, instances where the images of the IFU did not correspond exactly to the state of the HepatiCan device were immediately detected by some participants and led to confusion and hesitation regarding which section they should be working on as they tried to interpret the discrepancy. These events were predominantly caused by instances in the IFU, which used images from a different section of the circuitry to serve as an example to illustrate a general procedure.

Other discrepancies or ambiguities in the images, which sometimes caused participants to ask for clarification, included a lack of scaling of circuit diagrams to real-life tubing, which meant participants sometimes had difficulty identifying corresponding physical features in the real-life tubing and thus the correct orientation of the tubing.

Summary of the Think-Aloud and Observational Studies' Findings

Participants' interactions with the IFU revealed that, while detailed information was considered useful and necessary for novices, it can also be counterproductive for experienced practitioners. Our observations revealed that, for our sample, such detail was often unnecessary, difficult to interpret, and disrupted their workflow in practice. It also led some participants to default to tasks according to their prior routines, sometimes ignoring the IFU altogether. Images, however, consistently played an important role in supporting user interpretation. Most participants responded positively to the use of these images and were even allowed to follow the IFU accurately by depending on images alone. Nevertheless, we also acknowledge that there may be limits to the generalizability of these findings beyond assembly tasks and the context of extracorporeal devices, which we reflect on further in the "Discussion" section below.

Discussion

Principal Findings

In our study, we identify the key role that IFUs play in allowing experienced learners, such as HCPs, to familiarize themselves with the knowledge necessary to operate a complex medical device. We further establish how HCPs use their existing knowledge to prioritize their attention and time for certain tasks or to prepare for specific risks. However, information that is considered too "obvious" or redundant may negatively impact the performance of experienced users by condoning skipping behaviors that can result in users missing relevant information, such as safety information or confusing the sequence of procedures. Both our observations and participants' feedback further suggest that visual instructions alone were largely sufficient for HCPs to identify how to proceed with navigating unfamiliar assembly procedures.

In the following sections, we explore the main design implications for HCP-oriented IFUs, namely, the need for memorization, use of prior knowledge, impact of redundant information, and the benefit of visual information, which we summarize in Table 2. Additionally, we present future directions for research and limitations encountered.

XSL•FO
RenderX

Table . Design implications for HCP[a]-oriented IFUs[b].

Design implication	Summary
Support memorization	• Recognize that users' end goals are to memorize and reduce the need to reference the IFU where possible • Design of medical devices should be intuitive, and allow users to work out procedures with guidance even if IFUs are not available • Using clear labels, color coding, mapping, numbering, etc within the device itself to support user learnability
Identify similarities with other devices and distinguish "novel" information	• Designers should be familiar with common medical devices used by the target group and recognize that HCP users are not learning to use a novel medical device in isolation, but draw from previous knowledge of related devices for common procedures and to anticipate challenges • Instructional design should provide clear cues delineating "common knowledge" and "novel information," so users can more easily identify relevant information
Reduce redundant information	• Avoid redundancies and overrepetition in text and content so users are not encouraged to legitimize behaviors such as skipping, which increases the risk of confusing procedural sequences, delaying learning, and missing relevant information
Recognize the importance of visual information for experienced users	• Provide clear visual aids, diagrams, photos, and pictures of procedure sequences to support understanding, clarity, and ease of referencing during usage • Supports user goals to minimize reliance on IFUs by reducing the need for slower, text-based information processing for HCPs

[a]HCP: health care professional.

[b]IFU: instruction for use.

Support Memorization

We found that participants relied on instruction documents predominantly for memorizing procedures and for engaging in deliberate practice that was key for developing both their skills and knowledge. One of the benefits of memorization may be linked to speed and convenience, which is often important for HCPs, as they must contend with a variety of competing tasks in their work [40]. Indeed, checking reference materials can slow down performance. In the observational study, participants were often observed actively attempting to minimize interactions with the IFU, with behaviors such as relying only or predominantly on images rather than reading the text; attempting to work out their next steps based on their prior knowledge, intuition, or on the tubing map in the workstation interior; and skipping quickly through steps without referring to other sections in the IFU even when instructed to do so in the text. These findings indicate that, where possible, both the system and instructional designs should prioritize learnability, notably memorization.

Our findings further highlight the need for device designs to be as intuitive as possible, in order to reduce cognitive load and the need for memorization in the first place. Participants' positive feedback to the system design of HepatiCan demonstrates potentially useful strategies—for example, clear color coding and number coding, along with a wall map of the circuitry layout—which can minimize the need for user learning. Many participants in the observation were able to simply match up components to the correct location during assembly without directly referring to the IFU, which meant they were able to quickly assemble the device. This can increase the likelihood with which individuals carry out correct procedures in cases where they may fail to recall the relevant knowledge.

Identify Similarities With Other Devices and Distinguish "Novel" Information

Findings from the semistructured interview study suggest that participants were able to apply their existing knowledge across different extracorporeal systems to assist with prioritizing and anticipating potential issues. This is in line with cognitive load theory, outlined above, which suggests that experienced individuals have well-established cognitive processes that can facilitate the processing, memorization, and learning of information more quickly if it relates to the experienced domain, even when the information was originally new or previously unknown to the user [19].

Participants were able to refer to an extensive knowledge base of common patterns across the different medical devices they worked with, including technical knowledge of system components and procedures. This knowledge allowed them to anticipate potential problems and minimize risk by being selective about where and how they directed their attention. In the observational study, participants were also able to use their existing knowledge of Luer connections to deduce the correct procedures without reading the protocol and provided advice on the information that would be most relevant for a user to know. Previous research on the behaviors of expert individuals found that they were also able to fixate more quickly on

XSL•FO
RenderX

task-relevant information because they were more quickly able to discern where they should allocate their attention compared to novices [41-43]. The results from our project consolidate these findings and identify how selective attention strategies translate in real-world contexts to support expert users when learning new domain-related information.

It would therefore be beneficial for developers of complex medical systems to be aware of what components are considered "standard" or "common knowledge" within their field, and what components may be completely novel to users and would require extra guidance. Developers could then present all technical components of a medical system and group them according to what is standard and what is novel. This could not only help users understand how the system operates overall [44], but also allow experienced users to quickly identify the information that is relevant to them.

Reduce Redundant Information

In line with the predictions of the "expertise reversal effect" [24], we observed that more detailed information impeded, rather than supported, performance when users were already familiar with the domain. A key example of this was the repetition of descriptions for recurring protocols, such as Luer connections, which, despite positive feedback during the think-aloud study, were noted to be cumbersome to read and interpret in practice. During feedback in the think-aloud, participants indicated an appreciation for details, but in practice, they were observed engaging in undesirable behaviors such as skimming or even skipping steps in the IFU entirely. In the case of our particular assembly task, as we outline in the "Limitations" section, the consequences of skipping the Luer protocol information were not severe, and errors were usually easily identifiable and recoverable. However, it does highlight the differences between WAI and WAD and provides key insights into some of the conditions that may result in undesirable deviations from WAI.

Importantly, these differences emphasize that it is important for instructional designers not to assume practitioner engagement with IFU. Though in our case, the repetition of the Luer protocol information meant participants were justified in skipping over this information, what was undesirable was the fact that this, in cases, led to users accidentally skipping over genuinely novel or unfamiliar information. Indeed, experts who lapse into automatic or routine behaviors are more vulnerable to errors [26,27,45], and so it is important that designers are thoughtful and careful about repeating information that may appear to legitimize skipping behaviors in practitioners. It should also be acknowledged that participants themselves still indicated an appreciation for extra details and the need to include them to support less experienced individuals. Overall, there were 3 main situations where participants clearly saw the need for additional information (1) to highlight exceptions to the rule, (2) to identify crucial areas for attention, and (3) to inform and clarify genuinely unfamiliar or novel procedures.

Appropriate information delivery in IFUs must therefore strike a balance between providing information that is relevant to users, without giving so much detail that it disrupts comprehension. One way to achieve this balance may be, as some participants suggested in the interview, to provide references that tell users where to find additional information, if deemed necessary. References could either redirect users to previous pages or lead them to a specific glossary or appendix for relevant information. The advantage of this approach is that it can reduce the cognitive load of experienced users, allowing them to focus on information more directly related to their specific task needs, without running the risk of assuming user expertise by excluding information that may be beneficial for less experienced users.

Recognize the Importance of Visual Information for Experienced Users

Visual information was identified as critical for supporting HCPs to complete tasks. This was made explicit during the in-person studies, with some participants completing the assembly tasks by relying predominantly on images. This supports the findings of Kalyuga et al [17], who ran a study that demonstrated how experts could achieve a similar level of performance using only images, compared to novices using both image and text. This finding suggests that not all information, and certainly not all textual information, is required in IFUs for experienced users such as HCPs to achieve adequate performance and to feel confident about completing a task. This further concurs with the existing literature on IFUs for medical devices, highlighting the effectiveness of visual aids for comprehension [46,47].

However, we acknowledge that in many instances, reliance on visual materials alone can be limited beyond assembly tasks, and a degree of reliance on text-based or alternative media of instructional materials is needed to ensure clarity, especially when communicating the rationale behind different procedures the user may be unfamiliar with. Nevertheless, even in text-based materials, we suggest that visual cues in formatting, such as the use of colors, bolding, or formatting (eg, via bullet points for emphasis), could still be important in supporting experienced users to quickly identify relevant information.

One interesting observation within our study was that participants appeared to prefer images that corresponded more closely to the real-life context of the workstation. Abstract representations, such as the circuit section diagrams, were also useful for understanding the orientation and features of a specific tubing section, although participants ultimately preferred to use photos and the wall map to complete the final assembly. This may be because it was easier for participants to "translate" the positions and features in the photos and wall map to their assembly context, meaning less effort was required for interpretation [48].

Limitations

We identify 3 key limitations of this study. The first is the relatively limited number of participants recruited, which impacts the representativeness of the sample and the extent to which our findings may be generalized to other practitioners in the field. This was predominantly due to difficulties in accessing the relevant target end users, a prevalent issue for clinical research with medical practitioners [49]. We navigate this by using a variety of in-depth self-report measures and an

XSL•FO
RenderX

observational study to collect rich, detailed data to inform our findings.

Another issue as a result of the small sample was that 3 out of the 4 participants studied in the observation took part in the think-aloud study 3 weeks prior as well. Thus, by the time of the observation, there may be some degree of familiarity and anticipation of the procedures with the HepatiCan and the IFU, which may affect how participants interact with the device. However, we argue that as there were at least 2 to 3 weeks between the think-aloud and observation, and no participant had seen the IFU prior to the think-aloud, it was unlikely that any of the participants had become sufficiently familiar with the IFU or the procedures for assembling the HepatiCan to have a significant influence on their assembly performance. Nevertheless, a possible avenue for future work could be to more explicitly explore and manipulate features of the IFU on 2 different groups of naïve users, and to compare performance and feedback within each group in order to establish a causal relationship between designs and desired outcomes.

Finally, we recognize that our recommendations for the contents of IFU design do not consider how external factors such as regulations, legal considerations, and risk management may also impact IFU content, as this can differ widely across medical devices, countries, and institutions. Nevertheless, the findings of our study and recommendations highlight the conditions needed for an "ideal" IFU design where the goal is to optimize learning, efficiency in performance, and minimize the effects of negative knowledge transfer for HCPs. Instructional designers and developers should therefore apply individual discretion and evaluation of their own contexts when considering how to balance these recommendations with other legal and regulatory requirements for IFUs.

Future Work

Previous works that have explored user needs for instructional designs (eg, [46,50]) typically explore user performance for smaller-scale medical devices, such as asthma inhalers, or nonmedical contexts. Our study examines user responses to instructional designs for a much more time-consuming and complex medical device assembly task. However, we recognize that there may be limitations in the generalizability of our conclusions to other types of device operation tasks. For example, from a procedural perspective, the assembly of the circuits within the medical device involved many repetitions of similar, simple-to-execute behaviors (ie, connecting tubing through Luers and attaching the tubing to the device), which may explain why users skipped through materials or did not feel the need to pay close attention to the IFU, as mistakes made during these procedures were often easy to notice, address, and were relatively inconsequential at this phase of operation.

Future works could therefore focus more on exploring the issue of attention for HCPs' use of instructions, for example, by testing whether HCPs are more likely to pay close attention to tasks where execution is more complex, and/or where there are greater consequences for patient safety and error recovery, even if the information is already familiar to them. One example of a potentially relevant procedure to study this is device priming, which involves running saline solution through a device in preparation for operation. Priming is a complex task, requiring not only knowledge of the placement and positions of key components (eg, blood warmer and filters), but also domain knowledge regarding the procedures and purpose of priming. This includes knowledge about best practices, monitoring of the priming process, awareness of the status of different components and measures such as pump speed, and the ability to intervene and troubleshoot problems. In such cases, the increase in task complexity and need for monitoring and troubleshooting may mean HCPs are more likely to remain engaged with the IFU. Future work could therefore use the approaches outlined in these studies to explore whether task complexity and higher stakes improve user attention and adherence to the materials.

In addition, we suggest that a focus on providing users with visual cues in instructional design, both for the instructions themselves and for the purpose of locating important information, can be useful. For example, in cases where recommendations in the IFU may differ from participants' own experiences and practices, experienced users may benefit from clearly visually outlined, emphasized, and easy-to-scan bullet points, colors, and presentations explaining developers' justifications for their recommendations, so users could quickly locate and compare practices and motivations underlying different practices. However, further research could explore whether such cues are more appropriate or useful for different types of information and task needs. If different types of information could be identified in order of importance and relevance for users, then they could be explicitly identified and extracted during the design of IFUs.

Another potential area for exploration is to consider how the effects of prior expertise may result in challenges or issues over the course of long-term learning and training. Our user studies provide only a cross-sectional examination of user interactions with the IFU in the early stages of learning, but longitudinal methods using quantitative metrics of performance may be able to provide further insights and comparisons between experienced and nonexperienced users in the formation of specific habits, changes in mental workload, and changes in performance over the course of learning [51]. In the case of the HepatiCan, a direct comparison between HCPs and patient users was not feasible, as the device was intended solely for clinical use. However, we believe this line of research can be particularly fruitful in relation to medical devices designed for both clinical and patient users [13], so that future developers may be better able to clarify the differences in instructional needs for both user groups.

Conclusions

This paper offers important insights into the little-researched field of instructional design for HCPs. Using a combination of interviews and observational methods, we identified that users prioritized memorization and efficiency in task completion. We further identified evidence that the "expertise reversal effect" applies to HCPs in the context of IFU use, and that highly detailed explanations and instructions regarding information already known to the individual can prompt undesirable behaviors such as skimming or skipping. We suggest that developers, in designing IFUs, should focus on identifying

XSL•FO
RenderX

common knowledge constructs and terms within a target user base, so that appropriate emphasis can be placed on information more directly relevant to user needs. We further recommend that developers should emphasize conveying information through visual media such as images and diagrams, which not only communicate key positional information but are also succinct and quick for users to process. Through these findings, we aim to provide guidance for developing medical device instructions that are more intuitive, easy to learn, and easy to apply, to support HCPs better in performing their roles.

Acknowledgments

We would like to acknowledge the support of the research team that developed HepatiCan and the participants in this study.

Abstract

Background: Pulse palpation is essential for accurate traditional Chinese medicine diagnosis. However, this tactile-sensory-dependent technique is not feasible in teleconference, leaving traditional Chinese medicine underserved by conventional tele-practice frameworks. To address this, we developed an Assistive Pulse Data Collection (APDC; Logistics and Supply Chain MultiTech R&D Centre) device.

Objective: This study aimed to evaluate feasibility and to preliminarily examine the Chinese medicine practitioners (CMPs) agreement on real-person pulses and machine-generated pulses and collect users' feedback.

Methods: Following World Health Organization guidelines for piloting new medical technologies, a 2-phase, dual-method evaluation was conducted. In the feasibility phase, 10 participants' pulses were recorded using the APDC device. Overall, 5 CMPs evaluated the participants' and machine-generated pulses using a 5-point Likert scale (1="Strongly Disagree" to 5="Strongly Agree"). In the pilot phase, 10 CMPs assessed pulses from 42 participants and refined the regenerated outputs for comparison. Quantitative and qualitative feedback from CMPs and participants was collected.

Results: CMPs evaluated machine-regenerated pulses across 4 parameters: frequency (mean agreement score 4.1, SD 0.6), rhythm (mean 3.8, SD 0.6), width (mean 2.7, SD 0.9), and force (mean 2.4, SD 1), indicating moderate-to-high agreement for frequency or rhythm but lower consensus for width and force. Following device refinements (eg, adjustable armrest, pressure calibration, and pulse algorithms), the pilot phase CMPs' agreement improved for frequency (mean 4.3, SD 0.7) and rhythm (mean 4, SD 0.8), while width (mean 3, SD 0.9) and force (mean 2.8, SD 0.9) remained suboptimal. CMPs reported enhanced clarity (mean 4.3, SD 1) but persistent inefficiency (mean 2.5, SD 0.5) and neutral satisfaction (mean 2.6, SD 0.5). Participants maintained favorable ratings for comfort (mean 4, SD 0.7), easy to use (mean 3.9, SD 0.8), and high satisfaction (mean 4, SD 0.7).

Conclusions: The APDC device is feasible and enables CMPs to take remote pulse feature assessment, but further optimization of pulse force and width is warranted.

Trial Registration: ClinicalTrials.gov NCT06974227; https://clinicaltrials.gov/study/NCT06974227

KEYWORDS

traditional Chinese medicine; tele-practice; pulse sensing; pulse regeneration; wireless network

Introduction

The COVID-19 pandemic has profoundly disrupted global health care systems, compelling a rapid shift toward tele-practice to mitigate barriers to in-person care [1,2]. While virtual consultations have proven effective for many medical disciplines, their application faces significant challenges in practices requiring tactile diagnostic methods, such as traditional Chinese medicine (TCM) [3]. A major barrier to tele-practice in TCM was the inability to conduct physical examinations, particularly pulse examinations on patients [4]. In TCM, pulse palpation is a diagnostic cornerstone where practitioners assess

XSL•FO
RenderX

the depth, rhythm, and waveform of the radial artery to identify pathological patterns [5] and treatment formulation [6-8], which is irreplaceable for accurate TCM pattern diagnosis [9]. This tactile-sensory–dependent technique is not feasible in teleconference, leaving TCM underserved by conventional tele-practice frameworks. To bridge this gap, innovative solutions are urgently needed to replicate tactile diagnostic interactions remotely. Emerging research proposes robotic systems capable of capturing, quantifying, and recreating pulse waveforms through haptic interfaces, thereby enabling a remote pulse diagnosis [9]. Such technology could not only address pandemic-induced limitations but also expand access to TCM care in underserved regions, underscoring its transformative potential for both tele-practice and traditional practice.

Various sensor technologies have been used for the noninvasive monitoring of radial artery pulses. Currently, the main types of pulse sensors include pressure sensors, photoelectric sensors, and ultrasonic Doppler sensors. Each type has its distinct mechanisms and characteristics. Pressure sensors directly measure the radial artery pulse using piezoelectric, piezoresistive, or piezocapacitive sensors: piezoelectric sensors offer high repeatability and heat resistance but cannot detect static pressure [10-12]; piezoresistive sensors, known for high sensitivity and mature technology, are the most widely used [13,14]; piezocapacitive sensors provide accurate dynamic measurements but exhibit nonlinear characteristics [15,16]. In contrast, photoelectric sensors detect variations in light reflected from blood vessels, converting them into electrical signals [17,18]. While they are less affected by interference, they require a radiation source that complicates the circuitry. In contrast, ultrasonic Doppler sensors analyze reflected ultrasound waves to derive pulse signals from changes in blood flow speed and vessel volume, offering rich data but at a higher cost than the other types [19,20]. All 3 devices primarily focus on detecting and digitizing pulse data. However, in clinical practice, these digitized pulse readings are not easily interpretable by Chinese medicine practitioners (CMPs). Therefore, a device that can convert the collected pulse data back into a pulse format resembling human pulse features that is suitable for CMPs' assessment is critically important for clinical practice.

To fill this critical gap in TCM tele-practice, we developed an Assistive Pulse Data Collection (APDC) device (Logistics and Supply Chain MultiTech R&D Centre, Hong Kong SAR). The APDC device integrates a high-fidelity pulse sensor to capture radial artery waveforms, digitizes key pulse features (eg, rhythm, frequency, and amplitude), and transmits data wirelessly to a robotic regeneration interface. Unlike conventional telemedicine platforms that are limited to audiovisual communication, this system enables TCM practitioners to remotely palpate and interpret pulse waveforms through haptic feedback, thereby replicating the tactile dimension essential for accurate pattern diagnosis. By bridging the sensory disconnect inherent in virtual consultations, the APDC device has the potential to enhance diagnostic precision and expand access to TCM care in remote areas and pandemic-restricted settings.

Validating such a device is imperative to ensure its accuracy, reliability, and safety for clinical use. It is essential to confirm that the device can accurately capture and reproduce the pulse features, as any discrepancies could lead to misdiagnosis and inappropriate treatment. We, therefore, conduct this feasibility and pilot study to evaluate the feasibility and to preliminarily examine the CMPs' agreement on real-person pulses and machine-generated pulses, and to collect CMPs' and participants' feedback on the device. This dual-method evaluation aligns with World Health Organization guidelines for piloting novel medical technologies, ensuring both technical accuracy and user experience are prioritized [21].

Methods

Study Design

The study consisted of 2 phases, namely the feasibility phase (phase 1) and the pilot phase (phase 2). The reporting of this study adhered to the guidelines of the CONSORT (Consolidated Standards of Reporting Trials) statement: extension to randomized pilot and feasibility trials [22].

Phase 1: Feasibility

This phase aimed to preliminarily assess the feasibility of the APDC device in collecting participants' pulse features and regenerating the pulse for CMPs. CMP's rating of the agreement on the likeliness between participants' and regenerated pulse was also preliminarily assessed. User experiences from both CMPs and participants were collected for the team to refine the setting of the APDC Device. The CMPs and participants were recruited from 20 to 28 November 2024.

Procedure

The study procedure was conducted in the following steps:

1. The participant's right-hand pulse features were recorded using the APDC Device.
2. Five CMPs assessed the participant's pulse and then the pulse regenerated from the APDC Device.
3. The CMPs rated the agreement, using a predefined record form on the likeliness between the participants' pulse and APDC-regenerated pulse, in the respects of frequency, rhythm, wideness, and force (5-point Likert for each domain, from "Strongly disagree" to "Strongly agree").
4. The CMPs' and participants' experiences were assessed using a questionnaire.

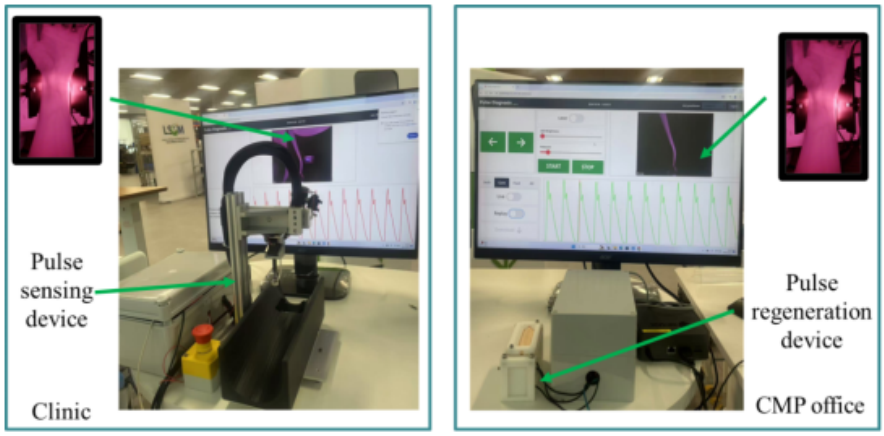
Phase 2: Pilot

In the pilot phase, the APDC device was refined by the team using the same procedure as above. Details of the refinement can be found in our previous publication regarding the technical development of the ADPC [23], while this study focused on the users' evaluation by participants and CMPs. A total of 42 participants' pulse features were collected, and 10 CMPs each assessed 10 - 11 participants' pulse (a single participant's pulse was assessed by 2 to 3 CMPs) and APDC-regenerated pulse and rated the agreement on the likelihood. They were asked to provide their feedback. The CMPs and participants were recruited from March 1-14, 2025.

Participants Recruitment

The study included participants who met specific inclusion criteria: individuals aged between 18 and 65 years, with a BMI

XSL•FO
RenderX



ranging from 18.5 to 30 kg/m², and those willing to provide informed consent. Participants were excluded if they had a dorsally located radial artery.

We recruited registered CMPs with at least 5 years of clinical experience from social media to assess the participants' pulse and the machine-regenerated pulse. Afterward, they completed a predefined record form to evaluate the pulse characteristics.

Tested Device

A prototype of the APDC device (Logistics and Supply Chain MultiTech R&D Centre) was developed using a standard tele-practice infrastructure as an assistive technology for TCM pulse diagnosis (Figure 1). The system comprises 2 primary components: a pulse-sensing device at the clinic and a pulse-regeneration device at the TCM practitioner's office. A pulse collection device was used at the patient's location, featuring a screen to display pulse information. Correspondingly, at the CMP end, a pulse-regeneration device equipped with a screen displayed the transmitted data. Patients can place their arms on a pulse-sensing device. CMP can remotely control the device to adjust its position and precisely determine the optimal location for pulse sensing, as the accuracy of pulse diagnosis is highly dependent on proper positioning. Both modules feature digital interfaces for real-time data visualization, with the sensing unit displaying pulse data acquisition parameters and the regeneration unit showing the transmitted pulse characteristics. The sensing unit incorporates position-adjustable mechanisms that can be remotely controlled by TCM practitioners. This bidirectional setup enables patients to position their arms on the sensing platform, while allowing practitioners to optimize measurement locations remotely.

Figure 1. Overview of the proposed traditional Chinese medicine pulse–based tele-practice system. CMP: Chinese medicine practitioner.

Pulse Sensing Device

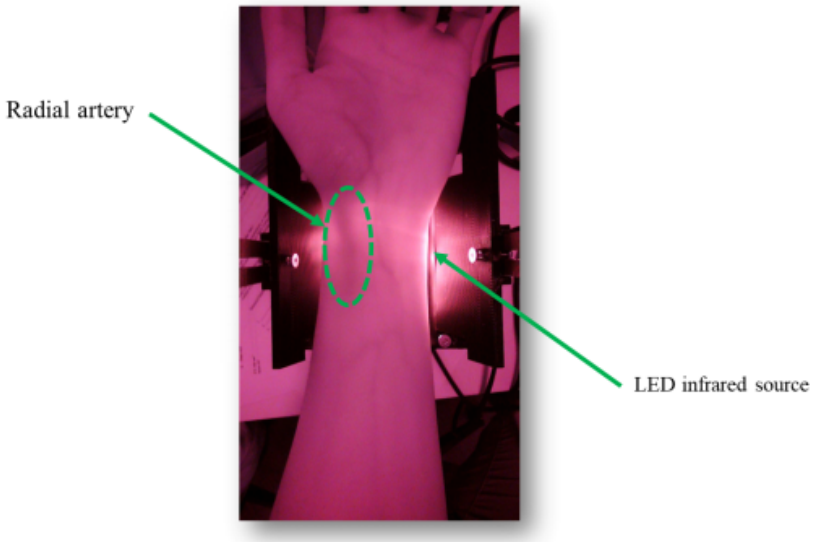
Palpation is a professional procedure used in TCM. Practitioners determine the palpation location on the participant's arm and the applied force based on their expertise and experience [24]. The proposed pulse-sensing device features 2 key components: a radial artery viewing device and a dynamic force control, which assist practitioners in accurately determining the palpation location and the appropriate force to apply.

Radial Artery Viewing Device

The APDC system uses infrared technology to illuminate a patient's arm and capture images using an infrared camera, as shown in Figure 2. Unlike the conventional blood vessel viewing device [25], the participants' arm is positioned on a stabilizing device with an infrared light source beneath it and an infrared camera to capture the images shown in Figure 3.

XSL•FO
RenderX

Figure 2. Infrared image of a participant's arm showing the position of radial artery. LED: light-emitting diode.



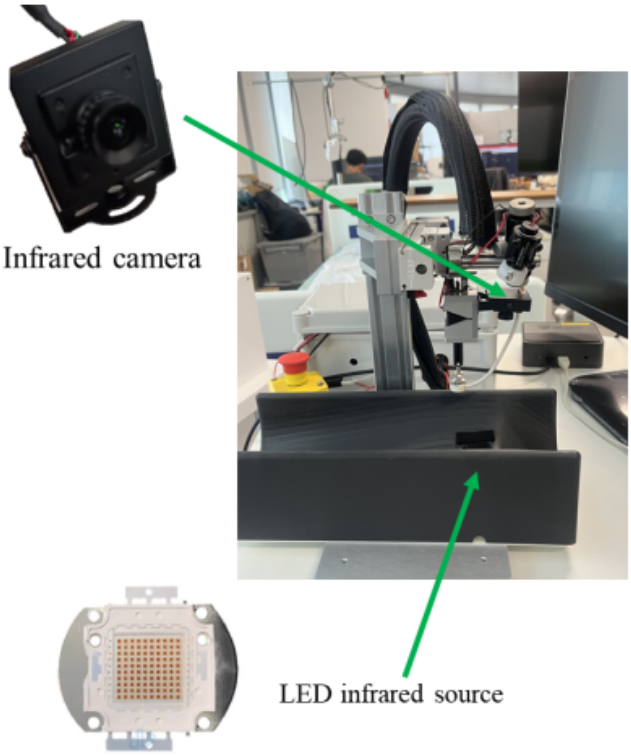


Figure 3. Key components of radial artery viewing device. LED: light-emitting diode.

Pulse-Taking Procedure

The CMPs evaluated the participants' pulse as they would in a clinical setting. The principal investigator assessed each participant's pulse and used a marker pen to mark the radial pulse (cun, according to TCM theory). The technician then assessed the participant's radial pulse, using the principal investigator's mark as a guide, with the aid of infrared light, and began recording the pulse waveform data using the APDC device. The device recorded the participant's pulse for 30 seconds at the wrist (*cun*, *guan*, and chi positions in terms of TCM) individually during the feasibility phase, and simultaneously during the pilot phase, after being upgraded to include 3 probes instead of a single probe based on feedback from CMPs during the feasibility phase.

After the APDC device recorded the pulse, the participant was seated on a chair with their arm resting on a table and their wrist positioned on a pulse pillow. The CMP assessed the pulse of the participant's right or left hand for up to 1 minute each, as

XSL•FO
RenderX

if in clinical practice, and recorded their pulse description on a chart. Subsequently, they assessed the regenerated pulse produced by the APDC device for up to 1 minute. Finally, they rated the agreement between the real participant's pulse and the machine-generated pulse.

Outcome Assessment

The user experience with the APDC device, which comprised a pulse collection device and a pulse re-generation device, was evaluated separately. Quantitative feedback from both participants and CMPs was gathered through a self-developed questionnaire. Qualitative feedback was collected through open-ended questions.

Agreement Between Participants' and Regenerated Pulse

CMPs were instructed to indicate their level of agreement with statements regarding the similarity between the machine-generated pulse and the actual pulse of participants. Responses were recorded using a 5-point Likert scale, ranging from 1 (Strongly Disagree) to 5 (Strongly Agree). The questionnaire evaluated 4 key pulse attributes: frequency, rhythm, wideness, and force. CMPs were asked to assess the extent to which they agreed that the frequency of the machine-regenerated pulse accurately resembled that of a real person's pulse. Similarly, they evaluated the rhythm, wideness, and force of the machine-generated pulse in comparison to the actual pulse. This structured approach allowed for a comprehensive analysis of CMPs' experiences and perceptions, contributing valuable data to the study of machine-regenerated pulse accuracy.

CMPs' Feedback on the Device

A self-developed questionnaire was used to evaluate CMPs' comfort, ease of use, efficiency, and overall satisfaction with the machine. CMPs were asked to indicate their level of agreement with each statement using a 5-point scale. First, CMPs rated their comfort level during the measurement process, with options ranging from "Very uncomfortable" to "Very comfortable." Second, they assessed the ease of understanding the instructions and using the machine, with responses from "Very difficult" to "Very easy." Third, CMPs evaluated the efficiency of the measurement process, indicating their agreement with statements about its quickness and effectiveness, from "Strongly disagree" to "Strongly agree." Finally, they expressed their overall satisfaction with the experience, choosing from "Very dissatisfied" to "Very satisfied."

Additionally, qualitative feedback was collected through open-ended questions in a self-completed questionnaire, seeking insights on "How would you describe the overall experience of using the pulse regenerating device?" and "What were the most noticeable differences in terms of the pulse features between the machine-regenerated pulse and that of the participants?" and "If you could suggest improvements to the machine, what would they be?"

Participants' Feedback on the Device

Participants' feedback on their experience with the pulse measurement process was collected. Participants were asked to indicate their level of agreement with various statements using a 5-point Likert scale. The questionnaire focused on 4 key areas: comfort during the measurement process, ease of understanding and using the machine, the efficiency of the measurement process, and overall satisfaction with the experience. It aimed to assess the user-friendliness and effectiveness of the machine from the Participants' perspective.

Finally, qualitative feedback was gathered through open-ended questions in a self-completed questionnaire. Participants were asked to describe their overall experience with the pulse measuring device, suggest any improvements they would recommend for the machine, and share any additional insights or aspects of their experience that were not addressed in the previous questions. The questions used were: "How would you describe the overall experience of using the pulse-measuring device?" "If you could suggest improvements to the machine, what would they be?" and "Is there anything else you would like to share about your experience or any other aspect that was not covered in the previous questions?"

Statistical Analyses

All analyses were performed using SPSS (version 28.0; IBM Corp). The CMPs' and participants' sociodemographic characteristics, including age and gender, presence of chronic diseases, and the CMPs' rating on the likeliness between participants' pulse features (frequency, rhythm, wideness, and force) and machine-regenerated pulse using descriptive statistics. Both parametric measures (mean [SD]) or nonparametric measures (median [IQR]) were reported accordingly due to the small sample size. Categorical variables (eg, gender and presence of chronic diseases) were expressed as frequencies and percentages (n, %).

Ethical Considerations

The study was reviewed and approved by the Hong Kong Polytechnic University institutional review board (reference number HSEARS20240801005) and registered at ClinicalTrials.gov (Ref. NCT06974227). We recruited participants through social media and mass emails at the University. All participants signed a consent form to confirm their voluntary participation in pulse data collection. As an incentive, each participant received an HK $100 supermarket coupon (equivalent of US $12.81) upon completing either phase 1 or 2. Pulse recordings and associated demographic information were deidentified immediately after collection, and any potentially identifying information was removed or coded to safeguard participant privacy. All data were stored on encrypted, password-protected institutional servers accessible only to authorized research team members, and findings are presented in aggregate form to maintain confidentiality.

Results

Feasibility

During the feasibility phase, 5 CMPs and 10 participants were recruited. The 5 CMPs had a mean age of 36 (SD 6.2) years, 3 (60%) were female, and had a mean clinical experience of 11.2 (SD 6.3) years (Table 1). The 10 participants had a mean age

XSL•FO
RenderX

of 41.1 (SD 15.2) years, 1 female (10%), and a mean BMI of 23.7 (SD 3.2) kg/m^2 (Table 2).

CMPs' Rating on Machine-Regenerated Pulse at Feasibility Phase

Five CMPs each evaluated pulses of 10 participants and the participants' machine-generated pulses in terms of frequency, rhythm, width, and force. The results indicated an average agreement score of 4.1 (SD 0.6) for "frequency," suggesting consensus among CMPs that the machine's pulse frequency was consistent with the participants' pulses. The "rhythm" dimension obtained an average score of 3.8 (SD 0.6), demonstrating that CMPs tended to rate this parameter with moderate agreement. "Pulse width" received a lower average score of 2.7 (SD 0.9), reflecting CMPs' neutral to general agreement regarding this characteristic. The lowest average score of 2.4 (SD 1) was observed for "pulse force," indicating a slight leaning toward disagreement among the CMPs.

CMPs' Experience With Machine-Generated Pulse Measurement at Feasibility Phase

CMPs reported their "comfort level" during the measurement process with an average score of 3 (SD 0.7), indicating a neutral perception. The "clarity of instructions on using the machine" received an average score of 3.8 (SD 1.3), demonstrating relatively straightforward operational procedures. Regarding "efficiency," the significantly lower average score of 2.2 (SD 0.5) reflected moderate dissatisfaction among CMPs at the feasibility phase. Overall satisfaction with the measurement system yielded an average score of 2.6 (SD 0.6), suggesting a neutral appraisal of the machine-generated pulse assessments.

CMPs' Qualitative Feedback at the Feasibility Phase

Overall Perception

Performance in Pulse Reproduction

CMPs generally acknowledged that machines can reproduce pulse rate and rhythm with relative accuracy. However, simulations of pulse width and strength were suboptimal, prone to misjudgment, and occasionally exhibited asynchronous performance across the 3 pulse locations (cun, guan, and chi). This is particularly true in complex pulse characteristics during regeneration, inconsistencies in pulse strength variations, and notable deficiencies in detailed feature representation.

Usability Versus Diagnostic Precision

The CMPs deemed the device was user-friendly, although the devices demonstrated compromised overall accuracy, particularly in discerning subtle variations in pulse position intensity.

CMPs' Suggestion for Improvement After the Feasibility Phase

Temporal Continuity and Nuance Preservation

The machine-generated pulse showed discontinuities during pulse cycle transitions (eg, last-to-first beat replay artifacts),

XSL•FO
RenderX

which required mitigation through extended sampling durations (>60 s) to minimize transitional irregularities.

Interactive Visualization Enhancement

Implementation of multimodal feedback systems is proposed, particularly visual documentation of contextual factors (ambient conditions and patient posture) during acquisition phases to compensate for limitations in real-time pulse regeneration fidelity.

Participants' Experience With the Device at the Feasibility Phase

Regarding comfort during the measurement process, participants reported their "comfort level" with an average score of 4.1 (SD 0.7), indicating they felt comfortable. The ease of using the machine was rated at 4.1 (SD 0.7), suggesting the participants found the process easy to follow. For the efficiency of the measurement process, the average score was 3.8 (SD 0.9), reflecting participants' general agreement. Overall satisfaction received a score of 4.1 (SD 0.7), showing participants were satisfied with the machine-generated pulse measurement.

Participants' Qualitative Feedback at the Feasibility Phase

Overall Perception

Comfort

Most users found the device generally comfortable to use without significant discomfort, but it required strict wrist positioning and took some time to adjust.

Efficiency

The participants described the device as fast and efficient with easy-to-understand instructions. However, some participants encountered difficulties in locating accurate pulse positions, leading to prolonged measurement times.

Temperature Perception

The metal components felt colder compared to the warmth of human hands, although this did not cause major discomfort.

Participants' Suggestions for Improvement After the Feasibility Phase

Positioning Accuracy

Participants recommended integrating higher-precision sensors to enable automatic pulse localization, reducing the need for repeated positioning attempts.

Design

The participants also suggested the appearance can be improved. Examples included the exposed internal components and wires housing.

Comfort Optimization

The participants suggested incorporating padded cushions or cotton layers at wrist support areas and considering stabilizing straps to prevent displacement.

Adjustability Features

The participants suggested developing height-adjustable mechanisms for devices or seating to accommodate users' optimal measurement postures.

Pilot

After receiving feedback from the CMPs and participants at the feasibility phase, the team had refined the prototype of the device. The changes include "to increase the comfortability of arm rest from fixed to slidable and lockable when taking pulse," "to enhance initial pressure adjustment to improve the overall experience by adjusting relative pressure to static and dynamic pressure," "to refine dynamic pulse replication algorithms across cun-guan-chi to achieve clinical-grade realism in machine-generated pulse from "no achievable" to "in phase pulse waveforms'." The details of the changes are presented in Table 3.

XSL•FO
RenderX

Table . Changes in the prototype according to Chinese medicine practitioners' and participants' feedback.

Parts	Feedback from CMPs[a] or participants	Initial prototype (feasibility phase)	Final prototype (pilot phase)
Arm rest	Participants suggested the armrest needs to increase its comfortability when taking pulse	Fixed	Slidable and lockable
Pulse sensing technology	CMPs proposed optimizing multisensor arrays in pulse-taking devices to minimize signal artifacts during radial artery data acquisition.	Piezoelectric	Piezoresistive
Sensing parameter	Participants suggested enhancing initial pressure adjustment to improve the overall experience.	Relative pressure	Static and dynamic pressure
Number of pulse sensors	CMPs recommended using instruments equipped with simultaneous 3-finger pulse palpation to collect pulse data.	1	3
Force control technology	CMPs suggested enhancing sensor configurations in pulse-simulating devices to improve the accuracy of pulse waveform replication.	Load cell	Pulse sensor
Silicone skin	CMPs recommended integrating skin-like biomimetic materials into pulse-simulating devices to enhance the fidelity of pulse waveform reproduction	Off the shelf	Custom made
Three-pulse regeneration synchronization	CMPs emphasized refining dynamic pulse replication algorithms across cun-guan-chi to achieve clinical-grade realism in machine-generated pulse	Not achievable, as only one probe was used.	In-phase pulse waveforms are achieved by using 3 probes to collect pulses simultaneously at 3 positions.

[a]CMP: Chinese medicine practitioner.

CMPs and Participants' Characteristics

During the pilot phase, 10 CMPs and 42 participants were recruited. The 10 CMPs had a mean age of 41.5 (SD 5.9) years, 6 (60%) were female, and had a mean clinical experience of 16 (SD 5.8) years. The 42 participants had a mean age of 41.6 (SD 13.3) years, 28 (66.7%) were female, and had a mean BMI of 21.6 (SD 2.1) kg/m^2.

CMPs' Agreement on Machine-Regenerated Pulse at Pilot Phase

Ten CMPs each evaluated 10 or 11 participants' pulses and their machine-generated pulses in terms of frequency, rhythm, wideness, and force. The results indicated that the average agreement score for frequency was 4.3 (SD 0.7), suggesting that CMPs found the machine's pulse frequency to be in agreement. Similarly, the rhythm received an average score of 4 (SD 0.8), indicating that CMPs perceived the rhythm as generally agreed. The wideness of the pulse was rated with an average score of 3 (SD 0.9), reflecting CMPs' views that it had general agreement. Finally, the force of the pulse garnered an average score of 2.8 (SD 0.9), showing that CMPs felt the force reached general agreement.

CMPs Experience With Machine-Generated Pulse Measurement at Pilot Phase

CMPs reported their "comfort level" during the measurement process with an average score of 3 (SD 0.8), indicating that they felt neutral. The "clarity of instructions on using the machine" was rated at 4.3 (SD 1), suggesting that CMPs found the process easily understandable. The "efficiency" of the measurement process was scored at 2.5 (SD 0.5), reflecting CMPs' views that it was less than satisfactory. Overall satisfaction with the experience was rated at 2.6 (SD 0.5), showing that the CMPs held neutral views regarding the machine-generated pulse measurement.

CMPs' Qualitative Feedback at the Feasibility Phase

Overall Experience

User Experience and Comfort

CMPs reported the device's rigid surface texture needed excessive palpation effort, with inaccuracy in the regeneration pulse at sunken (chen 沉), thready (xi細), and deficient (xu 虛) pulse regeneration.

Pulse Accuracy

While capable of replicating pulse frequency, rhythm, and width, the device underperforms in rendering vascular tension, directional force (maishi 脈勢), and pliability. Approximately

XSL•FO
RenderX

more than half of overall pulse morphology can be simulated, although individual variations in cun-guan-chi

Gender Impact

The device demonstrated better pulse reproduction for male participants than female participants, probably due to probe dimensions and positioning protocols, warranting anthropometric optimization through future adjustment.

CMPs' Suggestion for Improvement After the Pilot Phase

Operational Principles and Usability Enhancements

Stratified depth samples of the pulses feature can be collected for CMPs' comparison. The fixed cun-guan-chi spacing requires anthropometric re-engineering for clinical applicability. Noise arising from the motorized component should be reduced.

Automation and Ergonomic Optimization

They suggested developing automated cun-guan-chi localization algorithms and proposed frame expansion for enhanced ergonomics and upgraded depth sensing capabilities. To eliminate "pulsatile extrusion" artifacts, hemodynamic fluidity using algorithmic refinement can be explored. They also suggested implementing triple-finger span adjustability for anatomical adaptability.

Material Science Considerations

Optimize material compliance to mimic cutaneous pliability. Enhance vascular compliance in tubing systems to improve rendering of pulse turgor and tension states.

Participants' Experience With the Device at Pilot Phase

For comfort during the measurement process, participants reported their "comfort level" with an average score of 4 (SD 0.7), indicating that they felt comfortable. The "ease of using" the machine was rated at 3.9 (SD 0.8), suggesting that participants found the process easy to operate. Regarding the "efficiency" of the measurement process, the average score was 3.6 (SD 0.9), reflecting participants' views that it met expectations. Overall satisfaction with the experience was rated at 4 (SD 0.7), showing that the participants were satisfied with the machine-generated pulse measurement.

Participants Qualitative Feedback at Pilot

Overall Perception

Positioning Time Consumption

Prolonged durations during locating the pulse position were noted, requiring multiple attempts to achieve the accurate pulse position due to stringent placement requirements.

Pulse Taking Procedure

Strict postural immobilization requirements posed challenges. Compared to the device, face-to-face CMPs' manual palpation, particularly regarding pressure modulation subtlety, is more comfortable.

User-Driven Optimization Proposals

Implementation of graduated pressure escalation protocols (low initial force with progressive intensification) is advocated to optimize procedural comfort.

Participants' Suggestions for Improvement After the Pilot Phase

Comfort and Efficiency

The device was acknowledged as comfortable in general and operationally efficient. However, the participants suggested the probe interface can be optimized to enhance comfort. They suggested integrating padded cushions at wrist support interfaces and using probes with materials that will not induce cold feeling when touching the skin.

Pulse Localization

Participants reported the technicians faced persistent challenges in achieving accurate localization. Sensor precision upgrades enabling automated localization algorithms were strongly recommended to reduce multiattempt positioning requirements.

Device Appearance

The participants deemed that the appearance of the device could be further improved, and the hand placement space could be expanded.

Discussion

Principal Findings

TCM pulse diagnosis with modern tele-practice technology presents unique challenges in preserving diagnostic authenticity. Our innovative APDC device demonstrates the feasibility of remote pulse assessment through mechanical reproduction. The combination of noninvasive infrared vessel visualization and calibrated force control enables practitioners to locate and assess the cun-guan-chi positions with precision comparable to traditional palpation methods. This technical solution addresses a critical barrier in TCM tele-practice. In this study, the CMPs' and participants' feedback revealed that the APDC device was feasible in collecting pulse data and regenerating the pulse without major discomfort. The CMP deemed it easy to understand the instructions and use the APDC device. However, their rating on efficiency and overall satisfaction with the device per se fell slightly behind. The participants were satisfied with the device in terms of the comfort level and efficiency.

The COVID-19 pandemic highlighted the need for remote TCM diagnostic capabilities [26,27]. Pulse features have been regarded as important information for CMPs to make a proper diagnosis and formulate a treatment plan [7,28]. Our feasibility and pilot study data from the general public demonstrated both the use and limitations of remote pulse diagnosis. While the CMPs tended to agree that the device resembled the pulse feature in frequency and rhythm, they also pointed out the limitation of the device in reproducing the feature in wideness and force. They also reflect their expectation for improvements in the accuracy of reproducing some complex pulse characteristics, such as the depth and directional force of the

XSL•FO

pulse. These findings indicate the need for enhanced capabilities in dynamic pulse variation capture.

From the participants' perspective, the APDC device was generally deemed comfortable, easy to use, and efficient. Overall, the participants satisfied the APDC device performance. The participants' suggestions in the pilot phase were that the probe should adjust the physical pressure while sensing the pulse. Our team has replaced the piezoelectric probe in the prototype with a piezoresistive probe, which was used in other similar devices [29,30] and can help reduce discomfort when exerting pressure on the participant's wrist. The participants in both feasibility and pilot phases also suggested increasing the space and adding cushion pads to the hand placement rack. However, it may induce instability of the hand during pulse sensing. Therefore, we remade the rack into a slightly blended shape to fit the wrist posture. Future design can consider using straps to hold the hand position, but it may take longer time and reduce the efficiency of the device. In addition, our study found that the device performed better in male participants than in female participants. The lower agreement scores for pulse force and width observed among female participants may be influenced by the predominance of females in the pilot sample (9/15, 60%) as well as by sex-specific anatomical differences, such as a smaller radial artery diameter or differences in tissue compliance. Accordingly, future refinements incorporating anthropometric optimization are warranted to improve device performance across sexes. Moreover, in response to the qualitative feedback regarding the "cold feeling" and "rigid surface" of the probes, it would be appropriate to further discuss the necessity of adopting biomimetic or softer materials to better mimic human touch, as such material properties may directly influence practitioners' tactile perception and user experience.

From the practitioners' perspective, their overall satisfaction regarding the device did not improve and remained low in phase 2 even after adjustment. It is noteworthy that some key pulse features that are critically determinant in TCM pattern diagnosis were suboptimal, such as pulse width and strength [31]. Another issue was the pulse-taking process by the device that was deemed inefficient by the practitioners. Although we have pen-marked the participants' cun position, the technician needs time to adjust the probes (pulse sensors) to collect the pulse at 3 positions. The practitioners suggested developing automated cun-guan-chi localization algorithms. In addition, while the 3 probes were fixed in positions, this may lead to some inaccuracy in the pulse data collection as the width between cun-guan-chi positions can be varied with the participants' arm length. Therefore, some of the discrepancy between participants' and machine-regenerated pulses can be explained by the variation due to probe placement rather than faulty mechanical regeneration, but we were unable to quantify how much disagreement was attributed to this issue. In the future, the probes should be improved by adjustable in-between width and explore the possibility of automatic locating the pulse position rather than manually.

TCM pulse diagnosis includes diverse variations that reflect complex pathological conditions, and multiple pulse characteristics can coexist [11,32,33]. Given the significantly lower scores observed for pulse force and pulse width, we acknowledge that the APDC device is currently limited to basic hemodynamic monitoring. Consequently, further adjustment and optimization are required to enhance the diagnostic fidelity and clinical applicability of the device. More clinical trials involving diverse patients with well-documented TCM diagnoses would be essential for validating the system's efficacy across various TCM patterns and disease states. Blind tests can be done to have CMPs match the machine-regeneration pulse with the real participant's pulse. Further systematic studies with larger, demographically diverse samples are needed to validate the accuracy of the device in the clinical implementation.

Limitations

This study had some limitations. First, our participants were healthy volunteers recruited from nonclinical settings, without chronic illnesses or any acute or active disease conditions. As a result, the pulse characteristics examined may be less representative than those typically recorded by CMPs in clinical practice. Second, only 4 dimensions of the pulse were measured, and some complex pulse types, such as the tight pulse and soft pulse, require further assessment.

Conclusions

This study demonstrates that an innovative wireless pulse sensing and regeneration system for TCM tele-practice is feasible. This technology enables CMPs to take remote pulse feature assessment. While promising, additional clinical validation is needed to address limitations in capturing complex and dynamic pulse patterns. Future research should focus on enhancing pattern recognition and regeneration capabilities to optimize the device's application in TCM.

Acknowledgments

The authors thank all the participants for their contribution to this study.

Funding

This study received financial support from the Logistics and Supply Chain MultiTech R&D Centre.

Authors' Contributions

WY, LC, and YH designed the study and collected the data. WC, KF, and LC developed the intervention (APDC device). JR and MW analyzed the data. JR, WY, and SC wrote the first draft. All the authors contributed to the articles and approved the submitted version.

Abstract

Background: Entrapment of sickled red blood cells in the microvasculature leads to sudden painful vaso-occlusive crises (VOCs) in sickle cell disease (SCD). This is potentially triggered by autonomic nervous system–mediated vasoconstriction in the microvasculature. Indeed, vasoconstriction biomarkers derived from a single night of laboratory-based fingertip photoplethysmography (PPG) recording were predictive of a higher frequency of future VOC in SCD. Noninvasive, remote, and longitudinal monitoring of autonomic vasoreactivity will facilitate the development of predictive biomarkers of imminent VOC.

Objective: This study aimed to assess the feasibility and performance of a wearable wristband device to longitudinally monitor nocturnal peripheral autonomic vasoreactivity and to cross-validate the vasoconstriction parameters across the “gold-standard” finger sensor.

Methods: A total of 12 patients with SCD and 6 healthy controls were recruited to wear a wristband device (Biostrap) with a PPG sensor on a nightly basis. For cross-validation studies, 50% (3/6) controls wore both the wristband and a sleep monitoring device (AliceNightOne) with a finger PPG sensor. We quantified autonomic vasoreactivity by processing PPG signals and deriving vasoconstriction parameters—magnitude of vasoconstriction (Mvasoc) and photoplethysmography amplitude coefficient of variation (PPGampCV). We performed a correlation analysis of the vasoconstriction parameters within each device to investigate whether Mvasoc and PPGampCV can be used as surrogate markers of vasoconstriction, and then cross-validated the PPGampCV across the wristband and finger PPG devices.

Results: A total of 131 nocturnal PPG recordings were made with a wristband device (1 - 19 nights per participant; patients with SCD: n=79, 60%; controls: n=52, 40%). A total of 9 nocturnal recordings (3 nights per participant) were made with both wristband and finger sensor devices. Longitudinal continuous PPG recordings were feasible with the wearable device, with significant within-night and night-to-night variability in vasoconstriction parameters, suggesting dynamic changes in autonomic vasoreactivity. Mvasoc and PPGampCV significantly correlated within devices—the maximum overnight correlation was 0.82 (P<.001) for the finger sensor and 0.69 (P<.001) for the wristband sensor, suggesting that PPGampCV can serve as a surrogate for Mvasoc. Cross-validation analysis of PPGampCV across wristband and fingertip sensors showed statistically significant correlations on all 9 nights (overnight correlation coefficient ranging from 0.24 - 0.7), with some nightly segments of PPGampCV showing very strong correlation across devices.

Conclusions: Wearable wristband devices are feasible tools for the collection of continuous PPG measurements and vasoconstriction parameters, which serve as objective markers of autonomic vasoreactivity in users with and without SCD. We have optimized the methods of quantifying vasoconstriction from wearable device PPG signals, and cross-validated them with standardized sensors. These findings enable large-scale, real-time monitoring of autonomic vasoreactivity along with pain outcomes for the development of vasoconstriction parameters as biomarkers imminent VOC in patients with SCD. This biomarker also has the potential to impact other diseases involving autonomic vascular dysregulation.

KEYWORDS

sickle cell disease; wearable devices; microvascular blood flow; vasoconstriction; remote monitoring

Introduction

Vaso-occlusive crisis (VOC) due to obstruction of microvascular blood flow by sickled red blood cells is the prime reason for the morbidity and mortality in sickle cell disease (SCD) [1]. Peripheral vasoconstriction in the microvasculature due to dysregulated autonomic nervous system (ANS) responses and the subsequent reduced microvascular blood flow increases red blood cell transit time in the microvasculature, thus potentiating VOC [2-7]. Our recent work on the neurovascular physiology of SCD in humans has established that ANS-mediated decreases in microvascular blood flow, quantified by a novel vasoconstriction biomarker, strongly predict future VOC [8]. This novel vasoconstriction index, derived from the amplitude of finger photoplethysmography (PPG) signals, is a composite measure of the dynamic changes in peripheral blood flow occurring over time and is reflective of sympathetic neural inputs to the microvasculature. A single nocturnal measurement of this index in patients with SCD showed that a higher magnitude of vasoconstriction (Mvasoc) was predictive of increased hospitalizations for VOC in the upcoming years. However, day-to-day variations in autonomic vasoreactivity and their implications for imminent VOC risk remain unknown. All our previous measurements of peripheral vasoreactivity and ANS activity were performed in a well-controlled laboratory environment using standard finger PPG sensors to measure microvascular blood flow. Longitudinal remote monitoring of vasoconstriction events and ANS activity has a high potential for predicting and monitoring individualized pain episodes and is the necessary next step to develop nocturnal vasoconstriction indices as a predictor of imminent VOC.

Current wearable devices use optical PPG sensors to monitor heart rate variability and oxygen saturation. However, the raw PPG signals are often inaccessible before they go through automatic gain and processing, such that key information from the amplitude of the raw PPG signal is lost. Moreover, in the most commonly used commercial wearable devices, the PPG signal is measured from the wrist [9] or at the base of a finger [10,11]. These anatomic locations are not as highly perfused as the fingertip, and the PPG waveforms may be expected to be morphologically different from the fingertip due to differences in local vascular physiology and lower signal-to-noise ratios. On the other hand, wearable device PPG measurements are likely more reliable based on user compliance and practical considerations.

In this study, we established the use of PPG signals from a wrist-worn wearable device for real-time, remote monitoring of autonomic vasoreactivity and measurement of vasoconstriction events during sleep. The Biostrap EVO is a commercially available wrist-worn device (Biostrap LLC) that uses an optical PPG sensor to record standard continuous physiological data [12], including heart rate, computed respiratory activity, oxygen saturation (SpO2), and sleep and activity patterns [13]. Uniquely, our team was also able to access the raw PPG waveforms from the device, which is critical to quantify our key vasoconstriction parameters. The AliceNightOne (ANO) is a Food and Drug Administration–approved home sleep testing device (Koninklijke Philips N.V.), primarily designed to detect sleep apnea [14]. The 3-sensor device with a nasal cannula, finger PPG sensor, and chest belt detects nasal airflow pressure, SpO2, heart rate, respiratory effort, and body positioning. The ANO uses medical-grade “gold-standard” finger PPG probes to measure heart rate and oxygenation. The aims of this study were to

1. Assess the feasibility of wristband wearable devices to remotely monitor nocturnal peripheral autonomic vasoreactivity
2. Optimize the measurement of vasoconstriction parameters from wearable device PPG in patients with SCD and healthy controls.
3. Cross-validate the vasoconstriction parameters derived from a wearable wristband sensor (Biostrap) and a “gold-standard” finger sensor (ANO).

Methods

Ethical Considerations

The study was approved by the Institutional Review Board of the Children’s Hospital, Los Angeles, and all participants provided informed consent or assent to participate in the study. The study was conducted in accordance with the Declaration of Helsinki and the data was de-identified as per the Health Insurance Portability and Accountability Act (HIPAA), and subjects were compensated for their participation.

Study Setup

Patients with SCD and healthy controls underwent autonomic monitoring with a wristband sensor to measure continuous PPG during sleep. Recordings were automatically triggered at sleep onset and paused for 5 minutes every hour to allow syncing of data wirelessly to a phone-based app. The raw PPG waveforms were made accessible from a cloud-based server, exported as .csv files, and selected for analyses based on the quality and completeness of the overnight recording. Raw signals were first screened to determine if there were any segments with significant motion artifacts and were compared alongside accelerometer data also available from the Biostrap cloud server.

For the cross-validation of vasoconstriction parameters, a subset of the control participants wore the ANO sleep device with a finger sensor simultaneously with the Biostrap wristband sensor. Sleepware G3 (version 3.9.7.0; Respironics Inc) provides the capability of storing acquisitions from an ANO sleep device on a cloud-based server and exporting the .edf files (European Data Format) [15]. We converted data from both wristband and finger sensors into .Mat files (MATLAB) to compare them synchronously on 1 platform and derive the physiological parameters of interest.

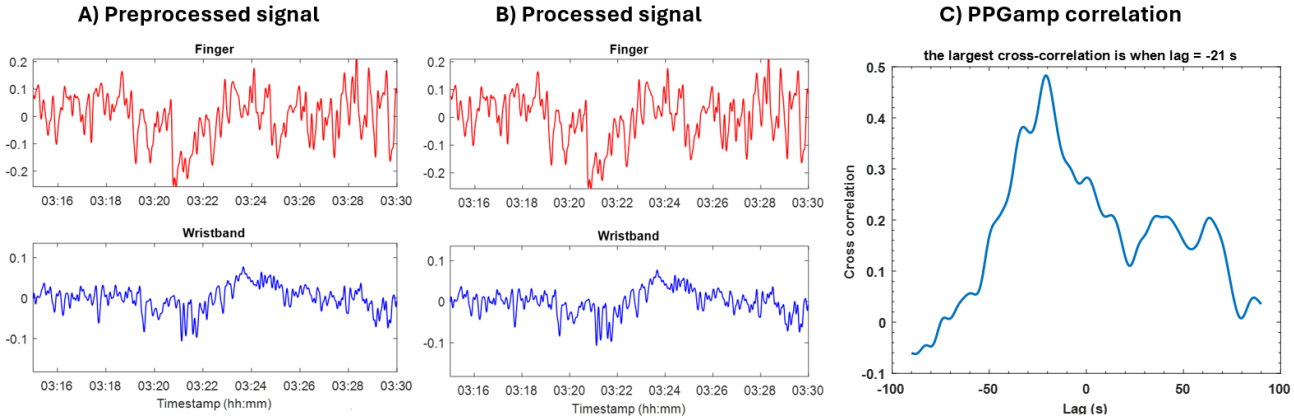
PPG Signal Processing and Derivation of Vasoconstriction Parameters

Signal Processing

The peak-to-trough amplitude of each pulse in the raw PPG signal reflects the pulsatile change in arteriolar blood volume, with a lower amplitude indicating vasoconstriction (Figure 1). The photoplethysmography amplitude (PPGamp), along with the pulse duration, was calculated from both wrist and finger raw PPG signals and divided into consecutive 15-minute segments (Figure 2A). First, segments with clear signal loss were visually identified and manually trimmed or eliminated. Second, outliers were removed by replacing values exceeding the 98th percentile within each segment with the 98th percentile value. Finally, the signal was normalized to its 95th percentile. After linear detrending, the respiratory influence (frequency >0.15 Hz) was filtered out from both wristband and finger PPGamp signals (Figure 2B). These processed "clean" PPGamp signals from each device were used to calculate corresponding vasoconstriction parameters.



Since each device had its own independent time base, the corresponding finger and wristband PPGamp signals had to be aligned in time in order to facilitate comparison of vasoconstriction parameters across devices. The cross-correlation function is a standard method in time series analysis that is used to assess the degree of linear similarity between 2 signals and has been comprehensively described in the literature [16]. We used this technique to compare and align the PPGamp signals from the 2 different devices. The PPGamp time series from each device was first autocorrelated to ensure that these signals represent physiological measurements rather than random noise. Thereafter, corresponding segments of the finger and wristband PPGamp signals underwent multiple time shifts over the other to locate the point of maximum positive cross-correlation within a +30 or –30 second window, thus synchronizing the PPGamp signals from both devices (Figure 2C).

Figure 1. Photoplethysmography (PPG) amplitude calculated from peak-to-trough of each pulse of raw PPG signal with a decrease in amplitude signifying vasoconstriction.

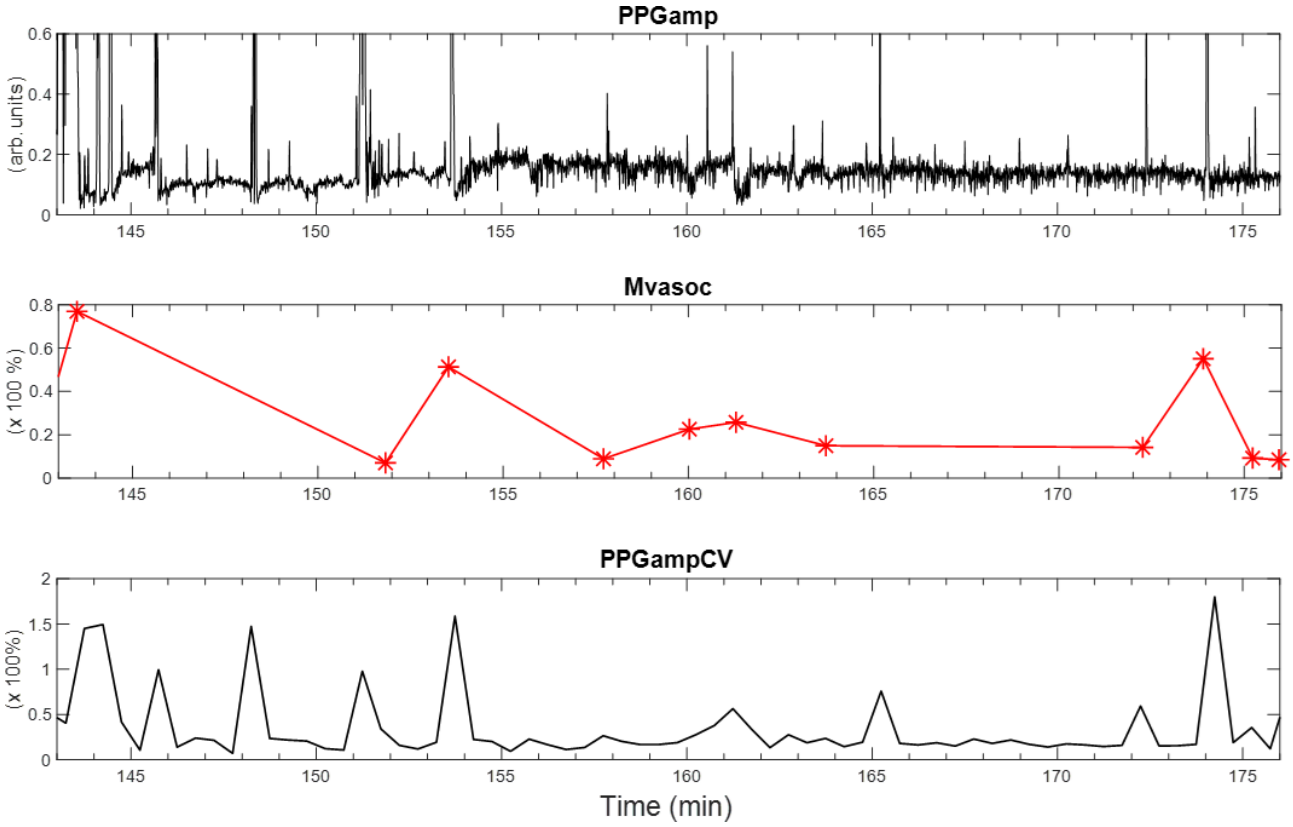
Figure 2. Representative 15-minute PPGamp segments from finger and wristband PPG sensors. (A) Preprocessed signals depicting finger and wristband PPGamp extracted from raw PPG signals. (B) Processed signals depicting "clean" finger and wristband PPGamp after removal of artifacts and respiratory influence. (C) Cross-correlation of the finger and wristband PPGamp segments. In this example, the maximal correlation occurs at a lag of −21 seconds. PPG: photoplethysmography; PPGamp: photoplethysmography amplitude.



Calculation of Vasoconstriction Parameters: Mvasoc and PPGampCV

We have previously introduced Mvasoc as a unique nocturnal vasoconstriction biomarker that takes into account the frequency, magnitude, and duration of autonomic-mediated spontaneous vasoconstrictions occurring each night [8]. The algorithm was developed to detect and quantify a vasoconstriction event as a significant reduction in PPGamp below the preceding 15-second baseline. Mvasoc is subsequently defined as the ratio of the area of the drop below baseline in PPGamp and the duration of the vasoconstriction, normalized by the baseline PPGamp level (described in detail in the supplement of Chalacheva et al [8]). Because many vasoconstriction events can occur during the night, the median Mvasoc value per night is used as a quantitative index of the user's nocturnal vasoconstriction behavior during a given night [8]. However, when the Mvasoc algorithm is applied to PPGamp signals, the rule-based measure can be sensitive to time-varying changes in signal-to-noise ratio, and thus the time locations and amplitude of the detected vasoconstrictions can vary across PPG devices. To overcome this limitation, we used a second measure to quantify the dynamic variability in beat-to-beat PPGamp. More specifically, the coefficient of variation (CV; CV=SD/mean) of PPGamp within a sliding time window of 5 minutes was calculated every 30 seconds. In initial studies, this parameter (ie, PPGampCV) correlated closely and robustly with Mvasoc, while simultaneously eliminating the need for a rule-based algorithm to detect "significant vasoconstriction" events. Figure 3 is a representation of Mvasoc and PPGampCV parameters from a wristband PPGamp segment.

Figure 3. The first row represents a PPGamp segment from wristband sensor, and the next 2 rows show corresponding Mvasoc and PPGampCV parameters derived from the PPGamp. PPGamp: photoplethysmography amplitude; PPGampCV: photoplethysmography amplitude coefficient of variation; Mvasoc: magnitude of vasoconstriction.

Within-Device Correlation of Mvasoc and PPGampCV Vasoconstriction Parameters

To rigorously assess whether PPGampCV can be used as a surrogate for Mvasoc, we performed a correlation analysis of the 2 parameters as measured by the fingertip sensor in the ANO device and wrist sensor in the Biostrap device and derived the following within-device correlation coefficient (r_{wd}) values:

1. Overnight r_{wd}: represents the correlation between vasoconstriction parameters Mvasoc and PPGampCV for the whole night
2. Peak r_{wd}: represents the segment with the maximum correlation of Mvasoc and PPGampCV out of all the 15-minute segments on a given night

Across-Device Cross-Validation of Vasoconstriction Parameter

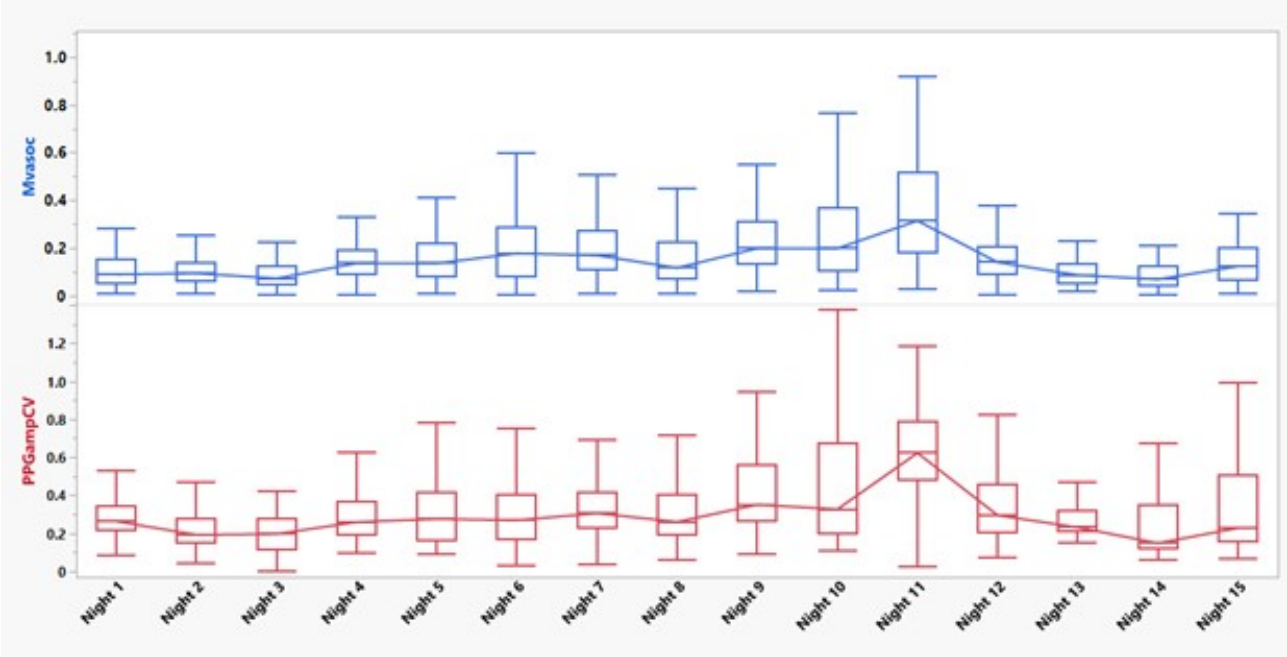
To determine if the wrist device gave the same results as the fingertip sensor, we correlated the PPGampCV parameter from the wristband and "gold-standard" finger sensors worn at the same time. The corresponding 15-minute segments from both devices were only considered for cross-correlation if at least 3 vasoconstriction events were detected within each segment. We correlated the PPGampCV between the finger and wrist PPGamp each night and derived the following across-device correlation coefficient (r_{ad}) values:

1. Overnight r_{ad}: represents the correlation of PPGampCV across wrist and finger sensor for all 15-minute segments per night
2. Peak r_{ad}: represents the segment with the maximal correlation of PPGampCV out of all corresponding 15-minute segments per night.

In all the analyses mentioned earlier, *P* values of <.05 suggested that the correlation between signals was statistically significant.

Results

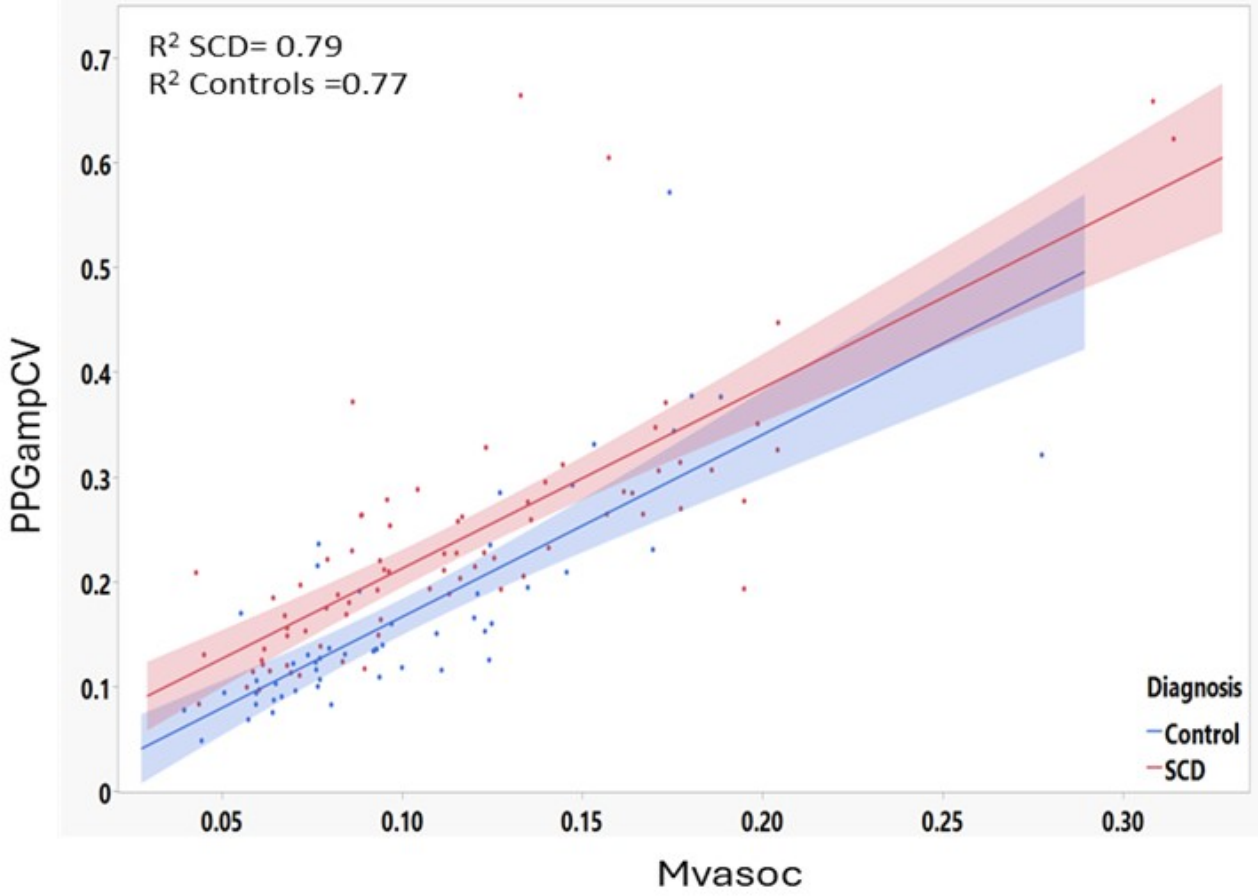
Longitudinal Monitoring of Vasoconstriction Parameters With Wristband Device



A total of 12 patients with SCD and 6 control participants participated in the study. The mean age of the sample was 25 (range 14 - 40) years. The mean hemoglobin was 8.6 g/dl (SD 1.9 g/dl) and 14.1 g/dl (SD 1.8 g/dl) for patients with SCD and controls, respectively. A total of 10 (83%) of the 12 patients with SCD reported the use of disease-modifying therapy with hydroxyurea at the time of the study. A total of 131 nocturnal PPG recordings were made with wristband devices in all participants. Patients with SCD had a total of 79 (60%) nocturnal recordings (range 1 - 15 nights), and controls had 52 (40%) nocturnal recordings (range 1 - 19 nights). While participants wore the wristband for a variable number of nights due to device availability, there were no reported logistical issues with functioning of the device, and participants reported ease of use.

Longitudinal measurements of Mvasoc and PPGampCV vasoconstriction parameters showed significant variability within each night and from night to night. A representative participant's longitudinal data are depicted in Figure 4 and show that there is a wider range of vasoconstriction activity on nights 10 and

XSL•FO
RenderX



11, with an increase in the median Mvasoc and PPGampCV noted on those nights, reflecting increased autonomic vasomotor activity. On visual inspection, the night-to-night changes in Mvasoc and PPGampCV appeared to closely track each other, suggesting a potential correlation between the 2 parameters. Indeed, the median Mvasoc of each night was closely correlated with the corresponding median PPGampCV both for patients with SCD and controls in all the nightly data (patients with SCD: R^2=0.79; controls: R^2=0.77; Figure 5).

Figure 4. Longitudinal monitoring of vasoconstriction parameters Mvasoc and PPGampCV in a patient with sickle cell disease from the wristband device. The box plot shows the median and IQR per night, and the midline shows the median of these parameters across all nights. PPGampCV: photoplethysmography amplitude coefficient of variation; Mvasoc: magnitude of vasoconstriction.

XSL•FO
RenderX

Figure 5. Correlation of median Mvasoc with corresponding median PPGampCV for all recorded nights from the wristband device among patients with SCD and controls. Mvasoc: magnitude of vasoconstriction; PPGampCV: photoplethysmography amplitude coefficient of variation; SCD: sickle cell disease.

Within-Device Correlation of Vasoconstriction Parameters (Mvasoc and PPGampCV)

While median Mvasoc and PPGampCV track closely in longitudinal nightly recordings, we further analyzed the correlation of these parameters during time segments within individual nightly recordings. Three control participants wore both finger and wristband PPG devices for a total of 9 nights, and each nighttime recording was divided into 15-minute segments. Table 1 shows the number of vasoconstriction (Mvasoc) events detected each night from both the finger sensor and wristband devices. There were a total of 113 viable segments over 9 nights, with an average of 10 and 11 vasoconstriction events detected during each segment from the finger and wristband sensors, respectively.

Table . Number of vasoconstriction events (magnitude of vasoconstriction) detected each night from the finger and wristband sensors.

	Finger sensor, n	Wristband, n
Participant 1		
Night 1 (5 segments)	34	56
Night 2 (8 segments)	90	104
Night 3 (12 segments)	140	152
Participant 2		
Night 1 (20 segments)	186	226
Night 2 (18 segments)	175	195
Night 3 (8 segments)	71	120
Participant 3		
Night 1 (19 segments)	206	214
Night 2 (18 segments)	200	190
Night 3 (5 segments)	40	57

XSL•FO
RenderX

Cross-correlation of Mvasoc and corresponding PPGampCV values were calculated for each segment of these 9 nights. Overnight r_{wd} correlation and segmental peak r_{wd} correlation coefficient data for all 9 nights (Table 2) show that Mvasoc was significantly correlated with PPGampCV each night within both devices and within almost all segments. The highest overnight r_{wd} correlation was 0.82 (P<.001) for the finger sensor and 0.69 (P<.001) for the wristband for all nights. The highest peak r_{wd} correlation was 0.99 (P<.05) in both devices for all nights (113 segments). Figure 6 shows the within-device overnight r_{wd} correlation between Mvasoc and PPGampCV for a representative night.

Table . Cross-correlation between magnitude of vasoconstriction (Mvasoc) and photoplethysmography amplitude coefficient of variation (PPGampCV) using overnight correlation coefficient (overnight r_{wd}) and peak correlation coefficient (peak r_{wd}) within wristband (Biostrap) and finger sensors (AliceNightOne).

Mvasoc versus PPGampCV correlation	Finger sensor	Wristband

Figure 6. Example of overnight correlation (r_{wd}) between vasoconstriction parameters, Mvasoc and PPGampCV, for 1 control 1 night in wristband (Biostrap) and finger sensor (AliceNightOne). Panel (a wristband*; r*=0.40; *P*<.005) and AliceNightOne device in panel (b finger sensor; *r*=0.82; *P*<.0001). The significant correlation between Mvasoc and PPGampCV assured us that PPGampCV can be used as a surrogate marker of the magnitude of vasoconstriction. Mvasoc: magnitude of vasoconstriction; PPGampCV: photoplethysmography amplitude coefficient of variation.

Across-Device Cross-Validation of Vasoconstriction Parameters (CV)

Since the PPGampCV serves as a surrogate marker of vasoconstriction and is overall easier to derive from the PPG and compare across devices, we chose the PPGampCV to perform cross-validation of vasoconstriction parameters between the 2 devices. The highest overnight r_{ad} cross-correlation for all nights was 0.70, and the highest peak r_{ad} cross-correlation for all nights was 0.99. Table 3 shows the PPGampCV overnight correlation (r_{ad}) coefficient and segmental peak (r_{ad}) correlation coefficient data for all 9 nights (123 segments). Figure 7 shows an example of correlation analysis of PPGampCV across devices in 1 corresponding 15-minute segment.

Table . Overnight r_{ad} correlation and peak r_{ad} correlation coefficients of photoplethysmography amplitude coefficient of variation between wristband (Biostrap) and finger sensor (AliceNightOne).

	Overnight r_{ad}[a]	Peak r_{ad}[b]
Participant 1		
Night 1 (5 segments)	0.24	0.76
Night 2 (8 segments)	0.50	0.90
Night 3 (12 segments)	0.70	0.89
Participant 2

Figure 7. Correlation of PPGampCV between the wristband and finger device for a representative 15-minute segment of 1 night. The left panel (A) shows the corresponding PPGampCV values from both devices over time, and the right panel (B) shows the correlation of PPGampCV values between the 2 devices (r=0.84; P<.001). PPGampCV: photoplethysmography amplitude coefficient of variation.

Discussion

Principal Findings

The sudden, unpredictable onset of VOC remains the major cause of morbidity and the leading cause of hospitalizations in patients with SCD [17]. While some patients experience an aura or premonition that a VOC is about to occur [18], there are no objective biomarkers that can predict the risk of an imminent VOC and thus open up a therapeutic window to abort its propagation. We have introduced nocturnal vasoconstriction indices of autonomic peripheral vasoreactivity that have the potential to be predictive biomarkers of impending VOC crisis. This study establishes the feasibility of measuring these biomarkers in a real-world setting with a wearable device, such that the vasoconstriction biomarker can be validated in larger populations. To the best of our knowledge, this is the first study that uses the PPG signal from a wearable-based sensor system to quantify microvascular blood flow changes accompanying peripheral vasoconstriction.

We successfully used the Biostrap wearable wristband device to longitudinally monitor raw PPG signals and derive autonomic vasoconstriction parameters. Participants reported ease of use, and no significant barriers were identified in using the device. There was substantial night-to-night variability in the median Mvasoc and PPGampCV parameters within participants, which implies varying levels of sympathetic vasoreactivity. This has potential implications for tracking pain and imminent VOC risk, as SCD physiology dictates that vasoconstriction and resultant decrease in microvascular perfusion increase the likelihood of vaso-occlusion.

Although Mvasoc is a direct quantification of vasoconstriction events from the PPGamp signal, we found that this parameter is more prone to artifacts that can plague wearable device signals. The PPGampCV is a more robust measure of variability of the PPGamp amplitude that closely reflects Mvasoc and is an acceptable surrogate for monitoring vasoconstriction. The ANO with a fingertip PPG sensor is a widely used Food and Drug Administration–approved home sleep device that represents a reduced version of the clinical polysomnography. The vasoconstrictions measured at the fingertip are generally stronger than the corresponding events measured at the wrist, and thus the signal-to-noise ratio of the fingertip signal is higher than that of the wrist signal. Physiologically, this is to be expected since the fingers are highly innervated by alpha-adrenergic fibers and are also highly vascularized along with large numbers of arteriovenous anastomoses, compared to the wrist. This results in much faster and stronger vasoconstrictive responses in the fingers vis-à-vis the wrist. These differences in perfusion also have the potential to impact the cross-correlation values of the PPGampCV signals between the fingertip and the wrist. Using a cutoff of ≥0.5 as an acceptable correlation coefficient, we still see that there is mostly moderate to very strong correlation of PPGampCV between ANO and Biostrap. This shows that the wristband performs comparably to the “gold-standard” fingertip PPG while being much more practical to use. The overall correlation of PPGampCV for each night also remained statistically significant and acceptable between devices, suggesting that the wristband device remains a viable and feasible tool to deploy for longer-term, easy-to-use remote longitudinal monitoring of autonomic vasoreactivity.

This study is also unique in the sense that most wearable devices that purport to provide information about autonomic function focus on heart rate variability and SpO2 changes, but do not monitor changes in PPG amplitude, indicative of peripheral vasoconstriction [9]. Our Mvasoc algorithm and PPGampCV biomarker can be adapted to any wearable device that uses the PPG signal to measure ANS activity and quantify vasoconstriction in users with and without SCD. Promising preliminary data suggest a correlation between the Mvasoc parameter and the intensity of daily pain in patients with SCD. In 10 patients with SCD from this same cohort, we successfully tracked daily pain data using a SMS text message–based red cap survey, along with wristband recordings. Presence of pain and intensity of pain were tracked on a scale of 1 to 10. Of the 68 nocturnal wristband recordings with concurrent pain diary entries, 25 days of pain were reported with a pain intensity

XSL•FO
RenderX

ranging from 3 to 8. While the data were not powered toward the prediction of a VOC crisis given the limited number of nights of autonomic vasoreactivity monitoring, we found that a higher vasoconstriction index (Mvasoc) and a greater parasympathetic withdrawal in the heart rate variability patterns predicted greater intensity of pain the next day on multivariate regression analysis [19]. While these data hint at possible temporal associations between autonomic vasoreactivity patterns and pain, they need to be validated with longer-term longitudinal monitoring of vasoconstriction parameters in larger patient populations with SCD in order to develop it as a predictive tool for imminent VOC.

In conclusion, our pilot data show that the implementation of PPG from wearable sensors has a high potential for the development of an autonomic vasoreactivity biomarker for VOC in SCD. The portability, cost-effectiveness, and low maintenance of these wearable sensors can make them suitable for remote use. Moreover, these vasoconstriction parameters derived from PPG amplitude can serve as easily accessible and readily quantifiable biomarkers of tissue perfusion that could be valuable in other disease states, such as migraine and coronary artery disease, where vasoreactivity plays a role in disease pathology.

Limitations

The small sample size of nocturnal recordings, especially with the ANO device, makes it difficult to generalize the results. About 20% of the PPG signal from the nightly recordings was further eliminated due to loss of signal, primarily from the finger sensor. However, the high number of vasoconstriction events detected within each night of the available data adequately powers the correlation analyses and improves the robustness of the data. Both devices were not synchronized on the same time scale; therefore, we attempted to perform cross-correlation to 15-minute segments within a +30 or –30 second window. This technique can result in segment selection errors and lower correlation values. Future studies with concurrent use of the wristband device during clinical sleep studies with finger PPG sensors can be used to validate these results in a larger population. While we have shared preliminary results on the relationship between Mvasoc and daily pain intensity, the study is primarily focused on the ability to detect vasoconstriction events with wearable devices, and we were unable to derive any clinical inference on any causal relationship with VOC onset, the impact of hemoglobin levels, or the use of hydroxyurea on vasoreactivity.

Abstract

Background: Central venous catheters (CVCs) are indispensable to contemporary critical care, perioperative management, and emergency resuscitation, yet their insertion remains fraught with preventable harm and inefficiency.

Objective: This study aimed to identify all areas of CVC placement that can be improved through device design using human-centered design and qualitative research methods.

Methods: This qualitative study was a contextual inquiry of CVC placement, which included observation alongside brief face-to-face interviews with physicians. It was aimed at providing a depth of understanding using evidence to demonstrate causality. This study was conducted at 3 hospitals in the emergency department, the intensive care unit, and the operating rooms. Where possible and with additional consent, sessions were recorded in video or still photography, or at times both. This study included 19 observations and 24 interviews.

Results: In this study, the approach to CVC insertion was consistent across hospitals and care environments, with moderate variability spanning a few sections, such as suture and dressing use or lack thereof in specific care environments. The described and observed difficulties leave room for improvement in device design. The results of this study indicated that there are 34 discrete steps to placing a CVC line, with most time spent during sterile preparation. As a result of the device or kit design, challenges were observed. These included missing essential materials from kits, difficulty distinguishing between nonsterile and sterile items, challenges with lidocaine ampules, patient claustrophobia from draping, and a lack of user preference for kit contents. Additional challenges included obscured ultrasound views, kinked guidewires, overall procedural untidiness, and considerable waste management issues.

Conclusions: An intuitive kit that aligns with predictable human behavior and eliminates unnecessary multistep detours can reduce novice failure rates, cognitive load, and practice inconsistency, and it could also curb nonrecyclable waste from "backup" kits opened for a single missing item. By reframing CVC systems as sociotechnical solutions rather than static assortments of parts, the same design moves that minimize improvisation and coordination errors for physicians may also reduce dwell time and manipulation events for patients, thereby advancing the core triad of safety, procedural efficacy, and everyday usability. By examining how clinicians place central lines, this study reveals modifiable design flaws that perpetuate risk despite decades of

XSL•FO
RenderX

procedural standardization. Contextual inquiry provides the evidentiary bridge between clinical imperatives to reduce complications and the practical realities of device use. Embedding such investigations at the outset of design and iteratively throughout product life cycles offers a path toward safer, more efficient, and more humane central venous access for both patients and providers.

KEYWORDS

contextual inquiry; central line placement; medical device design; patient safety; ease of use

Introduction

Central venous catheters (CVCs) are indispensable to contemporary critical care, perioperative management, and emergency resuscitation, yet their insertion remains fraught with preventable harm and inefficiency. Large contemporary syntheses estimate that approximately 30 in every 1000 patients with a CVC in place for 3 days will experience at least one serious complication, be it arterial cannulation, pneumothorax, central line–associated bloodstream infection (CLABSI), or deep venous thrombosis, whereas catheter malfunction alone occurs at roughly 6 events per 1000 catheter days [1]. Additionally, the insertion process can be a source of complication. CLABSIs still claim thousands of lives each year in the United States and add billions of dollars to health care costs despite decades of prevention bundles and increasingly routine ultrasound guidance intended to curb mechanical mishaps and accelerate successful cannulation [2].

While epidemiological surveillance and randomized trials may have helped refine insertion checklists and sterility protocols, far less attention has been paid to the concrete interactions among users, tools, and environments that shape everyday practice. Human factors frameworks may be an impetus to study actual work as done rather than work as imagined. The US Food and Drug Administration's 2016 guidance on applying human factors in medical devices and the Association for the Advancement of Medical Instrumentation TIR51 standard on contextual inquiry may provide the grounding for early, field-based observation and interview techniques to surface latent use errors, cognitive burdens, and design mismatches before devices reach market or are iterated for safety [3,4].

This study applied a structured contextual inquiry across 3 hospitals and multiple care settings to showcase how central line placement unfolds in real-world settings minute by minute, from presterile preparation to dressing application. By triangulating in situ observation with brief clinician interviews, 34 discrete steps were catalogued, mapping procedure time distributions and documenting recurrent friction points that compromise sterility, ergonomics, and situational awareness. This study aimed to identify all areas of CVC placement that can be improved through device design. From the drapes that obscure patients' faces and guidewires that become kinked to the missing of essential or preferred components, this study highlights the basis for next-generation kit architecture, accessory design, and room layout that align with real user needs in both chaotic and controlled environments.

Methods

Overview

This qualitative study was a contextual inquiry of CVC placement, which included observation alongside brief face-to-face interviews with physicians. It was aimed at providing a depth of understanding using evidence to demonstrate causality. According to Maxwell [5,6], qualitative research is well suited for causal inference as it allows for detailed examination of specific processes and mechanisms in real-world contexts, revealing how and why outcomes occur beyond mere correlations [5,7]. A detailed description of the process, tools, and people involved is provided below. The technique of contextual inquiry is promoted by the Food and Drug Administration human factors guidance (2016) to determine user needs at the start of any design process. The data collected in this study included both observational and interview data, with 3 main areas of focus: the user, the environment, and the tasks as part of the steps and workflow.

This study was conducted at 3 hospitals in the emergency department (ED), intensive care unit (ICU), and operating rooms (ORs). Where possible and with additional consent, sessions were recorded on video or still photography, or at times both. This study included 19 observations and 24 interviews (Table 1). The total number of observations and interviews conducted at each site was determined by the clinical need and patient-clinician consent at the time of the study. In instances in which patient consent was not provided but physicians wanted to participate, the physicians could opt to demonstrate their placement technique using a simulated patient in the care environment.

Table 1. Breakdown of observations and interviews by location.

	Cincinnati, Ohio, n (%)	Wake Forest, North Carolina, n (%)	Sacramento, California, n (%)
Observations (n=19)	9 (47)	7 (37)	3 (16)
Interviews (n=24)	8 (33)	8 (33)	8 (33)

A total of 24 physicians were involved in this study, including emergency medicine, critical care, and anesthesiology specialists. Observations and interviews were conducted in perioperative rooms, ORs, EDs, and ICUs.

XSL•FO
RenderX

Within each hospital, the same brand of kit was used; however, in one instance at Wake Forest, there was a different type of kit used between the OR and the ICU and ED. The kits consisted of other brands and product identification numbers (Table 2).

[a]CVC: central venous catheter.

All interviews followed the core principles of contextual inquiry studies in that they were conducted in the users' real-world environment, with the research team establishing a master (physician)-apprentice (researcher) relationship. As the procedure unfolded, and at opportune times, the researcher would share interpretations to uncover observations and deeper insights. All the interviews were guided by the tasks in the CVC placement procedure and focused on the usability of each element. Typical observation or interview experiences ranged from 45 minutes to 1.5 hours, as influenced by clinical responsibilities and the participants' availability.

Ethical Considerations

The study protocol was appropriately reviewed by the University of Cincinnati institutional review board, which determined that it did not constitute human participant research under federal regulations, as the primary focus was on device improvements and quality of care rather than generating generalizable knowledge about individuals. Despite the nonresearch classification, informed consent was required from all participants. As detailed observations were conducted of clinical procedures that could capture sensitive patient information or professional performance details, robust measures were in place to protect privacy and confidentiality. In addition, efforts were made to ensure a diverse participant pool to avoid biased insights that could perpetuate disparities in device design or procedural improvements.

Results

In this study, the average overall time to place a CVC varied across care environments (Table 3). In discussions with clinicians, some postulated that procedure times vary proportionally with the provider's perceived control over the patient and environment (ie, that the more chaotic the environment, the longer the procedure).

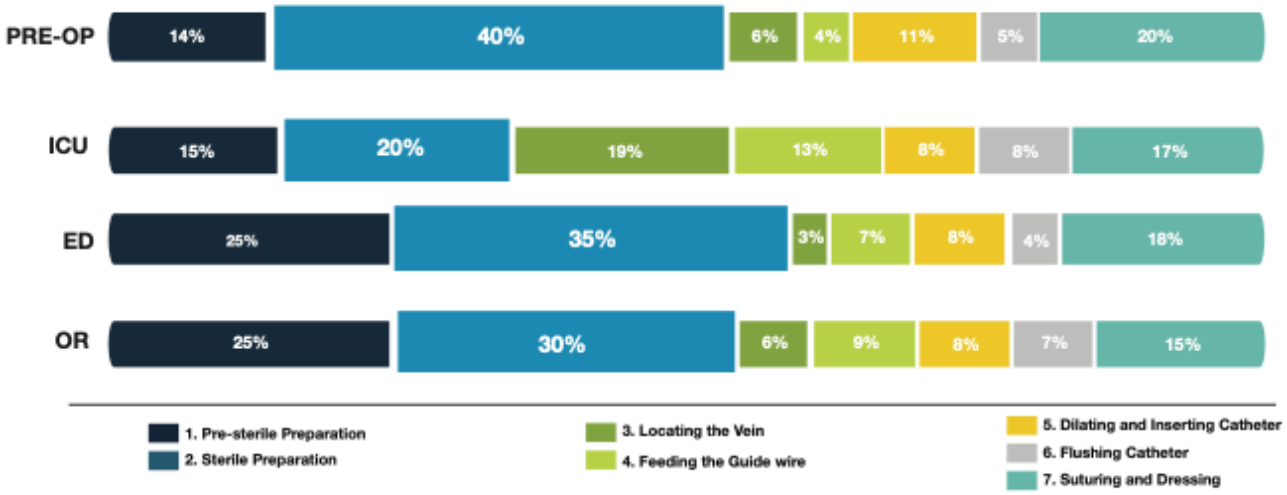

Table 3. Average central venous catheter (CVC) placement timing in different environments of care.

Environment	CVC placement time
Operating room	16 min, 48 s
Preoperative care	20 min, 15 s
Intensive care unit	27 min, 53 s
Emergency department	35 min, 28 s
Overall, mean (SD)	25 min, 6 s (7 min 12 s)

Procedural timing was also broken down into 7 distinct sections within the overall procedure (Figure 1). These included the following: presterile preparation, sterile preparation, vein localization, guidewire insertion, catheter dilation and insertion, catheter flushing, and suturing and dressing. Of note, time from presterile to sterile preparation accounted for more than half of the overall procedure time in all locations except the ICU. The research team noted that the number of staff members participating in setting up for the procedure varied across sites and care environments.

XSL•FO
RenderX

Figure 1. Percentage of time per section of the central venous catheter placement procedure by environment. ED: emergency department; ICU: intensive care unit; OR: operating room.

The patient experience during CVC placement highlights conditions that impact overall safety, efficacy, and usability. Draping a conscious patient can be problematic. During procedure preparation, the provider unpacks sterile drapes from a kit and prepares a sterile field directly over the patient (Figure 2). This extends the sterile field, albeit an unstable one, directly over the patient. As a result of patient movement, the required equipment for the procedure can fall out of the sterile field or become lost. Uncooperative patients require additional procedures, such as intubation, muscle relaxation, and sedation, before CVC placement.

Figure 2. Patient acting as an extended sterile work surface.

In the OR, the patients were intubated and unconscious. However, in the ED and ICU environments, the patients were often conscious and mobile. In all cases, draping covered the patient's face throughout the procedure, creating a potentially claustrophobic and challenging environment (Figure 3). In clinical practice, there is substantial variability in body habitus across the patient population. As a result, the drapes provided in the kits may not fit patients classified as obese. In some cases, the aperture provided by the drape is not large enough to accommodate the insertion location, resulting in the provider improvising by creatively engineering a larger opening.

XSL•FO
RenderX

Figure 3. A patient drape placed over the patient's face in the intensive care unit.

Patient airways require management throughout the procedure. In this study, patients in the ICU were fitted with an oxygen mask. A mask is often placed in case a future procedure is needed to avoid disturbing the sterile field.

Gaining access and positioning can often lead to patient discomfort. Patients are required to hold awkward Trendelenburg positions with their head turned and extended to optimize their anatomy for successful CVC placement (Figure 4). Patients were instructed to maintain position throughout the procedure, although it can be uncomfortable because the plastic portion of the drape may be directly on a patient's skin. For conscious patients, this at times required further anesthesia and posed challenges for physicians, given that, as access was gained, patients would move. This position proves challenging for patients who are obese who may also require additional supplies and more extended periods to complete procedure preparation.

Figure 4. Aperture opening of the drape adhered directly to a patient's face.

The provider experience during CVC placement also underlines conditions that could impact overall safety, efficacy, and usability. Physicians are required to don personal protective equipment in tight spaces without compromising sterility (Figure 5). In this study, the order of preparation varied across care locations. For example, ED physicians sometimes elected to preclean the patient before gowning, which allowed time for the chlorhexidine preparation to dry. In contrast, in the OR, some physicians prepared personal protective equipment in advance.

XSL•FO
RenderX

Figure 5. Donning of personal protective equipment in a tight space.

In the CVC procedure, 34 individual steps require the provider to locate key pieces of equipment and determine where and how to use them while maintaining a sterile workspace. During this multistep process, physicians often improvise, which may place a heavy cognitive burden on them and require coordination. For example, physicians will think through the procedure before beginning, questioning whether they have all the necessary supplies and where to place them to maximize access while maintaining the sterile field and coordinating with other support personnel.

Across all sites and use environments, at least 2 physicians were present. This enabled 1 sterile operator and 1 support person to adjust patient drapes, including using a towel to protect the patient's face; retrieve items that were required but not readily available in the kit or forgotten; and sterilely prepare the ultrasound probe.

Physicians were often in awkward positions due to suboptimal biomechanics resulting from product design, room layout, or both. For example, physicians struggled to fit all the necessary equipment on a single surface due to space constraints. The equipment is often split between multiple work surfaces (ie, patient and table), forcing the provider to turn to access both surfaces and remove their focus from the patient. The space constraints also make it difficult to avoid touching a nonsterile surface during the procedure. Furthermore, flushing with a standard syringe requires an uncomfortable and awkward hand movement needed to achieve aspiration, as the device is designed to deliver a solution. When ultrasound is used for safe access, both hands are required to hold the equipment, which can make aspiration a challenging one-handed maneuver (Figure 6).

XSL•FO
RenderX

Figure 6. One-handed aspiration while holding the ultrasound probe.

Physicians held the syringe and introducer needle at a 45 to 30° angle and subsequently lowered the angle while advancing the needle (Figure 7). To verify position, physicians would draw more blood and assess color and pressure gradient. Some commented that some step was the highest "stress" point in the procedure. One intensivist even remarked that finding the vein was the most stressful part and that, once the wire was in and the needle was out, their stress subsided. At this point, there is a risk of pneumothorax or perforation of the carotid artery. It was observed that maintaining stability and aspirating to visualize venous blood return is ergonomically challenging for physicians. This is further complicated by the ultrasound monitor being placed outside the provider's field of view (Figure 8).

Figure 7. Access needle angle relative to the ultrasound probe.

XSL•FO
RenderX

Figure 8. Ultrasound monitor position requires physicians to look away from the access site.

Additionally, the pressure that the user applies to the vein with the ultrasound probe can alter central venous anatomy when the device is withdrawn from the skin surface. Physicians were at times compelled to make slow, careful movements, with risk controlled by the user's experience. Rather than an intuitive device design, advanced troubleshooting or error prevention during the procedure may depend on the provider's expertise and dexterity.

While simultaneously troubleshooting and preventing errors, physicians are exposed to sharps and biohazards once access to the vein is achieved. For example, users are exposed to the access needle, where the skin incision scalpel is typically contaminated with the patient's blood within the working area (Figure 9).

Figure 9. Opening the kit midprocedure with the sharps anchored in the kit.

While efforts were made to control and maintain the safety of sharps, the CVC kit design places the cognitive burden, safety, and responsibility on the provider. As vein dilation occurs, the access site often becomes highly disordered and poses a biohazard to health care physicians (Figure 10). Once the vein was dilated, increased blood flow increased the stress and inconvenience of the procedure in that the guidewire itself became a slippery surface. It could become misplaced, requiring additional intervention. This hazardous situation also extends to catheter insertion (Figure 11).

Physicians were required to thread the catheter over the guidewire and adopted a coiling behavior to maintain control and reduce proximal tip movement, which can complicate device alignment (Figure 12).

XSL•FO
RenderX

Figure 10. Advancement of the dilator over the wire in slippery conditions due to venous return.

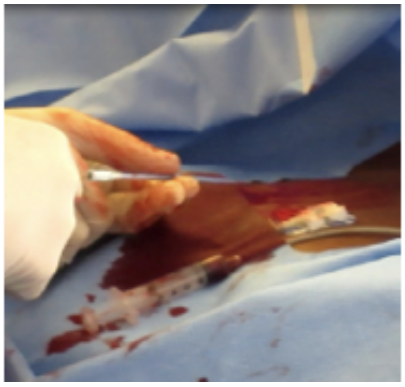

Figure 11. Catheter insertion with exposure to biohazard.

Figure 12. Coiled guidewire enabling control during catheter insertion.

These situations were particularly challenging for novice health care providers, who grappled with each step of the procedure (Figure 13). Consequently, inexperienced health care physicians often have unsuccessful attempts to place CVCs.

The product design of traditional CVC kits was not always entirely optimized for streamlined assembly. Many kits, for example, did not have all the supplies or the preferred supplies for CVC placement. As a result, clinicians often spent additional time gathering the necessary materials (eg, skin preparation, gauze, saline, and lidocaine) as well as the preferred materials because the valves provided in the kits were at times not compatible with other hospital equipment, thus suggesting better packaging so that the risk or delay in the procedure is minimized. Some users preferred vertical valves such as clave connectors (Figure 14). Physicians who chose to use nonstandard or additional supplies often opened a secondary kit sourced from separate locations within the hospital. Items collected may include additional drapes, Mayo stand, lidocaine, sterile flush syringes, chlorhexidine preparation, and ultrasound devices or supplies.

XSL•FO
RenderX

When physicians remove the guidewire, there is no proper receptacle to place it in; it is thrown away with nonsharp materials or hazardous materials. In this study, some physicians did not use sharps holders during the procedure, preferring to leave sharps on the tray (Figure 15), suggesting an unmet need among users. For those who used the temporary sharps holder provided in some trays, it was poorly secured and became top-heavy, often leading to dropped sharps. Additionally, there were no safeguards for the disposal of all sharps.

Figure 13. Novice users have increased exposure to biohazards.

Figure 14. Different forms of valve connectors.

Figure 15. Sharps are placed on top of the kit during the procedure.

There is a considerable amount of nonrecyclable waste and challenges because of the kit design (Figure 16). In this study, the kits at times lacked a clear delineation between the layers that designate items and specify when they should be used. There were excess materials not used in the procedure, which contributed to the overall waste. Physicians often draped the sterile area and manipulated the drape around the patient's face and head, making it easier for the patient to breathe and reducing claustrophobia.

XSL•FO
RenderX

Figure 16. Waste accumulation because of the kit design.

The quality and design of the CVC products' individual elements pose usability challenges, including misalignment with predictable human behavior, heavy reliance on memory, and a lack of visual or tactile references. One challenge in this study was that the guidewire kinked frequently. When this happened, physicians would often try to remove the kink or use the wire regardless. If this guidewire is rendered unusable, the provider may open a new kit to replace the failed one or, in some instances, a missing part (Figure 17).

Figure 17. Three kits opened for the guidewire and dilator due to kinking.

In this study, the dilator was the same color as the draping and could be camouflaged, eventually getting lost in it, causing health care providers to search. Additionally, due to the complex setup, components sometimes fell outside of the sterile field. Another detail that caused some difficulty in the guidewire design was the "J" curve. While it can provide safe intravascular advancement, this curve on the wire can also make the guidewire more difficult to thread into the catheter. Some physicians were observed making what some may describe as counterintuitive workarounds and flipping the guidewire to the straight end to easily advance it through the catheter. Though well intended, this variation in CVC placement may increase the risk of complications.

Furthermore, there is little to no tactile feedback from the guidewire feeder, making it difficult for the user to know whether the wire is advancing. This is further complicated by blood-stained gloves, which make the guidewire markings difficult to see and grasp. The results of these outdated design decisions can create an unnecessary burden on physicians to judge catheter alignment on the guidewire and insertion depth.

Discussion

Principal Findings

In this study, the approach to CVC insertion was consistent across hospitals and care environments, with moderate variability spanning a few sections, such as suture and dressing use or lack thereof in specific care environments. The described and observed difficulties leave room for improvement in device design (Table 4).

XSL•FO
RenderX

Table 4. Summary of use-related issues throughout the procedure.

Procedure section and device used	Problem area
Presterile preparation	
Central venous catheter kit	• It does not include all essential materials needed for central line placement, resulting in unnecessary delays. • It is unable to distinguish nonsterile and sterile items during nonsterile preparation.
Nonsterile syringe	• Health care providers typically empty 3-5 syringes (30-50 mL) of saline solution into the kit basin from nonsterile saline syringes. These were not included in the kit.
Lidocaine	• Because the lidocaine is not sterile, health care providers will either have someone hold it for them, tape it to a Mayo cart, or chase down the ampule while loading the syringe.
Sterile preparation	
Patient drape	• Due to the placement of the full-body drape, patient claustrophobia can occur; it is challenging for the provider to maintain sterility and manage the patient during the procedure.
Locating the vein	
Introducer needle	• Physicians expressed a preference for the 18-gauge introducer needle without a catheter over the 20-gauge needle with an 18-gauge catheter assembly. For patients with obesity, physicians noted that the length (2.5 inches) of the needle was not sufficient. The introducer needles were not echogenic; thus, they were difficult to view in the ultrasound monitor.
Ultrasound	• The ultrasound monitor was not placed within the line of sight of the provider, making it difficult for them to effectively use the tool. • Health care providers do not generally document ultrasound use by capturing an image of the procedure as required by major insurers for reimbursement.
Feeding the guidewire	
Guidewire	• Wire kinking while executing the procedure was problematic, and once deemed unusable, the provider would open another kit only to access an additional wire. • The “J” tip of the wire was difficult to thread and feed. • Physicians had difficulty estimating how much of the wire was inserted. If they were unsure, they took the wire out of the delivery system. Once the wire is removed from the delivery system, it is difficult to reload; thus, once it is out, it typically stays out. Markings on the wire were also not clear to the providers. • Due to the inherent messiness of the procedure, blood is often on the providers’ hands, making it difficult to handle the guidewire delivery system.
Dilating and inserting the catheter	
Dilator	• The dilator often kinks if the provider aggressively pushes. If the dilator is no longer usable, another kit is opened only to access another dilator. • The dilator length (4 inches) is not sufficient for patients with obesity.
Catheter	• Threading the catheter over the wire is a difficult task. Physicians have a hand tremor when performing this task. • It is difficult for the provider to determine whether the tip of the catheter has reached the superior vena cava. Physicians will estimate placement and follow up by x-raying the patient to confirm proper placement.
Flushing the catheter	
Syringe	• Physicians faced challenges with maintaining proper syringe grip during aspiration and flushing. Physicians struggle with the current syringe design to alternate between 2 grips.
Valves	• The T-shaped valves provided in the kit also present challenges when flushing the line after placement. The syringe often slips off the valve when flushing the lines.
Suturing and dressing placement	
Suture loop (feature) on the catheter	• The suture loop anchor and box clamp were not always used. If there is excess catheter outside of the patient’s body, depending on the insertion location and the patient’s anatomy, the provider will use the suture loop anchor and box clamp.

This contextual inquiry reveals that central venous catheterization is not merely a sequence of technically codified steps but also an intricate sociotechnical performance in which device design, environmental constraints, and clinician

XSL•FO
RenderX

improvisation intersect to shape risk. Our mapping of 34 discrete actions, the dominance of preparation time in most settings, and the recurrent need to compensate for missing or poorly engineered components align with contemporary estimates that roughly 3% of patients exposed to a catheter for 3 days sustain a major complication [1]. Large contemporary reviews showcase that CVC is now routine, roughly 8% of hospitalized patients need a CVC, and more than 5 million are placed annually in the United States. Ultrasound-guided puncture should be the default. However, Kehagias et al [8] found that observations of obscured monitors, awkward one-handed aspiration, and improvised wire handling show how the safest technique on paper can still be undermined by poor ergonomics and kit design.

Our findings build on imperatives for field-based inquiry into real work conditions to surface latent design hazards. We observed exactly the kinds of use errors that are of concern: kinking guidewires without tactile feedback, dilators camouflaged against drapes, valves incompatible with existing hospital hardware, and ultrasound displays positioned outside the operator's natural sightline. Such mismatches between device affordances and predictable human behavior may shift cognitive burden to clinicians, who must remember workarounds and coordinate ad hoc assistance while maintaining sterility. A contextual inquiry approach is designed to elicit these mismatches; our study demonstrates its value in an acute, invasive procedure where seconds and millimeters matter. The imperative to integrate these insights into formal design controls is clear.

Several concrete implications for device and kit redesign emerge from our contextual findings and accord with human factors guidance that interventions must fit users' capabilities, workflows, and environments to sustain adoption and fidelity [9-12]. The suggested improvements and justifications are mentioned subsequently.

First, rather than perpetuating one-size-fits-all assortments, kits could be organized and sufficiently complete for the intended procedure and patient mix, thus minimizing secondary searches and redundant openings so that routinely needed sterile flushing media, local anesthetic, echogenic introducer needles of adequate length for patients classified as obese, and valve connectors compatible with local infusion hardware become immediately available; these specific component choices derive from our observations, whereas the general mandate to reduce cognitive and physical load is articulated in human-centered design literature [9,12].

Second, because the procedure advances in a sequential order, CVC kit components should be packaged in the same order to reduce cognitive burden. High-risk elements could incorporate salient visual and tactile affordances such as blood-tolerant depth markings on guidewires, textured feeders that signal advancement, and color-contrasted dilators that cannot visually disappear against drapes, an approach consistent with human factors recommendations to engineer cues that support rapid, accurate action under stress [12].

Third, ultrasound ergonomics require particular attention: practice reviews emphasize that the operator should keep the puncture site, needle, and image within a single line of sight, yet we repeatedly observed monitors positioned laterally or behind the user, encouraging awkward posture and one-handed aspiration [9-11].

Fourth, because maintaining stability of the introducer needle at the insertion site is critical, there is an opportunity for a device that minimizes hand movement or stabilizes the ultrasound probe during vessel access.

Fifth, converging evidence from simulation and ergonomic assessments shows that suboptimal screen and table positioning increases musculoskeletal strain and facilitates needle advancement errors, especially among novices, supporting the design of articulating mounts, probe-holding accessories, and workstation layouts that free the dominant hand and keep the image within the operative field [10-12].

Sixth, additionally, as insertion components are introduced sequentially, combining the components associated with adjacent actions into a single integrated unit would significantly simplify the procedure.

Seventh, as threading the dilator over the guidewire is related to a risk of kinking, a device may reduce or eliminate the need for over-the-wire threading while reducing the risk of guidewire kinking.

Eighth, patient experience is also inseparable from considerations of safety. Drapes that blanket a conscious patient's face created anxiety and impeded airway access, whereas Trendelenburg positioning with head rotation was difficult to sustain, particularly for individuals classified as obese, who then required additional supplies and time. Our observations suggest that rethinking drape architecture to permit facial exposure without compromising sterility and integrating oxygen delivery ports or transparent windows could mitigate claustrophobia and facilitate airway monitoring.

Because CLABSI remains among the costliest hospital-acquired infections on a per-case basis, the marginal gains from such design tweaks may translate into substantial economic and human benefit when scaled across millions of annual insertions [13]. Even in the era of prevention bundles, catheter dwell time remains a potent infection driver; CLABSI rates in one 2-year adult cohort climbed from 4.80 to 8.64 per 1000 catheter days as dwell exceeded 20 days, with multidrug resistant *Acinetobacter baumannii* predominating, mirroring some of our concerns that missing components, repeated kit openings, and ad hoc maintenance steps prolong setup and line life, thereby compounding exposure to contamination [14]. It has been previously emphasized that complication profiles can hinge on site choice, catheter caliber, and positioning—adult data (eg, 3SITES study) link subclavian access to fewer infections but more pneumothoraxes, whereas pediatric series show different risk patterns—and it has been reiterated that neutral rather than exaggerated positioning and meticulous ultrasound use can reduce failed passes and arterial hits, resonating with our field notes on stressful needle advancement angles, off-axis screens, and repeated punctures at the point deemed to be of the highest stress [15]. Other recommendations also somewhat align with our design proposals: select the smallest necessary lumen count;

XSL•FO
RenderX

favor nontunneled catheters for fewer than 3 to 4 weeks and peripherally inserted central catheters when therapy exceeds 6 days; cap prolonged catheterization (approximately 14 days) to curb bacteremia; and mandate real-time ultrasound, chlorhexidine alcohol preparation, and daily site surveillance [16]. These were practices that our contextual inquiry somewhat related to and found were variably executed or actively hindered by kit incompleteness, unclear layer sequencing, and drapes that compromise both sterility and patient comfort. In a simulation of 40 anesthesia providers, patient safety (mean importance score 83.9/100), ease of use (mean score 64.6/100), and reduced clinician error (mean score 61.1/100) topped the selection criteria. A novel CVC system with a sequentially organized tray, enhanced labeling, and a guidewire funnel earned significantly higher scores for satisfaction overall, ease of use, layout, and safety ($P \leq .01$ in all cases) and reduced 5 of 7 common risks (including clinician error and contamination or infection), aligning with the usability deficits (wire kinking, component hunting, and ambiguous tray hierarchy) that our study catalogued [7].

This study also highlights how waste and sharps handling were downstream consequences of kit design. The absence of designated receptacles for used guidewires and scalpels, the lack of sharps holders integrated into trays, and the routine opening of multiple kits for a single missing part create biohazard exposure and substantial nonrecyclable waste. While our qualitative approach did not quantify environmental impact, other health systems work has emphasized the financial and ethical importance of reducing unnecessary disposables; therefore, future prototypes should embed closed-loop sharps to capture and minimize redundant components to support infection prevention and sustainability goals simultaneously. This inference from our data warrants targeted life cycle and cost analyses in subsequent studies.

Viewed through the intersecting lenses of safety, efficacy, and usability for patients, providers, and products, our findings provide the basis for an argument that a device ecosystem should simultaneously consider the precepts mentioned subsequently.

The first precept is to shield patients from infection, vessel injury, and the cascade of “extra” procedures (intubation and deep sedation) by shortening setup and puncture time and by making correct J-wire orientation and tip control essentially foolproof.

The second precept is to protect clinicians from sharps and blood under tension, awkward postures, and protocol drift by embedding ergonomic grips; one-handed aspiration aids; and closed, labeled receptacles that keep contaminated instruments off ad hoc trays.

The third precept is to streamline the product itself with sequential, memory-light assembly; color and texture coding; and built-in safeguards (eg, wire funnels, depth markings visible through bloodied gloves, and lockable sharps wells) that are robust and attuned for real-world conditions such as low light; urgent timelines; moving patients; and gloved, fatigued hands. In effect, an intuitive kit that aligns with predictable human behavior and eliminates unnecessary multistep detours can reduce novice failure rates, cognitive load, and practice inconsistency, just as it could serve to curb nonrecyclable waste from “backup” kits opened for a single missing item.

By reframing CVC systems as sociotechnical solutions rather than static assortments of parts, the same design moves that minimize improvisation and coordination errors for physicians also reduce dwell time and manipulation events for patients, thereby advancing the core triad of safety, procedural efficacy, and everyday usability.

Limitations

Our findings should be interpreted considering several limitations. This study was conducted in 3 US hospitals and included 19 observations and 24 interviews, which constrains generalizability, particularly to resource-limited settings or institutions that use different kit vendors. Although we captured real procedures, observer presence and video recording may have altered behavior, and some demonstrations on simulated patients cannot fully reproduce the stressors of an emergent cannulation. We did not measure clinical outcomes linked to the specific use problems we identified, nor did we quantify cognitive load or musculoskeletal strain. Furthermore, our sample comprised physicians; nurses, technicians, and infection preventionists often influence setup, maintenance, and postplacement care, and their perspectives warrant inclusion in a fuller systems analysis.

Conclusions

Future work should transition from description to intervention. Rapid-cycle prototyping informed by these contextual insights, followed by high-fidelity simulation and usability testing in accordance with relevant guidelines, could generate validated design changes. Eye tracking, motion capture, and workload assessment tools may quantify how redesigned components alter gaze patterns, posture, and error rates. Multicenter trials comparing integrated, human-centered kits with current products could measure effects on insertion time, complication rates, waste generation, and cost. Furthermore, translating these methods to maintenance phases, including line access and dressing changes, could extend human factors benefits beyond placement to the complete catheter life cycle.

By examining how clinicians place central lines, this study reveals modifiable design flaws that perpetuate risk despite decades of procedural standardization. Contextual inquiry provides the evidentiary bridge between clinical imperatives to reduce complications and the practical realities of device use. Embedding such investigations at the outset of design and iteratively throughout product life cycles offers a path toward safer, more efficient, and more humane central venous access for both patients and providers.

Abstract

Background: Mobile device–enabled interventions known as digital therapeutics (DTx) are increasingly used to prevent chronic disease by targeting psychological and behavioral processes. Individuals' unique experiences while receiving DTx comprise real-world evidence (RWE) for evaluating DTx performance. An emerging strategy for early-stage DTx formative work uses small sample sizes, which facilitate efficient iteration and agile learning, while evaluating performance against descriptive benchmarks defined a priori, therefore minimizing the risk for confirmation bias. This study test benchmarks from the DTx RWE framework to formatively evaluate a novel DTx (the eMOTION study) to enhance affective response (ie, how people feel) during physical activity (PA).

Objective: This study aimed to determine whether the eMOTION DTx met a priori benchmarks for safety (<1% of participants report an adverse event), plausibility (≥51% of participants experience increased enjoyment in PA), usability (eg, ≥51% of participants report adequate usability), sustainability, feasibility (eg, <70% of participants report dissatisfaction), and equity (equity and accessibility are approximately equal across subgroups).

Methods: Participants (N=36; mean age 46, SD 14 years; 20/37, 54% female) underwent stratified random assignment to test one of four DTx versions for 14 days (n=9 each): (1) intensity PA goals, (2) affect PA goals with type and context recommendations, (3) affect PA goals with savoring exercises, and (4) affect PA goals with type, context, and savoring. Participants completed daily intervention sessions, asking them to focus on achieving a target heart rate (intensity) or feeling good (affect) during PA. Smartwatches were used to track PA and answer ecological momentary assessment (EMA) questions about how they felt during PA. Performance toward benchmarks was primarily assessed via official Institutional Review Board reporting channels (safety), interviews (plausibility, accessibility, and usability), and questionnaires (System Usability Scale [usability], Delighted-Terrible Scale [sustainability and feasibility], and equity).

Results: The eMOTION DTx versions exceeded all a priori safety, plausibility, accessibility, usability, sustainability, feasibility, and equity thresholds. For safety, no adverse events were reported. Regarding plausibility, more than half of the participants who received affect goals reported increased PA enjoyment at the end of the study. Moreover, 64%-72% (23-26 out of 36) of participants rated the DTx at or above the standard System Usability Scale cutoff point for acceptable usability. More than 60% (22/36) of

XSL•FO
RenderX

participants reported satisfaction with all DTx components, supporting DTx sustainability and feasibility. Finally, there was evidence for equity, with plausibility and accessibility comparable across sex, race, ethnicity, income, age, BMI, mobility, and physical constraint subgroups.

Conclusions: Since DTx RWE Framework benchmarks for safety, plausibility, accessibility, usability, sustainability, feasibility, and equity were largely met, the eMOTION Study DTx is ready for a full-scale efficacy trial to refine the DTx and optimize efficiency and feasibility. Our approach incorporated transparent decision-making to generate results that are more readily translatable, easily replicable, and reflect current best practices in the field of DTx.

Introduction

Digital Therapeutics

Widespread smartphone ownership and expanded wearable device capabilities have steadily facilitated a paradigm shift in health care delivery. The medical system has traditionally used in-person examinations and pharmaceuticals to detect, treat, and manage chronic diseases. However, such diagnostic care is incredibly costly—with global spending projected to reach US $47 trillion by 2030—and inefficient, given that many noncommunicable diseases are potentially avoidable via behavior modification [1]. While clinicians counsel patients about the importance of a healthy lifestyle for mitigating chronic disease risk, compliance with preventive care recommendations remains low. Digital therapeutics (DTx)—mobile device software systems that deliver evidence-based behavioral intervention packages to treat or prevent disease in real-world environments—are poised to complement and improve upon these efforts. For example, DTx can extend preventive care beyond the clinic by facilitating behavior change in daily life and empowering patients to monitor their own progress. High-resolution digital treatment evaluation data collected by DTx serve as real-world evidence (RWE) that can be used for efficient performance assessments during research and development. Even as forecasts show a DTx market compound annual growth rate of 27.2% until 2030 [2], the transition from DTx research and development to regulatory testing and public release remains disjointed and inefficient.

Benchmark-Driven Formative Testing as a Rigorous Approach to Early-Stage DTx Development

DTx involves complex sociotechnical systems with multiple interdependent components—user interfaces, behavioral protocols, technical infrastructure, and human-technology interactions—each of which must function adequately for the intervention to succeed. Failure to establish a robust foundation across all these components before initiating large-scale trials substantially increases the risk of type III error, wherein a study is conducted rigorously but fails to test what it intended to test because the intervention itself was inadequately developed or the control condition was poorly specified.

Traditional approaches to early-stage DTx research face a methodological paradox: formative studies must remain small to enable rapid, resource-efficient learning and iteration; yet, small sample sizes preclude the use of inferential statistics with adequate statistical power. This creates a problematic situation where researchers either (1) inappropriately apply underpowered inferential tests that are likely to produce unreliable results, or (2) rely solely on qualitative interpretation of descriptive results, which introduces substantial risk of confirmation bias, the well-documented human tendency to interpret ambiguous data in ways that confirm preexisting beliefs and expectations.

To address this methodological challenge, leading experts in behavioral intervention science and DTx development have advocated for benchmark-driven formative testing as a rigorous alternative approach. This methodology, articulated in frameworks such as the Obesity-Related Behavioral Intervention Trials (ORBIT) model for behavioral intervention development and Phase II of the DTx RWE Framework, establishes a priori performance thresholds that can be evaluated using purely descriptive statistics while maintaining scientific rigor [3].

The Logic of Benchmark-Driven Formative Testing

Benchmark-driven formative testing addresses 4 fundamental tensions in early-stage intervention research.

First, the need for efficient learning requires small sample sizes that enable rapid iteration cycles and resource-efficient exploration of intervention components, implementation strategies, and potential adaptations for diverse populations. Large trials are essential for establishing generalizability, but they are inappropriate tools for the formative work of intervention refinement.

Second, the inappropriateness of underpowered inferential statistics in small samples is well established. When sample sizes are insufficient for adequate statistical power, *P* values become unreliable indicators of true effects, CIs become too wide to be informative, and the risk of both false positives and false negatives increases substantially. Running inferential statistics on samples of N=30-50 participants typically yields a power of 0.20-0.40 for detecting medium effect sizes—well below the conventional 0.80 standard. In such contexts, null hypothesis significance testing provides an illusion of rigor while actually undermining the validity of conclusions [4,5].

Third, the risk of confirmation bias affects all human judgment, including scientific interpretation. Without prespecified criteria

XSL•FO
RenderX

for success, researchers may unconsciously interpret ambiguous results favorably, seeing "promising trends" or "encouraging patterns" that align with their hypotheses. This risk is particularly acute in small samples where data can appear to support multiple narratives depending on how one frames the analysis.

Fourth, the distinction between statistical and clinical significance is critical but often conflated. A statistically significant finding may have minimal real-world impact, while a clinically meaningful effect may not reach statistical significance in an underpowered study. Effect sizes, minimal clinically important differences (MCIDs), and practical significance must be considered alongside *P* values; yet, traditional null hypothesis testing frameworks prioritize statistical significance over substantive meaningfulness [6].

How Benchmarks Address These Tensions

A priori establishment of benchmarks addresses all 4 tensions simultaneously.

Enabling Small, Efficient Samples

Because benchmarks can be evaluated descriptively (eg, "did 51% of participants report increased PA enjoyment?"). They do not require the large samples necessary for adequate statistical power. This enables formative studies to remain small enough for rapid iteration while still providing clear, interpretable evidence about intervention performance.

Avoiding Inappropriate Statistical Tests

Benchmark evaluation relies on descriptive statistics—percentages, frequencies, and comparisons to predetermined thresholds—rather than inferential tests. This eliminates the problems associated with underpowered hypothesis testing while still providing rigorous evaluation criteria relevant for formative work within small sample sizes.

Minimizing Confirmation Bias

By establishing success criteria before data collection, benchmark approaches create an objective standard against which results must be evaluated. If the benchmark specifies that ≥51% of participants must report increased PA enjoyment, then 45% represents clear failure to meet the criterion, regardless of how "close" it might feel or how researchers might be tempted to interpret it favorably. The threshold is predetermined and nonnegotiable.

Centering Clinical Meaningfulness

Benchmarks are explicitly designed to reflect what would constitute meaningful real-world impact, not merely statistical detectability. For example, in our study here, a 51% threshold for plausibility reflects the expectation that an intervention should benefit the majority of recipients—a clinically meaningful standard that is independent of sample size or statistical power considerations. Benchmarks can incorporate established MCIDs, align with clinically significant thresholds from previous literature, and balance what is both meaningful and plausibly achievable given the current state of the science.

Benchmark Selection and Justification

Rigorous benchmark-driven research requires that thresholds be established through a systematic process that balances clinical meaningfulness with plausible achievability based on previous evidence. Given the novelty of this line of work, our team developed benchmarks that have an initial plausibility of balancing both ambition and likelihood of being observed. While these benchmarks were not explicitly based on previous literature—due to the lack of extant work—they represent a potential baseline that others can improve upon in future proof-of-concept trials.

The process of benchmark development should be transparent and documented, ideally through preregistration, to ensure that thresholds are truly a priori rather than post hoc. In our study, benchmarks were established before data collection and documented in our preregistered analysis plan on Open Science Framework [7].

Interpreting Benchmark Results

Critically, results from benchmark-driven formative studies must not be interpreted as generalizable to broader populations. Meeting benchmarks indicates that an intervention has achieved a sufficient foundation to warrant progression to the next development phase, but it does not establish external validity or population-level efficacy or effectiveness. Those determinations require adequately powered randomized controlled trials with representative samples.

Instead, benchmark-driven formative testing serves a specific purpose in the intervention development pipeline: to establish whether all essential components of an intervention function adequately, whether the intervention can be delivered as intended, whether it demonstrates sufficient signal of benefit to justify further investment, and whether potential implementation barriers can be identified and addressed before committing to large-scale testing. This is analogous to Phase I/II trials in pharmaceutical development, which establish safety, dosing, and preliminary efficacy signals before proceeding to Phase III confirmatory trials.

Meeting formative benchmarks provides evidence that an intervention is "ready" for larger-scale testing—that the foundation is sufficiently solid that a properly powered trial can be conducted without high risk of Type III error. Failing to meet benchmarks indicates that further refinement is needed before proceeding, thereby protecting against the waste of resources on large trials of interventions that are not yet adequately developed.

Rigor in Formative Research

The methodological rigor of formative research is achieved not through the application of inferential statistics to underpowered samples, but through:

1. Systematic benchmark establishment grounded in previous literature and clinical meaningfulness.
2. Prespecification and transparent documentation of all benchmarks before data collection.
3. Comprehensive assessment across multiple domains (safety, plausibility, usability, feasibility, and equity).

XSL•FO
RenderX

4. Objective evaluation of whether benchmarks were met using descriptive statistics.
5. Honest interpretation that acknowledges the formative, nongeneralizable nature of findings.
6. Iterative refinement based on benchmark performance before proceeding to larger trials.

This approach represents a methodologically sound framework for early-stage intervention development that avoids the false precision of underpowered inferential testing while maintaining scientific rigor through prespecified, clinically meaningful evaluation criteria. As Czajkowski and colleagues [3] note in their comprehensive guide to behavioral intervention development, early-stage work should prioritize intervention optimization, rather than hypothesis testing—a fundamentally different scientific objective that requires different methodological tools.

By embracing benchmark-driven formative testing, the field can conduct more rigorous early-stage research that provides a robust foundation for subsequent confirmatory trials. Ultimately, to improve the quality and efficiency of the entire intervention research-to-development pipeline, such early-stage work should systematically and iteratively assess DTx using real-world RWE. The DTx RWE Framework recently proposed by Kim and colleagues [8] incorporates RWE-guided decision-making against benchmarks congruent with existing regulatory standards throughout the DTx lifecycle. The Framework's step-by-step process aims to streamline the research and development-regulatory testing-public release process, facilitate greater transparency, and produce DTx that reflect current best practices and are more readily translatable to real-life settings. This has important public health implications, as emerging DTx are poised to collectively reduce health care burden and expand access to high-quality care via tailoring algorithms that deliver personalized and precise multicomponent treatment [9]. This study applied principles from the DTx RWE Framework in conducting benchmark-driven formative testing of an early-stage DTx intervention to enhance affective response during physical activity (PA) among physically inactive adults with overweight or obesity.

This Study

Overview

Inadequate PA engagement (ie, <150 min/week of moderate intensity physical activity [MPA]) confers substantial risk for a variety of chronic diseases, including cancer [10]. Despite widespread public health initiatives—and many individuals reporting a desire to become more physically active—less than 5% of adults actually meet the ≥150 minute/week MPA threshold [11]. Interventions targeting social-cognitive factors (eg, self-efficacy, intentions, and beliefs) have had limited success, accounting for only 31% of the variability in PA engagement [12-15]. This PA intention-behavior gap suggests that noncognitive factors might be hijacking people's best intentions to engage in PA [16]. According to the theory of hedonic motivation, humans are naturally drawn to activities that are pleasurable and avoid unpleasant activities [17]. Previous affective responses to a given behavior inform the development of affectively charged motivations to pursue or avoid the behavior in the future [18]. People with overweight or obesity are more likely than individuals of a healthy weight to experience pronounced negative affect (eg, discomfort) while engaging in PA, therefore decreasing the likelihood they will consistently engage in PA [19].

Factors that are potentially readily modifiable, such as PA intensity, type, and context, have been shown to be significant predictors of the affective response during PA. For example, most people experience pleasure when engaging in low-intensity PA and displeasure while engaging in vigorous-intensity PA [20], but affective responses to MPA are heterogeneous [21]. At moderate intensities, affective responses might be determined by the type (eg, hiking and dancing) or context (eg, being with others and outdoors) of PA [22-25]. Ultimately, affective responses vary inter- and intrapersonally and impact future PA behavior—but whether they can be experimentally manipulated to promote PA engagement in the real world remains unknown [26,27].

Developing a DTx Solution

Therefore, an existing DTx called MyDayPlan was modified to experimentally manipulate affective mechanisms associated with MPA among physically inactive adults with overweight or obesity. MyDayPlan has previously increased PA engagement in similar populations by leveraging self-regulation strategies posed by the Health Action Process Approach [28]. Specifically, smartphone sessions provide daily PA goals and prompt participants to plan how, where, and when they will accomplish the goal (action planning), identify potential barriers and solutions (coping planning), and monitor their goal progress (self-monitoring) [29]. In its original form, MyDayPlan provided goals focused on sustaining a certain intensity of PA (ie, "intensity-based goals"). The eMOTION Study incorporated affect-based PA goals and enhancements to modify affective mechanisms related to PA into MyDayPlan's existing self-regulatory framework. New affect-based goals asked participants to engage in PA types and contexts that would allow them to experience positive affect (eg, enjoyment) during PA. We hypothesized that participants who received affect-based goals would report more positive affective experiences during PA than participants who received intensity-based goals, which asked participants to attain a target heart rate. Iterative internal testing among research team members was performed to achieve a minimum viable product with a functioning interface, error-free programming, and a reasonable time burden.

Benchmark-Driven Formative Testing

Next, following guidance from Phase II of the DTx RWE framework, SMART (specific, measurable, actionable, realistic, and timely [or time-bound]) benchmarks were defined (Textbox 1). Benchmarks required the DTx to reach safety, plausibility, accessibility, usability, sustainability, feasibility, and equity standards during a formative study before initiating a resource-intensive Comparison Study to test efficacy. Broadly, benchmarks ensured that the DTx was unlikely to cause harm (ie, safety); the affect-based goals were associated with greater PA enjoyment compared to the intensity-based control (ie, plausibility); and the DTx was easy to use (ie, accessibility and usability); and practical for study staff and participants to sustain

XSL•FO
RenderX

over time (ie, feasibility and sustainability). We also explored whether DTx plausibility and accessibility were approximately equal for all participants, regardless of individual-level traits (ie, equity; this benchmark was exploratory and not statistically powered). This paper summarizes results from benchmark-driven formative testing of the eMOTION DTx by measuring performance against these a priori established benchmarks.

Textbox 1. eMOTION Formative Study SMART (specific, measurable, actionable, realistic, and timely [or time-bound]) benchmarks.

Safety:

- Only <1% of Formative Study participants will experience an adverse event.

Plausibility:

- The majority of participants (ie, ≥51%) receiving affect-based goals will report a perceived increase in enjoyment of physical activity at the end of the study.

Accessibility and usability:

- The daily intervention sessions and Fitbit smartwatch features will receive an average score at or above the System Usability Scale cutoff point (≥68).
- The majority of participants (ie, ≥51%) will report that they are able to (1) read the wording of the survey questions, (2) understand the wording of the survey questions, (3) select their answers for the survey questions, and (4) use the exercise settings on the Fitbit Versa smartwatch.
- The majority of participants (ie, ≥51%) will report being able to (1) read and (2) understand the daily intervention sessions on their phone.
- Participants will be given physical activity recommendations that appropriately consider their reported constraints.
- The majority of participants (ie, ≥51%) who remember receiving savoring questions will report being able to understand and follow them.

Sustainability and feasibility:

- The auto-detection algorithm for physical activity will correctly trigger event-contingent ecological momentary assessment (EMA) prompts ≥51% of the time.
- Less than 25% of participants will need to be sent a new Fitbit due to technical issues.
- A total of <70% of participants will report feeling dissatisfied with the Fitbit Versa (1) exercise settings, (2) prompt notifications, and (3) prompt burden.
- In addition, <25% of participants will be sent repeated (ie, >1) reminders to open their Fitbit app and sync their study data.
- Moreover, <70% of participants who remember completing daily intervention sessions will report feeling dissatisfied with the daily intervention sessions.
- Additionally, <70% of participants will report feeling dissatisfied with the Fitbit app.
- In total, <70% of participants who remember receiving physical activity recommendations will report feeling dissatisfied with the physical activity recommendations.
- Furthermore, <70% of participants who remember receiving savoring questions will report feeling dissatisfied with the savoring questions.

Equity:

- Plausibility and accessibility of the eMOTION Intervention will be approximately equal between groups (ie, sex, race, ethnicity, age, BMI, income, mobility, and physical constraints).

Methods

Study Design

A 3-week formative study was used to test DTx RWE Framework benchmarks. Treatment components targeting intensity-based goals and affect-based goals were examined separately in different groups of participants. Stratified random assignment placed participants (N=36) into one of four groups (n=9 each): (1) intensity-based goals, (2) affect-based goals with the type and context enhancement, (3) affect-based goals with the savor enhancement, and (4) affect-based goals with type, context, and savor enhancements. Published recommendations for proof-of-concept and formative studies using similar measures to our own support the use of homogenous samples as small as 5 to 10 subjects per user group [30-32]. Our sample (n=9 per group) precludes comparisons via inferential statistics, but corresponds with current best practices by prioritizing efficient iterations central to early-stage work—and is ultimately still amenable to descriptive statistics to determine whether the DTx meets preliminary benchmarks. Strata within each condition were based on age (ie, <45 vs ≥45 years), sex at birth (ie, male vs female), and BMI classification (ie, those with overweight vs those with obesity) to allow for approximately equal numbers of subgroup participants within each treatment group. The study was triple-blinded so that participants, research staff interacting with participants, and statisticians conducting analyses were all unaware of group

XSL•FO
RenderX

assignment. Methods were preregistered in Open Science Framework [7].

Participants

Rolling recruitment occurred from September 2023 to March 2024 via ResearchMatch, a national health volunteer registry created by academic institutions and supported by the National Institutes of Health as part of the Clinical Translational Science Award program. An online screener assessed participant eligibility. The eligibility criteria are shown in Textbox 2.

Textbox 2. Eligibility criteria.

Inclusion criteria were as follows:

- Ages 18 years and older.
- Residing in the United States.
- BMI ≥ 25 kg/m^2.
- Current engagement in ≤60 minutes of structured physical activity (PA) per week.
- Smartphone ownership.
- Residing in an area with Wi-Fi connectivity.
- Able to speak and read English.
- Interested in starting a PA program.
- Willing to wear a smartwatch every day.
- Able to read the small font on a smartwatch screen.

Exclusion criteria screened out individuals who:

- Had cognitive disabilities precluding participation and/or the ability to provide informed consent.
- Had physical disabilities or medical issues limiting PA engagement.
- Were unable or unwilling to wear a smartwatch.
- Were currently pregnant.

Ethical Considerations

All procedures were conducted remotely, and approval was provided by the University of Southern California Institutional Review Board (ID UP-22-00332). Eligible individuals provided written informed consent to participate in study procedures. Data were not deidentified or anonymized, so a number of protections were implemented to maintain participant privacy and confidentiality. These included the use of pseudonyms in place of names to organize study records, as well as the storage of data on secure databases and encrypted university servers. Participants were compensated up to US $75 for completing all study procedures.

Procedures

Following informed consent, participants completed a baseline questionnaire via REDCap (Research Electronic Data Capture; Vanderbilt University) [33,34]. Onboarding included a 1- to 3-day trial that was “passed” by completing two brief text message surveys within a single day. Participants who “passed” the trial received a Fitbit Versa 3 smartwatch in the mail and attended a 45-minute orientation session to learn about participation activities, finish technological setup, and review a PA guidebook. For the first week of the study, assessment components (eg, Fitbit smartwatch monitoring and check-ins) were introduced gradually. Then, for the following 2 weeks, participants engaged in the full DTx. Participants were asked to wear the smartwatch on their nondominant wrist for ≥23 hours/day. Smartwatch-based ecological momentary assessment (EMA) prompts (ie, “check-ins”) were delivered during PA sessions to measure affective responses to PA. EMA is a methodology involving brief repeated surveys that capture subjective experiences as they unfold in real time [35]. Participants were also instructed to press an exercise button on the smartwatch before starting a planned PA session. Researchers performed remote monitoring of participant compliance and contacted participants if missing data were detected in the study server. Finally, an exit interview and poststudy questionnaire collected feedback relating to the formative study’s SMART benchmarks.

DTx Intervention

The eMOTION DTx was a multicomponent treatment package that was delivered under unsupervised, real-world settings and included the following elements.

PA Guidance and Scheduling

Participants were given a prescription to start at their own pace and comfort level, slowly increasing MPA volume over the course of the study. Because PA was performed asynchronously, a digital guidebook was provided as a reference summarizing strategies to gauge PA intensity and proper warm-up and cool-down procedures. Additionally, on Sundays, participants completed a smartphone-based scheduling survey by indicating the days they intended to engage in PA for that upcoming week.

XSL•FO
RenderX

Daily PA Goal Sessions

On days participants reported they intended to engage in PA, they completed 2 smartphone-based interactive intervention sessions: one in the morning and one in the evening. A text message push notification and up to 4 reminder notifications (once per hour) with a REDCap link alerted participants to complete each session. Morning sessions were scheduled for 6 AM local time. They provided a PA goal for the day ("goal module") that differed according to the participant's random group assignment. Participants then created a plan ("action plan module") to achieve their goal by specifying details, including the time they planned to engage in PA that day. The final module ("coping plan module") asked participants to anticipate barriers and brainstorm potential solutions to reach their goal. Text messages for evening sessions were sent at 7 PM local time and featured a "self-monitoring module" that asked participants to reflect on whether they met their PA goal.

In the intensity-based goal condition, participants were asked to maintain a target heart rate during PA. Target heart rate was based on the approximate age-adjusted maximum heart rate (HRmax; HRmax = 207 – [0.7 × age]), reflecting 55% HRmax for week one and 60% HRmax for week two. In the affect-based goal condition, participants were asked to engage in a type (25% of daily goals) or context (75% of daily goals; alternating places, social situations, and listening contexts) of PA that they found enjoyable. The instructions were generic to encourage self-selection (eg, "Today, your goal is to try a TYPE of PA that makes the experience more enjoyable while you are doing it").

Enhancements

Participants randomized to receive the type and context enhancement were provided tailored recommendations for PA types or contexts most likely to satisfy their unique psychological needs, as measured at baseline (ie, relatedness, social esteem, individual esteem, creativity, mindfulness, learning, challenge, entertainment, escapism, aesthetic appreciation, and morality). Recommendations were generated by an algorithm trained on data from a crowdsourced panel of adults on Amazon Mechanical Turk who were asked to rate a range of PA types and contexts on the extent to which they satisfied psychological needs. Further details on the algorithm are outside the scope of this paper. Recommendations suggested PA types or contexts matched to the participant's most personally important psychological needs categories and eliminated types and contexts from consideration that coincided with any constraints reported at baseline.

Participants who were randomized to receive the SAVOR enhancement engaged in a brief savoring exercise to enhance the positive emotions experienced during their PA session. Immediately following the morning intervention session, these participants received a text message instructing them to click a REDCap link to complete the savoring exercise after they performed their planned PA session. The savoring exercise was comprised of two open-ended questions about the PA (eg, "Reflect on the most rewarding aspect of your PA session today. What made it feel like a success for you? How did this influence your experience?") and surrounding environment (eg, "Let's take a moment to focus on the environment in which you were active today. Can you describe what you saw, felt, heard, and smelled in that space? What aspects of the environment are you grateful for?").

Measures

Overview of Measures

Study variables evaluating DTx performance for SMART benchmarks were collected via questionnaires, videoconference exit interviews, and EMA. During exit interviews, if the participant's initial response to an open-ended question was too vague, the surveyor followed up with neutrally worded clarifying questions. During response coding for analysis, if any response contained conflicting statements and true clarity could not be achieved, the response was always treated conservatively (ie, biased toward the null hypothesis). Measures are briefly summarized by benchmark type below and are elaborated in detail in Multimedia Appendix 1.

Safety

Safety was assessed by calculating the number of adverse events reported via official Institutional Review Board (IRB) channels, which allow participants and study teams to report events. Participants were given IRB contact information for this purpose during informed consent.

Plausibility

Plausibility was primarily assessed with the following exit interview question: "When comparing your experience with PA before and after participation in the eMOTION Study, do you personally feel as if the degree of enjoyment you feel while engaging in PA changed or stayed the same?" Responses were transcribed, and enjoyment was coded as "decreased" (0), "stayed the same" (1), or "increased" (2).

Accessibility and Usability

Daily Intervention Sessions and Fitbit Smartwatch

The poststudy questionnaire included the 10-item System Usability Scale (SUS) to assess the accessibility and usability of the daily intervention sessions and the Fitbit smartwatch [36]. Participants indicated the extent to which they agreed with each statement using a Likert Scale ("strongly disagree" {0} to "strongly agree" {4}). Negative items were reverse-scored, all items summed, and the sum multiplied by 2.5 to yield a total score ranging from 0 to 100. Items displayed acceptable reliability (Cronbach α=0.78 and 0.91 for daily goals and Fitbit smartwatch, respectively). Participants were also asked investigator-created questions in the exit interview about their ability to read and understand the wording of the daily intervention sessions and check-ins; select their answers for the check-ins; and use the exercise buttons on the smartwatch. Responses were transcribed and coded as "unable" (0) or "able" (1).

Tailored Physical Activity Recommendation Enhancement

Multiple measures assessed the accessibility and usability of type and context recommendations. During the exit interview, participants were asked whether they were "generally able to follow the PA [type and context] recommendations" they

XSL•FO
RenderX

received. Responses were transcribed and coded as "unable" (0) or "able" (1). Reported inability was then considered alongside constraints reported at baseline. Specifically, in the baseline questionnaire, a set of questions asked about constraints related to PA type, location, and listening contexts. Participants indicated their ability to engage in 47 different activity types [37] by selecting as many options as applied for each one: "able to do it," "physically unable to do it," "no place to do it," "no equipment to do it," and "I don't know what this is." For some activities, "no equipment to do it" was not considered a constraint because no equipment was required (eg, bodyweight exercises); for others, "I don't know what this is" did not apply because participants were provided with instructional videos for the activity. Next, participants indicated their ability to access 19 different locations and facilities for PA by selecting "I'm able" or "I don't have access or can't get there" for each. Finally, participants selected "yes" or "no" for whether they were able to listen to music, audiobooks, or other media on their smartphone during PA. The total number of possible constraints across PA types and contexts ranged from 0 to 68.

Savoring Enhancement

Participants were asked during the exit interview whether they were able to understand and follow the savoring exercises. Responses were transcribed and coded as "unable" (0) or "able" (1).

Sustainability and Feasibility

Satisfaction With DTx Components

Most benchmarks for sustainability and feasibility were assessed with the Delighted-Terrible Scale [38,39] in the poststudy questionnaire. Participants were asked to indicate how they felt about the smartwatch exercise settings; check-in notifications and burden; daily intervention sessions; smartphone data syncing procedures; and type, context, and/or savor enhancements, as applicable. Multiple choice options for each item were: "delighted" (8), "pleased" (7), "mostly satisfied" (6), "mixed- about equally satisfied and dissatisfied" (5), "mostly dissatisfied" (4), "unhappy" (3), "terrible" (2), "neutral- neither satisfied nor dissatisfied" (1), and "I never thought about it" (0). Response options "mostly dissatisfied," "unhappy," and "terrible" were considered as dissatisfaction with the given DTx component.

Fidelity of PA Auto-Detection Algorithm

An algorithm triggered check-ins when the smartwatch sensors detected PA engagement via sufficiently elevated 10-minute rolling average heart rate (ie, 55% to 60% of age-adjusted HRmax). Heart rate data from smartwatch sensors were considered alongside Fitabase software prompting records, which contained timestamps associated with the timing of smartwatch check-ins.

Research Staff Burden

Some measures assessed whether DTx-associated workloads were sustainable and feasible for research staff to maintain. A REDCap form was used to track smartwatch inventory and document technical difficulties requiring device replacement. Staff also recorded all instances where they had to remind participants to sync their smartphone data due to >48 hours elapsing without data reaching Fitabase servers.

Equity

To explore equity, the proportions of participants recalling increased PA enjoyment after the study, and rating the daily goals and smartwatch at or above the acceptable cutoff point (ie, SUS score ≥68.0), were compared across sex, race, ethnicity, age, BMI, income, mobility, and physical constraints subgroups (subjective comparisons, given a lack of statistical power). Subgroup data were collected with screening and baseline questionnaires. Sex (male or female), race (White or non-White), ethnicity (Hispanic or non-Hispanic), and income (unsure; ≤US $44,999; US $45,000-$84,999; US $85,000-$124,999; or ≥US $125,000) were directly assessed with single items. Age was calculated as the difference between date-of-birth and baseline questionnaire completion date, then split into quartiles (≤37 y, 38-43 y, 44-58 y, and ≥59 y). BMI was calculated using reported height and weight and coded according to established clinical cutoff points (those with overweight ≤29.9, those with obesity ≥30.0). Mobility was assessed with an investigator-developed measure, which asked participants to indicate the degree to which they agreed with 5 different statements (eg, "I have had trouble bending over") using a 10-point sliding scale with the markers "not at all true" (1), "moderately true" (5), and "completely true" (10). Items were summed into a total mobility score (range 5 [least trouble] to 50 [most trouble]), which was then split into quartiles (≤13.5, 13.6-18.5, 18.6-28.5, and ≥28.6). Finally, for physical constraints, activity types designated as "physically unable to do it" by the participant at baseline were tallied to create a total number ranging from 0 to 47, which was split into tertiles (0, 1-4; ≥5).

Statistical Analysis

The formative study was not statistically powered to test hypotheses using inferential statistics. Rather, as is common for proof-of-concept trials, the sample size was chosen to balance monetary and personnel constraints while allowing the DTx to be applied and assessed in the target population. To minimize confirmation bias and reduce the risk of moving forward with a large-scale phase III comparison study prematurely, descriptive statistics were used to compare formative study evaluation data against a priori benchmarks with clear go or no-go criteria [8]. Sensitivity analyses featuring linear and logistic regression models were performed to compare person-level characteristics between the final sample and participants lost to follow-up. All analyses were performed using IBM SPSS Statistics software (version 29).

Results

Sample Characteristics

A total of 46 participants consented and enrolled in the eMOTION Formative Study. Of these, 9 participants left the study during onboarding and before the intervention: 2 withdrew due to personal obligations (ie, surgery and work demands), 1 was unenrolled due to technical difficulties associated with responding to text message EMA on their personal smartphone,

XSL•FO
RenderX

and 6 were lost to follow-up without explanation (ie, study staff were unable to reestablish contact).

Table 1 provides baseline characteristics for the 37 participants who completed the intervention. This baseline sample was 46% female (n=17), 86% non-Hispanic (n=32), and 86% White (n=32). Mean age was 46.2 (SD 13.4) years. A broad range of household incomes was represented (Table 1). One additional participant in the sample was lost to follow-up after completing the intervention but before the poststudy questionnaire and exit interview. Therefore, a final analytic sample of 36 participants who completed the study and provided at least partial outcome data was retained. Sensitivity analyses confirmed that the final sample did not differ from participants lost to follow-up on the basis of their sex (P=.88), age (P=.82), or BMI (P=.98).

The baseline sample comprised 37 participants, while 36 participants provided at least some information for the main outcomes of interest by filling out the poststudy questionnaire and/or completing the exit interview.

Table 1. Participant characteristics assessed at baseline.

Characteristics	Values
Age (years), mean (SD)	46.2 (13.4)
Sex, n (%)	
Male	17 (46)
Female	20 (54)
Ethnicity, n (%)	
Non-Hispanic	32 (86)
Hispanic	5 (14)
Race, n (%)	
White	32 (86)
Black	4 (11)
Asian	1 (3)
Native American	0 (0)
Pacific Islander	0 (0)
Multiracial	0 (0)
Household income (US $), n (%)	
≤44,999	7 (19)
45,000 to 84,999	9 (24)
85,000 to 124,999	8 (22)
≥125,000	10 (27)
Unsure	3 (8)

SMART Benchmarks

Safety

No adverse events were reported during the study. With 0% of participants experiencing an adverse event, the safety benchmark (<1% of participants) was met.

Plausibility

Of the 27 participants who received affect-based goals, 14 (52%) reported during the exit interview that PA enjoyment increased over the course of the study (ie, comparing enjoyment before the study vs after the study), while 13 (48%) said enjoyment stayed the same. Therefore, the plausibility benchmark was just met (ie, ≥51% recalled an overall increase in enjoyment).

Accessibility and Usability

Daily Intervention Sessions and Fitbit Smartwatch

The daily intervention sessions and Fitbit smartwatch received average total SUS scores of 72.4 (SD 17.2) and 73.1 (SD 22.9), respectively. These scores exceeded the prespecified cutoff point in the SMART benchmarks (ie, ≥68). Post hoc calculations additionally determined that 23 (64%) and 26 (72%) participants rated the daily intervention sessions and Fitbit smartwatch components at-or-above the cutoff point (ie, ≥68). The majority of participants also reported being able to read the smartwatch check-ins (n=34, 97%) and daily intervention sessions (n=34, 97%), understand the check-ins (n=32, 91%) and daily sessions (n=34, 97%), select answers for check-ins (n=33, 94%), and use exercise settings on the smartwatch (n=27, 77%), therefore meeting the associated benchmarks.

XSL•FO
RenderX

Type and Context Enhancement

Although 18 participants received type and context recommendations, 3 did not remember receiving them. Table 2 depicts results from the 15 participants who received and remembered type and context recommendations. There was no discernable relationship between the number of activity constraints and reported ability to follow type and context recommendations, suggesting that the benchmark was met (ie, participants were given PA recommendations that appropriately considered their constraints).

Only data from participants who both received and remembered receiving PA type and context recommendations (ie, n=15) were included in the table. An additional 3 participants received, but did not remember receiving, recommendations; 5 participants incorrectly reported that they received type and context (ie, when they did not receive type and context); these data were excluded from the table.

Table 2. Accessibility of type and context recommendations.

PA[a] constraint quartile	Reported being able to follow recommendations, n/N (%)
1	2/5 (40)
2	1/2 (50)
3	2/4 (50)
4	1/4 (25)

[a]PA: physical activity.

SAVOR Enhancement

Although 18 participants received savoring exercises, 4 did not remember receiving them. Of the 14 participants who received and remembered SAVOR, 12 (86%) reported being able to understand and follow the savoring exercises. Therefore, the associated benchmark (≥51% of participants who remember receiving savoring exercises will report being able to understand and follow them) was met.

Sustainability and Feasibility

Satisfaction With DTx Components

The proportion of participants reporting dissatisfaction with a DTx component (ie, Fitbit smartwatch exercise settings, check-in notifications, and check-in burden; daily intervention sessions; Fitbit app; PA type and context recommendations; and savoring exercises) ranged from 0% (n=0) to 39% (n=14; Table 3). Therefore, the associated benchmarks were met.

Table 3. Proportion of participants reporting dissatisfaction with digital therapeutics components.

Benchmark	Result, n (%)[a]
<70% of participants will report feeling dissatisfied with Fitbit features	
Exercise settings	6 (17)
Check-in notifications	12 (33)
Check-in burden	14 (39)
<70% of participants will report feeling dissatisfied with the Fitbit app	3 (8)
<70% of participants who remember an intervention component will report feeling dissatisfied with it	
Daily intervention sessions[b]	3 (9)
PA recommendations[c]	3 (23)
Savoring exercises[d]	0 (0)

[a]N=36 unless otherwise indicated.

[b]n=34 (2 participants did not remember receiving daily intervention sessions).

[c]n=13 (15 remembered receiving type and context recommendations, but 2 did not respond to the satisfaction item).

[d]n=12 (14 remembered receiving SAVOR, but 2 did not respond to the satisfaction item).

Fidelity of PA Auto-Detection Algorithm

All smartwatch check-ins were correctly sent when the rolling 10-minute average heart rate crossed the threshold specified in the algorithm (ie, 55%-60% HRmax). Therefore, the triggering algorithm achieved 100% accuracy and met the threshold (ie, the algorithm triggered smartwatch check-ins correctly ≥51% of the time).

Research Staff Burden

No replacement Fitbit smartwatches were sent out to participants due to technical issues; therefore, the meeting did not meet the associated benchmark (ie, <25% of participants needed a new Fitbit due to technical issues). Additionally, only 6/36 (ie, 17%) participants were sent a single reminder to sync their Fitbit data to their smartphone, and no participants (ie, 0%) required more than one reminder. Therefore, the benchmark (<25% of

XSL•FO
RenderX

participants will be sent repeated [>1] reminders to open their Fitbit app and sync their study data) was met.

Equity

Results for the equity benchmark are summarized in Table 4. Values are the proportion of participants in each subgroup who reported increased PA enjoyment and who scored the daily goals and Fitbit smartwatch at or above the accessibility and usability cutoff point. Cell sizes were too small to use chi-square tests between groups. Subjective comparisons generally suggested equal proportions across group levels, with a few notable exceptions. First, plausibility differed by sex, with 64% (n=9) of women reporting increased enjoyment during the study compared to only 38% (n=5) of men. Additionally, non-White participants reported greater accessibility, usability (4/5 to 5/5, 80%-100% vs 19/31 to 21/31, 61%-68%), and plausibility (3/4, 75% vs 11/23, 48%) compared to White participants. Accessibility and usability were comparable across all income categories except for the highest income group, 90% (9/10) of whom rated the daily goals and Fitbit smartwatch at-or-above the cutoff point (compared to 3/6 and 4/8, 50% to 6/9, 69% in the other groups). Finally, accessibility, usability, and plausibility were lowest among individuals reporting the most physical constraints compared to those reporting fewer than 5 constraints or no constraints, as well as those reporting greater mobility impairment.

In Table 4, proportions and percentages for accessibility and usability reflect participants who scored the daily intervention sessions and Fitbit smartwatch, respectively, at-or-above the System Usability Scale cutoff of 68. Proportions and percentages in the plausibility column are the participants in the affect-based groups who reported increased PA enjoyment over the course of the study. A total of 36 completed the accessibility and usability items in the poststudy questionnaire, and 35 completed the plausibility item in the exit interview. Cell sizes were too small to conduct chi-Square comparisons, so potential group differences were subjectively assessed.

Discussion

Principal Findings

The novel eMOTION DTx was systematically designed, developed, and formatively tested according to benchmarks recommended by the DTx RWE Framework. Multiple evidence-based intervention components were integrated to address the problem of inactivity due to low PA enjoyment among adults with overweight or obesity. Daily digitally interactive intervention sessions featured Health Action Process Approach self-regulatory strategies (ie, action planning, coping planning, and self-monitoring) to encourage attainment of PA goals [28]. Affect and Health Behavior Framework mechanisms, including affective responses during PA, were targeted with affect-based PA goals, as well as through two intervention enhancements [40]. The type and context enhancement involved a tailoring algorithm that generated recommendations for specific types and contexts of PA likely to satisfy personally relevant psychological needs. This was informed by a body of evidence demonstrating that the degree of importance ascribed to higher-order psychological needs varies between-persons

XSL•FO
RenderX

[41-44], as well as by our preliminary work suggesting that various PA types and contexts differentially satisfy psychological needs and enhance positive affect during PA [45,46]. The SAVOR enhancement leveraged savoring exercises to intensify the influence of affective responses on PA [47,48]. Savoring is a mindfulness practice that enhances the saliency of positive experiences via attentional deployment and gratitude-making [49,50]. The DTx underwent rigorous internal testing and iterative refinements during phase I to arrive at a minimum viable product for application in phase II.

Principal Results

SMART benchmarks determining success were defined a priori to maximize transparency and preregistered in accordance with open science best practices. Final benchmark results fully supported the safety and plausibility of the eMOTION DTx. Standards for safety and plausibility are considered the most important to uphold, with the Food and Drug Administration's various approval routes all requiring new medical devices to demonstrate sufficient safety and efficacy before public release.

Findings also confirmed eMOTION DTx accessibility and usability. Accessibility and usability were assessed for multidevice (ie, smartphone and Fitbit smartwatch) user interface, study-related functions, and specific intervention content based on previous work, underscoring the importance of these areas for participant engagement and intervention delivery [51-53]. While objective sustainability and feasibility benchmarks were all met, minor real-time iterative adjustments were made to decrease smartwatch check-in burden in response to participant feedback. Early into formative testing, many participants reported receiving a high volume of check-ins throughout the day that were only meant to be received during PA sessions. To increase the specificity of the algorithm (ie, improve differentiation between low-intensity lifestyle activities and structured MPA sessions), the original heart rate threshold (ie, 10-minute rolling average ≥50% HRmax) was increased to 55% HRmax.

In an effort to increase the validity of accessibility, usability, sustainability, and feasibility feedback, participants were asked whether they remembered receiving each of the intervention components (ie, daily intervention sessions, PA recommendations, and savoring exercises). Terminology for these questions was consistent with that used during onboarding and throughout all study materials. Only those who received and remembered receiving a given component were included in the respective analysis. Interestingly, we found that some participants had forgotten the intervention components they received during the study (ie, 2 did not remember receiving daily goal intervention sessions; 3, the tailored PA recommendations; and 4, the savoring exercises). This same general phenomenon has been described by other researchers engaging in complex, multicomponent interventions, in which participants fail to retrospectively identify—or otherwise misremember or misunderstand—critical aspects of the study [54,55]. By comparing objective study records with participant self-reports, we were able to control for this form of information bias [56].

Finally, equity in accessibility, usability, and plausibility was generally observed (via subjective comparisons) across sex, race, ethnicity, income, age, BMI, mobility, and physical constraints subgroups, although notable discrepancies did arise. First, a greater proportion of women reported increased PA enjoyment during the study compared to men. Previous work presents conflicting evidence for whether men or women are more likely to enjoy PA [57,58]. However, our findings might reflect those of others that consistently suggest the presence of sex-based differences in the relevance and plausibility of mHealth interventions for PA. Specifically, women are more likely to use PA-tracking mHealth apps [59], report using PA apps for the purpose of enjoyment [60], and experience more positive health outcomes following PA mHealth interventions compared to men [61]. DTx accessibility, usability, and plausibility also differed by race, but—contrary to what might be expected—favored non-White participants. This result is likely unreliable due to imbalanced cell sizes (ie, 31 White and 5 non-White) and was not necessarily a cause for concern, as the DTx was more accessible, usable, and efficacious for the traditionally disadvantaged group. Racial differences will be further explored using a larger sample in Phase III. More concerning trends were observed for household income, mobility, and physical constraint subgroups. Specifically, the DTx was most accessible and usable for the wealthiest and least efficacious for the lowest-income participants. The DTx was also the least accessible, usable, and least efficacious for participants with the most physical constraints and most limited mobility, respectively. To address these findings, a free YouTube channel was created for participants. The channel included exercise videos using positive, upbeat formats and featuring diverse instructors, contexts, and PA types. Videos required only minimal space with no equipment necessary, and provided optional physical adaptations for each exercise. These changes sought to provide a larger number of enjoyable PA options that were convenient, accessible, and affordable to all participants, regardless of their income or physical abilities.

Limitations

The extant literature contained very few validated measures for smartphone DTx accessibility, usability, sustainability, and feasibility. Therefore, we adapted existing measures from related technologies (eg, online websites and software systems) and created our own when appropriate. Investigator-developed items were highly specific to our particular DTx, potentially limiting generalizability to other DTx setups. Additionally, this phase II study's small sample size precluded the use of inferential statistics; findings were descriptive, therefore, and should be interpreted with caution. Similarly, results for safety, plausibility, accessibility, usability, sustainability, feasibility, and equity of the eMOTION DTx reflect preliminary findings in our small, homogenous sample. Specific subgroups were at times collapsed into more general "affect-based" and "intensity-based" groups, and we were unable to explore whether specific combinations of enhancements drove the main effects. However, the phase III study will feature a sufficiently powered, diverse sample (N=280) to rigorously analyze within- and between-group differences in DTx efficacy and optimize treatment components.

XSL•FO
RenderX

Conclusion

Overall, this study is one of the first to apply benchmarks recommended by the DTx RWE Framework to formatively test a novel digital intervention. By transparently reporting the specific measurement and analytic choices we made to operationalize the DTx RWE Framework, our study hopes to contribute methodology and results that can be replicated. This is an important undertaking, since recent investigations suggest that the inconsistent application of frameworks is hindering the advancement of knowledge in real-world implementation contexts [62]. Future work should aim to apply the DTx RWE Framework in other contexts to determine whether its processes are relevant across diverse health problems, target populations, and DTx formats.

All benchmarks were determined to be met satisfactorily following iterative improvements made to the eMOTION DTx during development. Preliminary evidence, therefore, supports a research transition into DTx RWE Framework phase III, in which a large-scale effectiveness trial will determine whether the eMOTION DTx produces a greater effect (ie, PA enjoyment) among the experimental (compared to control) group. Ultimately, our application of the DTx RWE Framework ensures that the design and development of the eMOTION DTx follow current best practices, increase the likelihood that regulatory standards are met, and facilitate an efficient translation from research to real-world practice.

Abstract

Background: Suboptimal design of infusion pumps may lead to usage errors, thereby compromising patient safety. Usability evaluation enables medical device design teams to identify and rectify design-related usability issues in a timely manner. Nevertheless, existing research on infusion pump usability continues to exhibit limitations in aspects such as task design.

Objective: The study aimed to evaluate the usability of an infusion pump (SLGO SP-200 [SLGO Medical Technology Co, Ltd]) through simulation-based testing with nurses in a usability laboratory designed to simulate an intensive care unit.

Methods: A total of 12 registered nurses with experience in using infusion pumps participated in this study. Nurses were asked to perform 12 operational tasks using the infusion pump. The participants were also asked to perform 7 knowledge tasks, where they were required to find relevant information in the user manual. Participants' behavioral measures (task completion time, frequency of manual query, frequency of asking for assistance from researchers, frequencies of operation difficulties, near-misses, and failures), perceptions (perceived ease of use, perceived concentration level required, perceived likelihood of making programming errors, perceived mental workload, satisfaction, and use intention) were collected to evaluate the usability and identify interface design deficiencies of the pump.

Results: The study found that the participants were generally able to complete the tasks. All operational tasks were completed within 3 minutes, and all knowledge tasks were completed within 2 minutes. Our study identified 79 difficult operations, 9 near-miss operations, and 36 operation failures. The causes of the above problems were analyzed. Participants generally found the infusion pump to be user-friendly, requiring a medium level of attention resources, and reported low levels of mental workload and likelihood of making programming errors.

Conclusions: The study results can provide a basis for the design of infusion pumps, help practitioners define the risks of use and the key content of training, and provide an important reference for the design of usability evaluation schemes for medical devices.

usability; medical device; infusion pump; simulated use; use error

Introduction

Infusion pumps are medical devices that deliver fluids, medications, or nutrients directly into the patient body in a controlled manner [1]. Well-designed infusion pumps of good quality are necessary for providing effective and safe patient care. However, infusion pumps are often involved in incidents and accidents [2-4]. A White Paper published by the US Food and Drug Administration (FDA) in 2010 (White Paper: Infusion Pump Improvement Initiative) indicated that between 2005 and

XSL•FO
RenderX

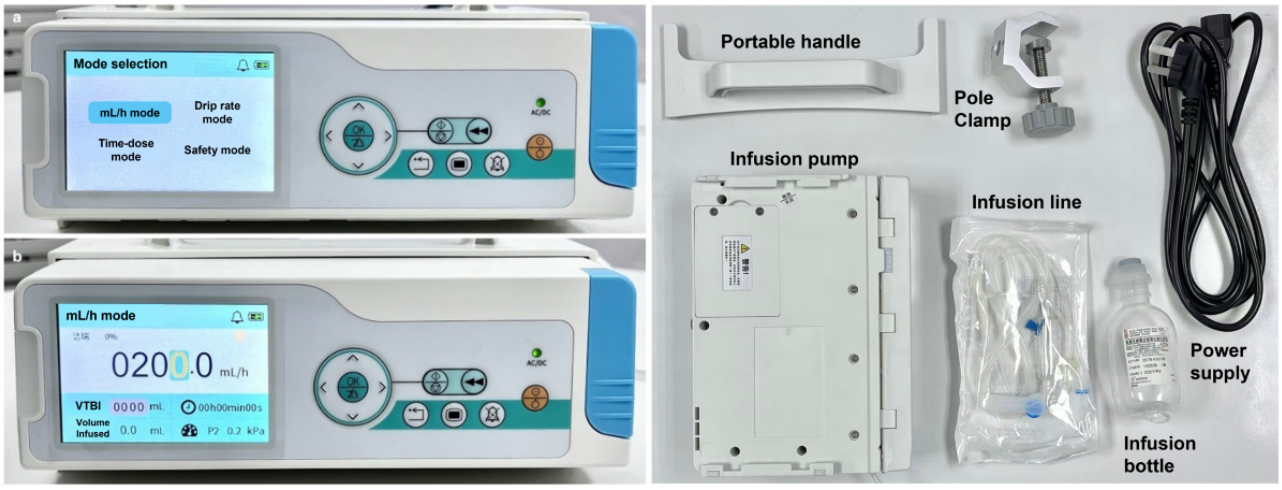
2009, the FDA received approximately 56,000 adverse event reports related to the use of infusion pumps, and there were 87 infusion pump models recalled due to safety concerns [4]. Other studies have indicated that the number of adverse events or near-miss incidents occurring during the use of medical devices is significantly higher than the data reported officially [5-7].

The poor human-machine interface design of medical devices (eg, unclear information presentation and ambiguous alarms) is one of the main reasons for use errors [5,8-11]. To address this issue, development teams for medical devices like infusion pumps need to incorporate usability engineering, which focuses on safety, efficiency, and user satisfaction during the use of medical devices [12,13]. Medical device regulators worldwide have published various guidelines and standards to integrate usability engineering into the device approval process [14]. In 2001, the American National Standards Institute (ANSI) and the Association for the Advancement of Medical Instrumentation (AAMI) released ANSI/AAMI HE74:2001, which described the usability engineering design process for medical devices; it was one of the earliest standards emphasizing usability [15]. In 2007, the International Electrotechnical Commission (IEC) released IEC 62366, detailing the usability engineering design process for medical devices [16]. This standard was updated in 2015 to further elaborate on the design process, considering risk management. In China, usability engineering for medical devices is still in its early stages. In 2020, the Center for Medical Device Evaluation of the National Medical Products Administration organized the drafting of the guidelines for technical review of human factors design for medical devices (draft for comments). In March 2024, the guideline was officially published, providing standards and regulations that define how usability testing should take place [17].

Usability testing is a crucial process within usability engineering, which consists of formative and summative testing. Formative testing is primarily conducted during the design and development phases of medical devices, while summative testing is conducted after the development phase to ensure that the designed device sufficiently meets user needs [18]. Simulated use testing is a common method of usability testing, where representative users are invited to use the medical device to perform representative tasks in a realistic setting [19-21]. This method allows for the observation and collection of user behavior data, revealing interface design flaws and identifying interaction strengths and opportunities for improvement.

Several previous studies have empirically evaluated the usability of infusion pumps [5,21-23]. For instance, Garmer et al [5] conducted a usability experiment to compare 2 interfaces for an infusion pump. Experimental tasks included setting or adjusting a flow rate or volume to be infused and starting or stopping an infusion. Liu et al [21] performed a heuristic evaluation and simulated use testing to compare the usability level of 4 infusion pumps to inform pump selection. Trbovich et al [22] examined how traditional pump, smart pump, and smart pump with barcode affected nurses' ability to safely administer intravenous medications. Schmettow et al [23] conducted a usability study to compare a novel syringe infusion pump prototype to an existing design. However, existing research still faces a series of limitations. First, previous usability evaluations only considered operational tasks related to pump use, while neglecting knowledge tasks associated with the use of the instruction manual. As an integral component of the system, the clarity, comprehensibility, accessibility, and instructional value of the manual also require evaluation [24]. Second, most evaluation tasks focused solely on core functions, such as infusion programming, with insufficient attention given to alarm handling and accessories installation. Third, current evaluations focused on observing operational difficulties without summarizing the underlying causes and potential risks of these issues. Through linking identified usability issues to potential use-related risks, it can offer a direct pathway from evaluation findings to specific, actionable design improvements aimed at risk mitigation [23].

The importance of usability testing for medical devices is gaining attention among professionals worldwide, highlighting the urgent need for research to establish guidelines for typical usability testing methods, processes, and data analysis. In light of this, this study invited registered nurses to conduct a summative usability test on a new infusion pump, aiming to identify human-machine interface design flaws and provide guidance for the design, evaluation, training, and use of infusion pumps.



Methods

Design

A summative usability evaluation of an infusion pump (SLGO SP-200, SLGO Medical Technology Co, Ltd; Figure 1) was conducted, where participants were required to complete a series of operational tasks and knowledge tasks in a simulated intensive care unit (ICU). During the evaluation, behavioral data (eg, task completion time, frequency of asking for help, frequency of difficult operation, frequency of near-miss operation, and frequency of operation failure) as well as subjective data (eg, subjective perceptions and interviews) were collected.

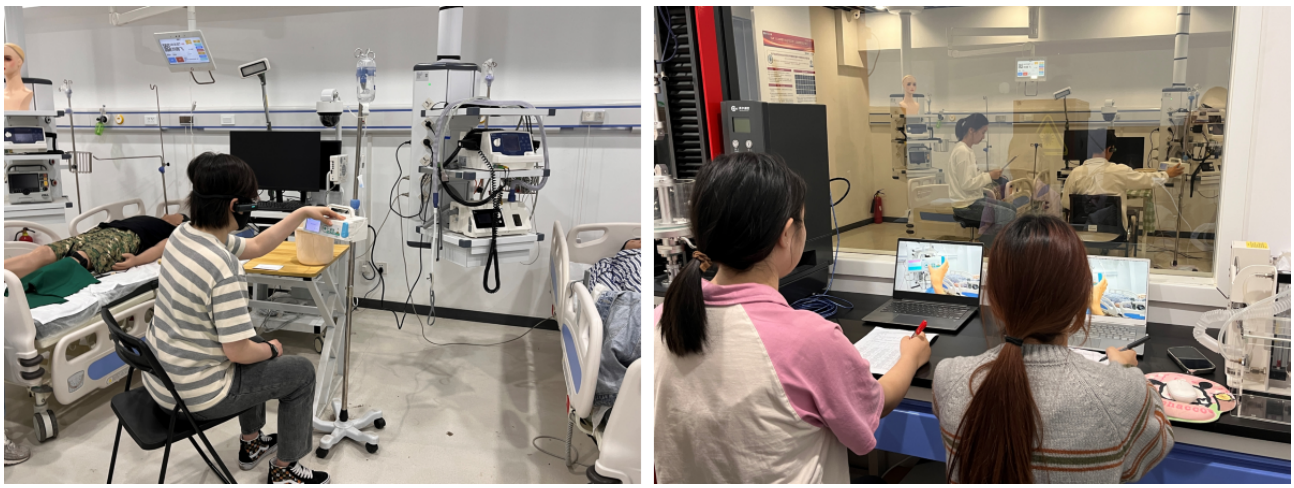
Figure 1. The infusion pump being evaluated—main interface (left) and its accessories (right).



Participants

A total of 12 nurses with experience in using infusion pumps were recruited from 2 hospitals in Tianjin, China. The participants were stratified by clinical unit (specialized or general hospitals), department (ICU, operating room, or medicine), and clinical experience (≤8 y or >8 y) [21]. The participants were aged between 25 and 55 years (mean age 35.3, SD 8.1 y). Previous literature in usability engineering indicated that 80%-90% of usability problems can be detected with 5-8 participants; beyond this point, the incremental yield of new issues diminishes significantly [25,26]. All participants received training on the infusion pump being evaluated before the evaluation.

Environment and Apparatus

The experiment was conducted in a usability laboratory designed to simulate an ICU. The laboratory consists of a testing room and an observation room, separated by a one-way glass. Participants performed experimental tasks in the testing room while wearing a head-mounted camera (Lenovo-Lx918) to continuously record their operations in real time. Observers in the observation room monitored the participant's operations through a computer screen displaying the live feed from the head-mounted camera (Figure 2).

Figure 2. The testing room (left) and the observation room (right) of the usability laboratory.

Task

A total of 12 operational tasks were designed (Table 1), including accessories installation, infusion programming, system configuration, and alarm handling. The 2 alarm handling tasks (tasks 8 and 10) were predesigned as part of the scenario, and the alarms were manually triggered by a research assistant at a planned point during the participant posttask interview. This approach allowed researchers to integrate the alarm response naturally into the ongoing tasks without relying on the participant to inadvertently cause the alert condition. Specifically, the air bubble alarm (task 8) was triggered by the research assistant intentionally introducing a small air bubble into the infusion line. No power connection alarm (task 10) was triggered by the research assistant disconnecting the pump from its power source. Participants were not informed in advance that these alarms would occur, so that we could assess their natural recognition and response to unexpected yet clinically relevant alarms. Additionally, we designed 7 knowledge tasks (Table 2), where participants were required to find relevant information in the user manual.

XSL•FO
RenderX

Table 1. The 12 operational tasks.

Task	Task description	Standard operation steps
1	Please install the pole clamp and portable handle on the infusion pump. Then fix the pump securely on the pole stand.	• Install the pole clamp • Install the portable handle • Fix the pump on the pole stand
2	Please install the power supply and turn on the infusion pump.	• Install the power supply • Turn on the pump
3	Please install the infusion line.	• Push the pump door latch outward and fold down the front panel • Install the infusion line horizontally from right to left and secure it into the guide port • Close the pump door
4	Please adjust the brightness level of the screen to the highest level.	• Press the menu key to enter the system setup interface • Select the key for brightness settings • Use the directional keys to adjust the level
5	Please open the roller clamp on the infusion line. Set the drip rate to 50 drops/min in drip mode. Start infusion after priming.	• Open the roller clamp • Select the drip rate mode on the main interface • Set the drip rate to 50 drops/min • Press the prime and bolus key to purge air from the infusion line • Press the start and stop key to start the infusion
6	Please set the volume to be infused to 58 mL and the infusion duration to 60 min in the time-dose mode, then start the infusion.	• Press the start and stop key to pause the previous infusion • Press the return key to enter to the main interface • Select the time-dose mode • Set the volume to 58 mL and the duration to 60 min • Press the start and stop key to start the infusion
7	Please adjust the flow rate to 254.5 mL/h in the mL/h mode and then start the infusion.	• Press the start and stop key to pause the previous infusion • Press the return key to enter to the main interface • Select the mL/h mode • Set the flow rate to 254.5 mL/h • Press the start and stop key to start the infusion
8	Please address the current alarm (ie, air bubble alarm) and then continue the infusion.	• Press the return key • Press the prime and bolus key until bubbles are discharged from the very end of the infusion line. • Press the start and stop key to restart the infusion.
9	Please set the flow rate to 99 mL/h and the preset volume to 1 mL in safe mode, then start the infusion.	• Press the start and stop key to pause the previous infusion. • Press the return key to enter to the main interface. • Select the safe mode. • Set the flow rate to 99 mL/h and preset volume to 1 mL • Press the start and stop key to start the infusion
10	Please address the current alarm (no power connection).	• Press the start and stop key to pause the previous infusion • Connect the power supply to the pump
11	Please turn off the pump, remove the infusion line, disconnect the power, and take the infusion pump off the stand.	• Turn off the pump • Disconnect the power supply, first the AC power, then the connection to the infusion pump • Remove the infusion line and close the pump door • Take the infusion pump off the stand
12	Please remove the pole clamp and the portable handle from the infusion pump.	• Remove the pole clamp • Remove the portable handle

XSL•FO
RenderX

Table 2. The 7 knowledge tasks.

Task	Question	Answer
1	What is the minimum distance required between the infusion pump and high-frequency surgical equipment?	At least 0.5 m
2	What are the contraindications for the use of the infusion pump?	It is prohibited for blood transfusion, insulin infusion, as well as analgesia, chemotherapy, and epidural anesthesia infusion
3	What are the infusion pump's alarm levels and their corresponding indicator colors?	Red for high priority, yellow for low priority
4	What is the normal operating temperature range for the infusion pump?	+5 °C to +40 °C
5	What is the required distance range between the infusion bottle and the infusion pump?	30 cm to 50 cm
6	Please confirm the meaning of the symbol. 	Confirm and alarm reset key. In the parameter setting interface, it cycles through editable parameters; during an alarm, it performs an alarm reset operation.
7	What is the troubleshooting method for an "Occlusion" alarm on the infusion pump?	Press the start and stop key to pause the infusion. Check if the tubing is kinked, if the roller clamp is closed, or if the needle is blocked. If the issue is due to medication viscosity, the pressure setting can be adjusted.

Procedures

Upon arriving at the laboratory, the researcher first introduced the objective and procedure of the evaluation to the participants. Participants were required to complete 12 operational tasks and verbally report "task completed" after finishing each one. They were instructed to use the infusion pump in the same manner as they would in their daily work. If they encountered difficulties, they could refer to the manual. If they were still unable to solve the problem after referring to the manual, they could seek assistance from the researchers. Participants were also required to complete 7 knowledge tasks, in which they were required to search the manual for relevant information and answer the questions. After completion of all tasks, participants filled out a questionnaire [21,27], which included 6 dimensions—perceived ease of use, perceived mental workload, perceived concentration level required, perceived likelihood of making programming errors, satisfaction, and use intention (Table 3). All items were measured using a 7-point Likert scale (1=strongly disagree and 7=strongly agree). Posttask interviews were held to gather overall user experience and suggestions for pump design. For operational tasks, interview questions included "Do you recall any errors you made while performing the tasks?," "Can you remember any instances where you almost made a mistake but realized it immediately?," "What is your overall impression of using this infusion pump for the first time?," and "Do you have any suggestions for improving this infusion pump?" For knowledge tasks, interview questions included "Did you find it easy to locate the relevant information?," "How would you evaluate the clarity of the corresponding content in the user manual?," and "Do you have any suggestions for improving the content of the user manual?" The duration of the experiment was approximately 60 minutes.

Table 3. Items used to measure participants' perceptions.

Dimensions	Items
Perceived ease of use	• Item 1: It is easy to prime and load a set. • Item 2: It is easy to load and unload a set. • Item 3: It is easy to program a basic infusion. • Item 4: It is easy to program a drug infusion from scratch. • Item 5: It is easy to titrate flow rates. • Item 6: It is easy to turn the pump on and o .
Perceived mental workload	• Item 7: Setting up and programming the infusion pump require a high level of mental workload.
Perceived concentration required	• Item 8: Using this infusion pump requires my high level of concentration.
Perceived likelihood of making programming errors	• Item 9: The design of this infusion pump is complex, making it easy for me to make errors.
Satisfaction	• Item 10: Overall, I am satisfied with this infusion pump.
Use intention	• Item 11: Overall, I am willing to use this infusion pump.

XSL•FO
RenderX

Data Analysis

Data on task completion time, frequency of manual query, frequency of asking for assistance, and frequencies of difficult operations, near-miss operations, and operation failures for each operational task were collected by integrating observers' records and extracting videos. Task completion time was defined as the time taken by the participant to complete a task, measured from when the researcher finished reading the task instructions until the participant verbally reported the task completed. Frequency of manual query referred to the number of times a participant consulted the manual during the task due to encountering difficulties. The frequency of asking for assistance was the number of times a participant sought assistance from the researchers while completing the task. According to the National Medical Products Administration guideline [17], a difficult operation is referred to as task completion that meets requirements but falls short of expectations, such as prolonged operation times or reduced efficiency. This also included tasks completed by chance. Near-miss operation refers to tasks completed under conditions where unacceptable risks were nearly encountered. Operation failure referred to user tasks that did not meet the expectations or were not completed, including instances of exceeding time limits, making mistakes, omissions, or interruptions. Descriptive statistical analyses were conducted on the behavioral and subjective data. The content analysis method was used to analyze the interview data. All interviews were audio-recorded and transcribed verbatim to create a textual dataset for analysis. Furthermore, 2 researchers (YW and KL) independently reviewed transcripts for coding. Any discrepancies were resolved through discussion.

Ethical Considerations

This study has been approved by the Ethics Committee of Tianjin University (TJUE-2024-278). All participants provided written informed consent. Each participant received 200 RMB (approximately US $28.64) as compensation for their time and contribution upon completion of the evaluation. All participant data were kept confidential and anonymized in accordance with the approved ethical protocol.

Results

Operational Task

Tables 4 and 5 present the task completion time and frequency of manual query, asking for assistance, difficult operations, near-miss operations, and operation failures for each operational task. Task 5 (priming the infusion line and setting up an infusion in drip mode) recorded the longest completion time (149.8 s) and was associated with considerable operational challenges. For example, nurses found it difficult to access the infusion mode function and encountered issues with priming the infusion line, which has extended task completion time. Similarly, task 1 (installing the pole clamp, portable handle, and fixing the pump to the stand) and task 6 (setting an infusion in time-dose mode) exhibited a high mean completion time and substantial operational issues. We observed that participants encountered difficulties in installing accessories, which extended the task completion time. Additionally, some participants spent excessive time when using the time-dose mode for infusion setup due to not understanding of the terminology presented on the screen. In contrast, simpler tasks, such as task 2 (installing the power supply and turning on the pump), were completed quickly (26.2 s) with minimal operational issues. Task 3 (installing the infusion line), task 4 (adjusting the brightness level), task 7 (setting an infusion in mL/h mode), task 9 (setting an infusion in safe mode), task 11 (turning off the pump and removing the infusion line from the pump), and task 12 (removing the pole clamp and portable handle from the pump) were completed in moderate times but still involved several operational issues. Alarm-related tasks also showed varied performance. Task 10 (addressing a power connection alarm) was completed relatively quickly with less operational issues than task 8 (addressing an air bubble alarm).

Table 4. Task completion time for each operational task.

Task	Time (s), mean (SD)	Time (s), median (IQR)
1	134.3 (70.3)	142.0 (62.3-192.3)
2	26.2 (5.9)	25.0 (21.5-29.0)
3	46.2 (20.4)	39.5 (33.5-54.5)
4	43.9 (44.8)	22.5 (19.3-51.0)
5	149.8 (130.5)	97.0 (61.5-190.8)
6	134.0 (91.8)	97.0 (57.3-234.8)
7	69.4 (58.7)	49.0 (32.3-73.3)
8	94.4 (36.1)	101.5 (52.8-119.0)
9	44.3 (16.9)	38.5 (30.3-58.5)
10	36.8 (32.0)	25.5 (14.5-42.0)
11	65.0 (14.2)	60.0 (54.8-80.5)
12	47.6 (38.2)	30.0 (22.8-51.0)

RenderX

Table 5. Frequency of manual query, asking for assistance, difficult operations, near-miss operations, and operation failures for each operational task.

Task	User manual query, n	Asking for assistance, n	Difficult operations, n	Near-miss operations, n	Operation failures, n
1	5	4	1	0	13
2	0	0	0	0	1
3	1	0	2	0	0
4	3	0	14	0	0
5	4	1	16	4	9
6	7	0	3	0	9
7	2	0	8	3	1
8	4	0	8	2	1
9	1	0	7	0	1
10	4	0	5	0	0
11	0	0	11	0	1
12	4	0	4	0	0
Total	35	5	79	9	36

Of the total recorded operations (Table 6), difficult operations were observed most frequently (n=79), with alarm resolution (n=15), screen brightness adjustment (n=12), turning off the pump (n=11), and accessing the infusion mode setting function (n=11) constituting the most prominent challenges. Difficulties in starting (n=8) and pausing an infusion (n=7), along with number adjustment (n=5), were also notable. Near-miss operations, although less frequent (n=9), were primarily characterized by occlusion alarms due to the roller clamp not being opened (n=5) and the use of an incorrect infusion mode (n=2). A total of 36 operation failures were documented. A number of nurses were not able to install the portable handle (n=8) or the pole clamp (n=4). Critical procedural failures involved not priming the infusion line correctly (n=5), not starting the infusion after programming (n=5), and failing to notice or address system alarms (n=7).

XSL•FO
RenderX

Table 6. Type and frequency of difficult operations, near-misses, and failures.

Type	Frequency, n
Difficult operations (n=79)	
Difficult to resolve alarm issues	15
Difficult to adjust the brightness level	12
Difficult to access to the function for infusion mode setting	11
Difficult to turn off the pump	11
Difficult to start the infusion	8
Difficult to pause the infusion	7
Difficult to adjust numbers	5
Difficult to remove the portable handle from the pump	4
Difficult to install the infusion line	2
Difficult to access to the function for brightness level adjustment	2
Difficult to install the pole clamp	1
Difficult to program infusion under the time-dose mode	1
Near-miss operations (n=9)	
Occlusion alarm triggered due to not opening the roller clamp	5
Used wrong mode for infusion	2
Air bubble alarm triggered due to incorrect priming	1
Input wrong number when programming an infusion	1
Operation failures (n=36)	
Installed the portable handle in wrong direction	8
Did not notice the alarm or do not fix the alarm issues	7
Did not prime the infusion line correctly	5
Did not start the infusion after programming	5
Unable to install the pole clamp	4
Installed the power supply in a wrong way	2
Input wrong number when programming an infusion	2
Used wrong infusion mode	1
Unable to install the portable handle	1
Did not open the roller clamp	1

Knowledge Task

Due to incomplete video recordings for 2 participants, the analysis of knowledge task was conducted for only 10 participants. All participants were able to complete the tasks within 2 minutes (Table 7). Among them, the accuracy of 4 knowledge tasks did not reach 100%.

Table 7. Completion time and accuracy rate of the knowledge tasks.

Task	Task completion time (s), mean (SD)	Accuracy rate (%)
1	60.2 (63.3)	100
2	82.4 (52.9)	50
3	98.3 (33.8)	60
4	59.3 (31.4)	70
5	91.6 (49.1)	100
6	35.1 (13.5)	100
7	75.7 (66.8)	90

XSL•FO
RenderX

Subjective Perceptions

The mean scores for perceived ease of use, satisfaction, and use intention were 6.0 (SD 0.7) or above, indicating that participants perceived the pump easy to use, were satisfied with it, and were willing to use it (Table 8). The mean scores for perceived mental workload and perceived likelihood of making programming errors were 2.7 (SD 1.1) and 2.1 (SD 0.9), respectively, suggesting that the participants did not experience significant cognitive load while using the pump. The mean score for perceived concentration level required was 4.2 (SD 1.3), indicating that participants held a neutral stance regarding the need for high levels of concentration when using the infusion pump.

Table 8. Subjective perception results.

Dimension	Mean (SD)
Perceived ease of use	
Overall (items 1-6)	6.3 (0.5)
Priming and loading a set	6.0 (0.9)
Loading and unloading a set	6.3 (0.9)
Programming a basic infusion	6.7 (0.8)
Programming a drug infusion from scratch	6.8 (0.5)
Titrating flow rates	6.2 (0.7)
Turning the pump on and o	6.0 (0.6)
Perceived mental workload	2.7 (1.1)
Perceived concentration level required	4.2 (1.3)
Perceived likelihood of making programming errors	2.1 (0.9)
Satisfaction	6.0 (0.7)
Intention to use	6.0 (0.7)

Interview

Reasons for Difficult Operations, Near-Miss Operations, and Operation Failures

During the installation and disassembly phases, participants encountered difficult operations, near-misses, and failures in key tasks, such as pole clamp installation or removal, portable handle attachment, power supply connection, and infusion line loading. The primary contributing factors were the users' unfamiliarity with accessory installation procedures and the absence of relevant instructional cues on the infusion pump or in its user manual (5/12, 41.7%). For example, as one participant noted,

> *I was unaware that the pole clamp required a pulling action. Even after consulting the diagrams in the instruction manual, I was unable to determine the correct method of operation.* [P7]

In system configuration, difficulties were observed in adjusting screen brightness and powering off the device. Several participants (5/12, 41.7%) reported that the brightness adjustment function was difficult to locate and there was no confirmation feedback after adjustment. For instance, one participant (P1) noted,

> *Following the brightness adjustment, selection of the 'OK' button provided no feedback, neither a return to the previous interface nor a confirmation, to indicate that the new setting had been implemented.* [P1]

The shutdown procedure also deviated from their familiar devices, resulting in prolonged completion times. For instance, one participant said,

> *Based on my prior experience with other infusion pumps, I expected that a long press would typically trigger a shutdown interface.* [P11]

During infusion setup, users experienced difficulties, near-misses, and failures in tasks including line priming, numeric input, mode selection, starting or pausing an infusion, and roller clamp operation. Several participants (4/12, 33.3%) indicated that the infusion mode setting function was not intuitively accessible, and terminologies were not clearly displayed, causing confusion. For example, one participant said,

> *I initially assumed that all mode selection options would be located within the menu system.* [P12]

Operational inconsistencies between this infusion pump and the participants' routinely used devices further contributed to uncertainty in initiating and pausing infusions (1/12, 8.3%). P4 noted a key operational discrepancy:

> *With our conventional infusion pumps, the infusion typically starts immediately upon pressing the confirmation button. However, this specific model requires an additional step of pressing a separate 'start' key to initiate the process.* [P4]

Unclear button labeling also increased the cognitive load during programming (2/12, 16.7%). P11 expressed confusion regarding button functionality, noting:

XSL•FO
RenderX

> *I used the 'OK' button to confirm system status, followed by the 'Pause' button to suspend operation, though I frequently encountered difficulty differentiating between these two controls.* [P11]

Moreover, omissions, such as incomplete priming, not opening the rolling clamp, and incorrect value input, were observed (7/12, 58.3%). For instance, participants said,

> *Initially, I had located the mL/h mode, but subsequently realized that the drip mode was the required setting for this specific task.* [P9]

> *I recognized that the occlusion was caused by not opening the roller clamp.* [P5]

In alarm handling tasks, several nurses (4/12, 33.3%) failed to notice active alarms, while others who did recognize them often could not interpret the alarm messages or determine appropriate actions to resolve the issues. For example, one participant indicated:

> *I observed that it did not affect the infusion process, so I did not address it.* [P5]

P7 reported confusion regarding a system alarm, stating:

> *Initially, I did not understand the meaning of Preset Complete, and consequently could not comprehend the reason for the alarm activation.* [P7]

Suggestions for Improvement of the Pump

Participants generally reported a favorable overall impression of the pump, with most describing it as user-friendly, easy to learn, and featuring a clear interface (11/12, 91.7%). Representative comments included:

> *The overall interface is somewhat better than the infusion pumps I have used before; for instance, the numerical values are more prominent.* [P1]

> *It is quite good that I could start using it without much difficulty on the first try.* [P5]

> *It is mostly similar to other infusion pumps; I should be able to use it by exploring a bit myself.* [P10]

> *The Chinese language is easy to understand, and setting the modes is relatively straightforward.* [P7]

Regarding comfort and weight, participants found the pump generally comfortable to handle (10/12, 83.3%), with comments such as,

> *It is still quite comfortable, and the key sensitivity is good.* [P1]

> *Acceptable, and not very heavy.* [P5]

> *The keys are comfortable, easy to press.* [P2]

Regarding the button design, participants suggested improvements to increase layout spacing, reduce ambiguity, and clarify key functions (6/12, 50%). For example, participants noted,

> *The operation keys are too crowded; making them slightly larger or spacing them further apart might make operation easier.* [P3]

> *The alarm reset key are sometimes confused.* [P4]

> *The start/stop key and the rapid bolus key are too close; I initially mistook the bolus key for the start/stop key.* [P5]

> *The menu and back keys are confusing; I could not find the mode adjustment interface.* [P6]

> *Making the start/stop key more prominent would be better, as starting and stopping are our most frequent actions.* [P9]

> *The meaning of the menu key is not entirely clear.* [P10]

Additionally, participants identified issues related to confirmation feedback, accessories installation, and infusion set loading (5/12, 41.7%). P2 highlighted the lack of feedback during adjustments:

> *Brightness settings and numerical input require some confirmation feedback.* [P2]

P7 expressed concern over functional ambiguity:

> *The OK key and the alarm reset key are combined, which I find confusing; I prefer each key to have a dedicated function.* [P7]

Regarding accessories, P3 raised a safety concern:

> *In clinical practice, infusion pumps are often suspended. The ones we use are one-piece, so we are concerned about whether this clamp pull-ring is secure enough to avoid detachment.* [P3]

Participants noted:

> *The infusion lines on the pumps I used were loaded vertically; I feel gravity might work better that way.* [P6]

> *Vertical loading is more convenient; horizontal loading requires figuring out the direction, which takes extra time.* [P8]

Further suggestions for design enhancement included increasing alarm volume, improving accessory installation, and incorporating touchscreen capability (4/12, 33.3%).

> *The alarm volume seems somewhat low; it is not very salient.* [P5]

> *It would be better if the pole clamp was permanently fixed to the pump. In clinical settings, we rarely need to detach it, and removable parts can get lost.* [P8]

> *Clinical settings have many tangled lines; it would be more convenient if the power cord could be stored attached to the pump after disconnection.* [P4]

P11 proposed using a touchscreen:

> *A touchscreen would be preferable, making numerical input less cumbersome.* [P11]

Suggestions for Improvement of the Manual

Participants generally perceived the user manual as clear and detailed (10/12, 83.3%), while proposing specific enhancements to optimize its utility. First, 2 (16.7%) nurses suggested improving the readability by enlarging the font size and

XSL•FO
RenderX

incorporating colorized interface diagrams to highlight critical information. For instance, participants mentioned,

> *The font size may be somewhat small for senior clinicians.* [P1]
>
> *The section illustrating the pump interface could be presented in color, matching the actual operational display, to facilitate easier use.* [P4]

Second, 1 (8.3%) participant advised consolidating alarm-related content by integrating alarm definitions with corresponding troubleshooting procedures. As P4 explained,

> *Placing the alarm descriptions and resolution methods on the same page would better support clinical workflow, since I typically identify the alarm type and immediately seek the solution.* [P4]

Third, nurses proposed adding a streamlined flowchart at the beginning of the manual to outline key clinical procedures (3/12, 25%). One participant suggested

> *…extracting a 2–3 page quick-reference guide covering essential operations and alarm handling for direct clinical guidance.* [P3]

P8 emphasized the need for "*an initial overview with a simple flowchart before detailed textual explanations*." Finally, 1 (8.3%) participant recommended supplementing certain operational details currently absent from the manual. P10 explicitly noted the absence of guidance on "how to install the pole clamp" as an example of missing critical information.

Remaining Usability Issues and Potential Risks

Table 9 presents the summary of remaining usability issues, potential risks, severity level, and corresponding design recommendations.

Table 9. Remaining usability issues, potential risks, and corresponding design recommendations.

Usability issues	Potential risk	Severity level	Design recommendations
Did not notice the alarm; difficult and unable to resolve alarm issues	Delay in responding to critical alarms	High	Clearly display the cause of the alarm and the steps to resolve it
Used wrong infusion mode	Dosage error	High	Distinctiveness of modes should be improved
Input wrong number when programming an infusion	Dosage error	High	A second confirmation for parameters is required
Difficult to program infusion under the time-dose mode	Inefficiency in programming and potential dosage error	High	Implement step-by-step instruction and clearly explain the meaning of the terminologies on the screen
Did not prime the infusion line correctly	Potential residual air in the infusion line	High	Visibility of pump status need to be clearly displayed; provide clearly instruction for priming
Did not open the roller clamp	Treatment delay	High	Visibility of pump status need to be clearly displayed; remind users to check the openness of the roller clamp before starting an infusion
Did not start the infusion after programming	Treatment delay	High	Visibility of pump status need to be clearly displayed; remind users to start infusion after programming, if not started within a set period, a reminder alarm should be triggered
Difficult to adjust numbers	Inefficiency in programming	High	Clearly indicate the method for rapid value entry
Difficult to start and pause the infusion	Treatment delay or unable to quickly stop the infusion	High	Provide a distinct start and stop key with clear labeling
Difficult to install the infusion line	Treatment delay	High	Provide clear instructions and incorporate error-proof design features
Difficult to find the function for infusion mode setting	Potential infusion in the wrong mode	High	Clear navigation
Difficult to find the function for brightness level adjustment and difficult to adjust the brightness level	Misreading or incorrect operation due to unclear screen display	Middle	Clear navigation; provide confirmation and feedback after settings
Difficult to turn off the pump	Inefficiency	Low	Provide clear instructions
Difficult or unable to install or remove the portable handle or pole clamp or power supply	Unstable or inconvenient device movement; Unstable installation or device falling; Power failure	Low	Provide clear instructions

RenderX

Discussion

Overview

This study reported on a summative usability testing process for an infusion pump. The overall usability level of the pump was assessed by observing nurses' operating behaviors when using the pump. The study identified difficult operations, near-misses, and failures encountered during tasks, analyzed the causes of these issues through participant interviews, highlighted the design advantages of the infusion pump as well as existing interface design flaws, clarified usage risks, and proposed design improvement suggestions. These findings can provide valuable insights for optimizing the infusion pump design, helping practitioners define use risks and training priorities, and offering important implications for the usability evaluation schemes of medical devices.

Main Findings

Generally, the examined infusion pump effectively assisted participants in completing the tasks. Participants were able to complete all operational tasks within 3 minutes, indicating high overall operational efficiency. For knowledge tasks, although all were completed within 2 minutes, suboptimal accuracy was observed in a portion of tasks. In most cases, the participants completed tasks independently. They generally found the infusion pump to be user-friendly, requiring a medium level of attention resources, and reported low levels of mental workload and likelihood of making programming errors.

However, participants encountered several difficulties when operating the infusion pump, reflecting that there were still some design deficiencies that needed to be addressed. First, the infusion pump should increase the visibility of system status [28]. This issue has also been reported in other studies on infusion pump usability [21,23]. Low visibility of system status may prevent nurses from accurately determining the operational status of the infusion pump, thereby potentially leading to adverse events. Second, function navigation should be improved. Some nurses had difficulty in locating brightness adjustment and infusion mode setting functions. Liu et al [21] also observed that certain functional menus of infusion pumps were difficult to access. This may be attributed to a misalignment between the system interaction flow and user expectancy. A clear and well-structured navigation system can prevent user errors during operation, while excessive navigation options, overly deep menu hierarchies, and ambiguous categorizations can significantly increase users' memory load. Third, the infusion pump interface should be aligned with the mental model of target users, and the operating logic of different infusion pumps should be as consistent as possible. Some nurses reported differences in operational logic compared with pumps they regularly used, resulting in increased difficulty and errors during usage. This constitutes a violation of the consistency principle in human factors design [29]. When nurses encounter an interface that does not align with their established mental models, they are compelled to relearn and reconstruct new cognitive schemas. Fourth, many participants neglected alarms or were unclear about their meanings, which poses significant risks in clinical use. Previous research has indicated that a significant number of nurses failed to comprehend the meaning of infusion pump alarms clearly, leading to untimely or absent responses [21]. This represents a violation of the human factors design principle that systems should support users in recognizing, diagnosing, and recovering from errors. Effective error messages should use plain, unambiguous language, precisely identify the nature of the problem, and offer constructive, actionable guidance toward its resolution. Alarm design can also consider combining visual and auditory signals and avoid masking effects to ensure quick perception in complex clinical environments. Fifth, a few participants made errors in entering infusion parameters or using incorrect infusion modes. Other researchers have reported that confusion regarding dosing units and/or concentrations when using infusion pumps can lead to medication overdoses [22,30]. Input errors pose serious risks to patient safety, and while some infusion pumps include features to detect unsafe infusion rates [31], such errors may not be entirely avoidable through system design [5]. Finally, the clarity and comprehensiveness of the manual should be improved. Participants noted that a combination of images and text might enhance understanding more than using text alone.

Implications

Our study results provide several important implications. For clinicians and educators, the findings pinpoint areas requiring focused training and competency assessment, moving beyond general device familiarity to targeted practice on high-risk, error-prone steps. The problem analysis provided concrete criteria to inform procurement decisions, allowing buyers to compare devices based on specific safety-related usability attributes rather than features alone. For manufacturers, the results offered actionable design improvement recommendations directly linked to mitigating identified use errors, supporting a user-centered design and risk management process as mandated by regulatory frameworks.

Limitations

First, due to constraints related to the duration of the experiment and the availability of participants, we only recruited 12 participants. Given that our primary objective was to identify predominant usability challenges rather than to quantify rare events, this sample size was considered sufficient to capture the majority of issues. Future studies can consider increasing the sample size to ensure statistical power and generalizability. Second, no alternative system interfaces were assessed; therefore, no comparable results were available in our study. This may limit our findings and ideas on system interface improvement. Third, the sequence of tasks was designed to reflect the standard clinical workflow for operating an infusion pump; however, it may induce potential order effects. Future studies can consider randomizing the order of the tasks. Fourth, the impact of training on infusion pump use was not considered. Fifth, the experiment was conducted in a quiet simulated ICU, and nurses' use performance in real clinical scenarios (eg, noise, interruptions, and multitasking) may differ from the testing conditions. Finally, future tests could integrate devices like eye trackers to study the impact of infusion pump interface design on users' visual attention allocation.

XSL•FO
RenderX

Conclusion

This study recruited 12 nurses with infusion pump experience to conduct a simulated usability test of an infusion pump. It not only assessed the current usability of the infusion pump but also identified the root causes of user errors by combining subjective and objective data. This approach can help mitigate potential interaction design issues that could lead to user errors, providing important implications for the design and evaluation of medical devices.

Acknowledgments

The authors extend their grateful acknowledgment to all the participants from Tianjin University Chest Hospital and Tianjin Medical University General Hospital, for their invaluable assistance throughout the research process. KL would like to thank the support of Xiaomi Young Talents Program (Xiaomi Foundation).

Data Availability

Data are available on request from the corresponding author.

Funding

This work was supported by the National Key Research and Development Program of China (2023YFF1203800) and the Open Research Projects (2nd Batch) of the Tianjin Key Laboratory of Quality Control and Evaluation Technology for Medical Devices (TJMDKT-2026T03).

Authors' Contributions

YW conducted the experiment and collected, analyzed data, and drafted the manuscript. KL led the project and cross-checked the data analysis. All authors contributed to the study design and protocol development and participated in the writing and editing of several versions of this manuscript.

Abstract

Background: Medication adherence is a critical challenge for people living with dementia and their caregivers. Standard care relies on appropriate medication management, yet there are few effective options beyond manual pill-counting and caregiver-administered dosing. These methods are prone to errors and impose a significant burden. Technologically enhanced adherence tools include smart caps, reminder apps, and electronic dispensers, which improve tracking but still depend on manual interaction, lack clinical integration, and are often unsuitable for cognitive impairment. The HiDO HomeCare System (HCS) is an artificial intelligence–enabled self-medication device, advancing the field by removing manual pill counting, automating the chain-of-custody, verifying consumption, and logging medication adherence through neuroscience-based logic and real-time monitoring.

Objective: This study evaluated the feasibility, usability, and performance of the HCS for at-home medication management in dyads of people living with dementia and their caregivers. We examined setup, dispensing accuracy, task efficiency, and user satisfaction.

Methods: A pooled analysis usability study was conducted with 35 caregiver-patient dyads at Rush University Medical Center, combining 2 sequential in-clinic cohorts run at different time points with the same protocol. Participants were recruited from the Rush Memory Clinic and Rush Alzheimer's Disease Center data repository. Participant dyads completed device setup, medication dispensing, and simulated medication use with the system's automated logging and dual-camera verification. Dyads repeated dispensing and simulated medication use following automated reminders sent to their mobile device. Dyads were encouraged to repeat dispensing tasks multiple times. Quantitative measures included setup time, time to dispense, success rates, reliability, and System Usability Scale scores. Qualitative measures also captured caregiver perceptions of usability, acceptability, and burden.

Results: All 35 dyads successfully completed at least one dispensing task using the HCS. The average time for the first dispense attempt was 1:41 (SD 1:13) minutes (n=35). The second attempt averaged 1:35 (SD 1:10) minutes (n=21). Attempt 3 averaged 2:03 (SD 1:34) minutes (n=6). The system maintained accuracy across all users, with some variability in timing across age groups. The HCS received an overall mean System Usability Scale score of 70.2 (SD 18.2; n=34), reflecting above-average usability of

XSL•FO
RenderX

the device. Caregivers reported that access to a system like HCS could reduce stress associated with medication administration and recommended improvements to specific design elements.

Conclusions: The HCS demonstrated early feasibility, accuracy, and usability as a self-medication device tailored to people living with dementia. By automating the medication safety chain from delivery through consumption, HCS reduces caregiver workload and enhances patient safety and medication management. These findings support HCS as a viable medication adherence solution, addressing limitations of prior devices and enabling better dementia care. Larger-scale, longitudinal studies are planned to examine clinical outcomes, caregiver burden, and cost-effectiveness within real-world home and community settings.

Introduction

Medication Management Challenges

By 2060, the number of individuals living with Alzheimer disease and Alzheimer disease–related dementias in the United States is projected to double [1]. People living with dementia-related conditions currently have no known cure despite ongoing research, leaving patients primarily reliant on medication-based treatments to manage symptoms and preserve quality of life. People living with dementia have quality of life needs similar to those without dementia, including the ability to complete activities of daily living. Preserving these functions is critical to support independence, enable individuals to remain at home longer, and reduce both caregiver burden and cost of care [2]. Because medication is the primary treatment pathway, the need for appropriate, low-burden medication management is central to maintaining both cognitive and physical health [3]. This can be particularly challenging, as people living with dementia often have multiple chronic conditions such as cardiovascular disease, diabetes, and hypertension [4]. Polypharmacy and cognitive decline are strongly associated with morbidity, higher health care costs, and earlier institutionalization [3,5]. Inadequate management of medications for these conditions accelerates functional decline, increases avoidable hospitalizations, and shortens time at home.

Medication mismanagement is defined as missed doses, incorrect timing, or taking the wrong drug, and is a common and escalating challenge among people living with dementia [3]. As dementia progresses and patients struggle to manage both dementia-related medications and treatments for comorbid conditions, mismanagement leads to disrupted sleep, heightened anxiety, poor nutrition, and increased depression [6,7]. This, in turn, fuels a cycle of decline that often results in institutionalization. These challenges also contribute to caregiver burden, manifesting as stress, depression, and health deterioration that further increase risk for emergency visits and hospitalizations of caregivers, which increases risks to people living with dementia [3,8,9].

Research has established that stabilizing underlying chronic conditions is critical for preserving brain health in people living with dementia, and the most common comorbidities are associated with impaired cerebral blood flow and oxygen delivery, which in turn contribute to neuroinflammation and accelerated decline [10]. Thus, adherence to consistent medication use and ongoing monitoring can impact disease progression and stabilize cognition [11].

Medication mismanagement has far-reaching economic consequences. Hospital stays cost Medicare nearly 3 times more for dementia patients than for other older adults, and these hospitalizations often lead to long-term care facility admissions rather than a return home [1,12]. The average cost of a nursing home stay for dementia care is estimated at US $28,078 per patient every day a patient is prematurely removed from the home, which adds to the billions of dollars per year spent on caring for people living with dementia [13]. Over 11 million individuals provide unpaid care to people living with dementia, resulting in over 18 billion hours of care valued at nearly US $350 billion annually [1,14]. Premature institutionalization due to medication errors represents a modifiable factor that amplifies both direct health care expenditures and the emotional and financial burden on families.

Scientific Premise

Memory relies on distinct systems in the brain. Declarative memory, mediated by the hippocampus and related temporal lobe structures, supports conscious recall and is severely impaired in Alzheimer disease [15]. Procedural (habit) memory is managed in the neostriatum and often remains intact for patients with Alzheimer disease [16]. Preserved habit memory in this population supports unconscious, repetitive learning, allowing people living with dementia to maintain routine tasks such as brushing teeth, dressing, or taking medication, even when declarative memory fails. Recognizing and building on this distinction provides an evidence-based rationale for habit-centered interventions to improve medication management.

The HomeCare System

The HomeCare System (HCS) is an innovative self-medication device (SMD) that builds upon this neuroscience-informed foundation. Current models of SMDs rely heavily on user programming and frequent manual loading, which are contraindicated for patients with dementia. The HCS device reduces common home medication errors by automating safeguards to ensure that the right patient receives the correct medication at the correct dose, limiting manual aspects of medication management. The design reduces reliance on manual activities and leverages habit-forming memory systems through chaining logic, a behavioral method that breaks down complex

XSL•FO
RenderX

routines into manageable, repeatable steps. This approach fosters habit formation and supports independence without requiring explicit recall. Subsequent dispensing and monitoring activities are conducted by the system. The device is designed to reduce errors and relieve caregiver burden by automating the medication safety chain from delivery to consumption. Core functions include (1) encoded medication data into RFID-enabled caps with automated detection of dosage and scheduling for up to 90-day supplies, (2) automated dispensing with chain-of-custody verification and logging, (3) dual-camera FaceID authentication, (4) clinical decision support for early intervention, and (5) customizable alerts and notifications for caregivers and providers delivered via mobile or electronic platforms. Real-time adherence monitoring is coupled with secure video capture of ingestion events, allowing for passive data collection on medication safety and user interactions.

The purpose of this study was to evaluate whether HCS features met the usability needs of patient-caregiver dyads. This was assessed by (1) in-clinic usability testing device set-up time less than 5 minutes, (2) completion of at least 75% of all usability testing tasks, (3) occurrence of no more than one noncritical error per dyad, and (4) mean System Usability Scale (SUS) score greater than 68. The secondary objective was to identify novel platform enhancements that could improve future device use in this population through qualitative feedback. Qualitative feedback was captured through group discussions with patient-caregiver dyads.

Methods

Study Design

HiDO Technologies, in collaboration with Rush University, conducted a human factors usability analysis study to validate the HCS prototype in dyads with people living with dementia and their caregivers. Two sequential in-clinic usability cohorts were run at different time points with the same protocol. Participants were recruited from the Rush Memory Clinic and Rush Alzheimer's Disease Center data repository. For the analysis presented here, data were combined into a pooled dataset, enabling integrated evaluation of usability outcomes and replication of findings. The study was conducted in-clinic and focused on evaluating the system's effectiveness in recognizing and accurately recording medication behaviors among persons with Alzheimer disease and related dementias.

Study Population and Recruitment Process

The study was conducted by the Rush Alzheimer's Disease Center at Rush University Medical Center, Chicago, Illinois. Participants were identified and recruited from 2 sources: the Rush Memory Clinic and the Rush Memory Clinic Data Repository. The Rush Memory Clinic, part of Rush University Medical Center and affiliated with the Rush Alzheimer's Disease Center, is a referral clinic that offers comprehensive clinical evaluations for complaints of memory loss or other cognitive and behavioral changes, and recommendations for managing these conditions. The Rush Memory Clinic Data Repository is a center-maintained institutional review board (IRB)–approved registry that collects and stores information that may help answer future questions about Alzheimer disease and other diseases and conditions associated with memory and aging. Registry participants are given the opportunity to indicate their willingness to be contacted about current and future research studies affiliated with the Rush Alzheimer's Disease Center.

Patients receiving clinical services at the Rush Memory Clinic and meeting preliminary inclusion criteria were identified and provided with information about the study (eg, IRB-approved study flyer) at the time of their clinical appointment or by phone afterwards. Registry participants meeting preliminary inclusion criteria who had indicated willingness to be contacted about future research studies were identified and contacted by phone by research staff to share study information and assess interest. All registry screening and study recruitment were carried out by research assistants at the Rush Alzheimer's Disease Center, specifically trained in cognitive research protocols.

Interested individuals were asked a set of screening questions to confirm eligibility, such as age and availability of a caregiver (age 18 years or older) willing to participate. Individuals with cognitive deficits and/or serious mental health or medical conditions that may have compromised safety or the ability to provide accurate user feedback were excluded.

Eligible and interested individuals were scheduled for an in-clinic visit to obtain informed consent and participate in the usability testing and group discussion session. A study-specific informed consent process was conducted using IRB-approved consent forms. Staff explained study aims, procedures, risks, and assessments, and used teach-back methods to confirm understanding. Written documentation of informed consent was obtained from both dyad members. All data were collected under the direction of the investigators.

Study Procedures

Once consented, dyads participated in usability testing and a group discussion session that included tasks related to the use of the HCS. HiDO staff, our human design expert (SB), and Rush Research Assistant team members gave a live demonstration of the HCS product and answered questions on device setup and medication dispensing prior to testing. There were 2 usability testing steps: setup and use. For the setup tasks, dyads were asked to conduct the HCS device setup, including completing facial recognition tasks and entering a security pin. The patients were required to complete this step, but were informed that if they needed assistance, they could consult their caregiver. Dyads were provided an opportunity to complete the setup up to 3 times. Repeated attempts were optional within the study visit, and lower numbers reflected participant preference rather than dropout after device failure.

Then, the patient was asked to use the HCS device to conduct a medication dispensing activity (vitamin C). The next activity was to successfully simulate "taking of medication" during the usability test, with video capture of this process. Taking medication was performed as a simulation, and no medication was actively taken. During device setup, dyads were asked to perform all device setup and registration steps using a "think-aloud" protocol. In a "think-aloud" protocol, the user completes each step in the process while saying it out loud. Participants were asked to say what came to their minds during

XSL•FO
RenderX

the task. The think-aloud process was recorded on paper data forms by the research assistants during the activity.

Once the device was enabled according to the protocol, patients were asked to complete a second set of predefined device use tasks: (1) recognize the medication reminder on the HCS device and the mobile phone that was in the room with the patient—each dyad had a mobile phone paired to the HCS, (2) unlock the HCS device with facial recognition, and (3) successfully simulate consumption of the dispensed medication (vitamin C). As with setup, this was a simulation, and no medication was taken.

The study team recorded critical and noncritical errors (predefined by the study protocol as developed by the HiDO team and the investigators at Rush) encountered by the participants after the 2-part usability study was completed with each dyad. A critical error was defined as an error that prevented full deployment of the system, preventing medication from being dispensed or dispensed correctly. A noncritical error was defined as an error that diverted the participant from the intended path but did not significantly affect the usability of the system.

Following the setup and use testing, dyads were asked to complete an SUS score with a 0-to-100 rating to measure the perceived usability of the system, as well as a 7-point likeability scale on their preferences related to the HCS. After SUS and likeability ratings were captured, dyads participated in semistructured group discussions. Group discussions included feedback about the device usability, relevance to use in the everyday home environment, enthusiasm, perceptions on setup, medication delivery experience, device ergonomics, alerting, challenges, and suggested improvements. The group discussion was conducted in English in a private room in the Rush Alzheimer's Disease Center conference room by the investigator (SB) with research assistants. The audio of the discussion was recorded and transcribed for analysis. Each session was scheduled for 60 minutes.

Data Collection

Time to set up the device, device task completion rate, number and type of critical and noncritical errors, and SUS scores were quantitatively measured. Setup time was documented in minutes and seconds, and successfully completed tasks were counted and numbered. SUS and likeability scores (reflecting questions targeting overall enthusiasm, setup, medication delivery, device ergonomics, alerting, and challenges) were recorded per dyad. Critical and noncritical errors in device setup and management were recorded, including when to take medication, retrieving the dispensed pill, taking the dispensed pill, and technical interactions with the device. Semistructured interviews were analyzed for targeted feedback about platform features. HCS video and other recorded data from the usability testing were captured and stored as audio files in the Microsoft Teams site of Rush Alzheimer's Disease Center for this study. Recorded think-aloud data and SUS scores were saved as Microsoft Word documents.

Ethical Considerations

The study was approved by the IRB at Rush University Medical Center (protocol 21033001-IRB01). All patient and caregiver participants provided written informed consent. All data used in this study were deidentified. Participants were compensated US $75 per dyad member (US $150 per dyad). The investigators and study staff monitored safety via adverse event reporting defined in the IRB-approved study protocol. Risks were minimal to participants, as they interacted with a device under close supervision by the study team in a clinical environment. No actual medications were administered during the study; vitamin C was dispensed by the platform but not consumed. Video capture was limited to the simulated dispensing session, stored in a secure deidentified form for analysis, and used only for protocol-defined usability assessment.

Statistical Analysis

The primary objective of this human factors usability study was to evaluate functional performance and user interaction with the HCS, not to test a clinical hypothesis. Power calculations were based on standards for usability testing rather than inferential statistical power. U.S. Food and Drug Administration human factors research guidelines suggest that a sample of 15-20 participants per user group is typically sufficient to identify at least 90% of usability issues within a defined task set [17]. Our pooled sample of 35 patient-caregiver dyads exceeded this benchmark and provided sufficient power to assess primary usability endpoints, including task success rate, time-on-task, and SUS scores.

The primary endpoint was the mean SUS score, with a prespecified benchmark of ≥68 indicating above-average usability. Secondary endpoints included setup time (<5 minutes), task completion rate (≥75%), and error rate (≤1 noncritical error per dyad). Given the iterative design of the HCS, 2 independent cohorts were analyzed to confirm the replicability of findings and assess potential improvements between study phases. The pooled analysis was used to ensure adequate power for quantitative comparisons while capturing qualitative insights across both groups.

Qualitative Data Analysis

All qualitative data collected during the usability sessions were analyzed to complement quantitative findings and identify areas for device optimization. Audio recordings from the "think-aloud" usability exercises and semistructured postsession interviews were transcribed verbatim and verified for accuracy by the research team at Rush Alzheimer's Disease Center.

A hybrid deductive-inductive approach was applied. Deductive codes were derived from the study's predefined domains of interest, including setup experience, device navigation, perceived usefulness, and caregiver burden. Inductive codes captured emergent insights related to user experience, accessibility, and design improvements. A trained researcher (SB) independently coded all transcripts. Codes were grouped into categories and overarching themes reflecting participant perceptions of usability, acceptability, and integration within daily routines. Given the formative usability purpose of the study, transcripts were coded by the trained researcher (SB) and discussed with the broader study team, including research assistants, to refine themes. This single-coder approach is a limitation.

XSL•FO
RenderX

A total of 35 transcripts were analyzed, and 547 quotes were coded, yielding 119 open codes and 5 primary themes that captured user experience variability across cohorts and age groups. These included (1) innovation and perceived value; (2) ease of use and learning curve; (3) physical design and environmental fit; (4) cognitive and emotional support for users; and (5) trust, safety, and the role of caregivers.

Results

Evaluation Results

User Statistics

A total of 316 dyads were contacted for study participation. Of those, 125 declined participation, 79 did not meet study eligibility, and 76 remained pending at the time enrollment closed (eg, did not return contact attempts and were still considering participation). A total of 35 dyads (people living with dementia + caregiver = dyad) participated in the study. Demographics and cohort details are defined in Table 1. Cohort 1 included 15 participants, and cohort 2 included 20 participants. People living with dementia were aged 50 years or older and diagnosed with mild cognitive impairment or early-stage dementia (Montreal Cognitive Assessment score 18 to 24, inclusive, or equivalent cognitive assessment) as noted in the chart.

[a]GED: General Education Development.

Across both cohorts, the overall mean age of patients was 74 (range 64-86) years and caregivers averaged 67 (range 34-81) years. In cohort 1, people living with dementia averaged 72 (range 64-86) years and caregivers averaged 64 (range 34-75) years; in cohort 2, people living with dementia averaged 75 (range 66-82) years and caregivers averaged 69 (range 46-81) years. Overall, 60% (21/35) of the people living with dementia were female. By race, 74% (26/35) were White, 20% (7/35) Black or African American, 3% (1/35) reported more than one race, and 3% (1/35) preferred not to answer. The level of education was predominantly higher, with 69% (24/35) holding a bachelor's degree or higher, 17% (6/35) reporting some college, 9% (3/35) reporting secondary level education or General Education Development. Most participants were married

XSL•FO
RenderX

(28/35, 80%), with 6% (2/35) divorced, 6% (2/35) never married, and 9% (3/35) widowed. Patterns were similar across cohorts.

Setup Times

Across the key measures, the overall average initial setup time was 2:59 minutes (n=35). Setup time varied by cohort 1 (3:31 minutes) and cohort 2 (2:35 minutes), with cohort 2 requiring slightly less time than cohort 1 across age groups. See Tables 2 and 3.

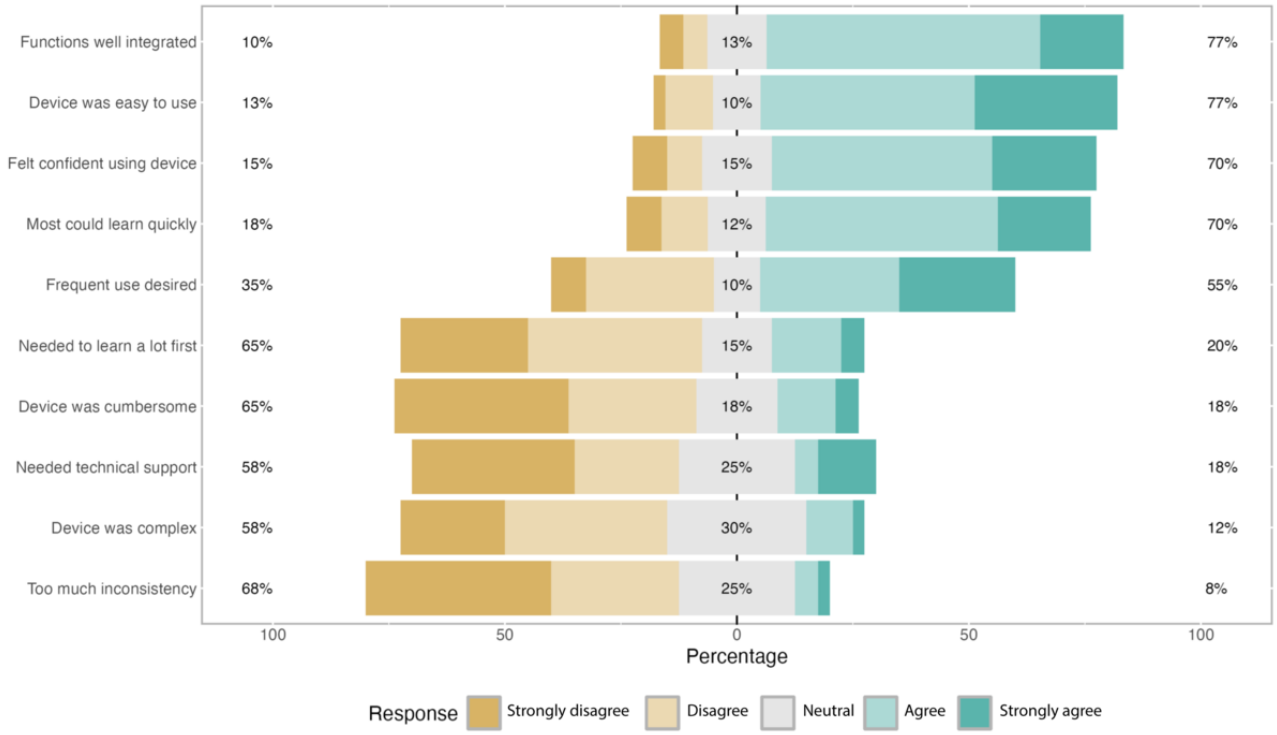
Medication Reminder and Dispensation of Medicine

All participating dyads (n=35) successfully dispensed medications using the HCS (Tables 2 and 3). Participants were allowed to complete dispensing as many times as they desired, with attempts ranging from 1 to 5 across the sample. Each attempt required participants to respond to a reminder, unlock the device via FaceID, and dispense medications, with time intervals between steps ranging from 5 to 15 minutes from reminder to completion.

Across all 35 participants, the average time for the first dispense attempt was 1:41 minutes (n=35). The second attempt averaged 1:35 minutes (n=21). Attempt 3 was conducted in an average of 2:03 minutes (n=6). The 64-69-year-old age group completed the first attempt faster than the 70-74 or 75+ age groups. Time improvement between attempt 1 and attempt 2 improved overall by 0:07 seconds, with improvement for the 70-74-year-old (–0:32 seconds, n=5) and 75+ age group (–0:12 seconds, n=11), and +0:18 seconds (n=5) for the 64-69-year-old age group. Setup and attempt times between cohort 1 and cohort 2 varied, with overall times slightly faster in cohort 2.

SUS Ratings and Task Performance

The overall mean SUS score across all participants was 70.2 (SD 18.2; n=34) (Tables 2 and 3), reflecting an above-average usability score. Mean SUS scores differed between the two study cohorts. Cohort 1 participants reported a mean SUS score of 79.0 (SD 18.2; n=15), and cohort 2 participants reported a mean score of 63.3 (SD 15.2; n=19). In cohort 1, the 64-69 age group reported the highest score at 83.6 (SD 15.1; n=7), compared to 73.8 (SD 12.4; n=2) for 70-74-year-olds and 75.4 (SD 23.9; n=6) for the 75+ group. In cohort 2, the 64-69 group scored 66.7 (SD 12.6; n=4), the 70-74 group scored 61.2 (SD 2.5; n=4), and the 75+ group scored 63.1 (SD 18.5; n=12).



Analysis of the pooled data by age group is summarized in Tables 2 and 3. The 64-69-year-old age group overall reported the highest mean SUS rating at 78.5 (SD 15.9, n=10). This decreased to 65.4 (SD 8.7; n=6) for 70-74-year-olds and was 67.2 (SD 20.6; n=18) for the 75+ year-old cohort. Task performance data demonstrated that the overall mean time for the initial task attempt (attempt 1) was 01:41 (SD 1:13; n=35). The overall mean time for the subsequent attempt (attempt 2) was 01:35 (SD 1:10; n=21), resulting in an average time improvement of 7 seconds (–0:07; n=21). Time improvement varied by age group: the 70-74-year-old age group improved on average by 32 seconds (–0:32; n=5), while the 75+ year-old age group improved by 12 seconds (–0:12; n=11). The 64-69-year-old age group took an average of 18 seconds (0:18; n=5) on their second attempt.

Likert Scale Findings: Usability

Several findings were reported related to usability based on the SUS [17] (Figure 1). Most participants (27/34, 77%) agreed or strongly agreed that the device was easy to use, the device's functions were well integrated (27/34, 77%), and reported confidence using the device (24/34, 70%). Over half of the participants agreed or strongly agreed that they needed technical support to use the device (20/34, 58%), the device was complex (20/34, 58%), and they needed to learn a lot before using the device (23/34, 65%).

XSL•FO
RenderX

Figure 1. System Usability Scale scores on device usability.

Critical and Noncritical Errors

Analyses of participant errors of the pooled sample (n=35) are reported in Table 4. All errors were recorded, and more than one error could be attributed to one participant. Two critical errors were recorded in the pooled sample, both of which occurred in cohort 1 by two unique users. There were 17 noncritical errors recorded by 11 unique participants in the pooled sample. In cohort 1, eight participants made 14 noncritical errors, and in cohort 2, three participants made 3 noncritical errors. The 75+ age group demonstrated the highest frequency of noncritical errors, with 4 participants accounting for 8 total errors. Errors were tracked through the HCS video interface.

Table 4. Critical and noncritical errors by cohort and age group[a].

Cohort and age (years)	Participants, n	Participants with ≥1 critical error[b], n	Total critical errors[c], n	Participants with ≥1 noncritical error[b], n	Total noncritical errors[c], n
Cohort 1					
64-69	7	1	1	3	5
70-74	2	0	0	1	1
75+	6	1	1	4	8
Overall	15	2	2	8	14
Cohort 2					
64-69	4	0	0	1	1
70-74	4	0	0	0	0
75+	12	0	0	2	2
Overall	20	0	0	3	3
Overall (both cohorts)	35	2	2	11	17

[a]The table presents (1) the number of unique participants with at least one critical or noncritical error and (2) the total number of errors recorded for each group. “Overall” rows summarize all age groups within each cohort; the bottom row pools both cohorts. Errors were scored based on predefined definitions and coded in the Participant In-Clinic Usability Case Report Form.

[b]Participants with ≥1 error: number of people who made at least one error of that type.

[c]Total errors: sum of all observed errors, including multiple errors by the same participant.

RenderX

Qualitative Results

Themes From Qualitative Data

Five primary themes emerged across the 35 dyad interviews which included (1) innovation and perceived value represented as enthusiasm for a technology that could reduce caregiver workload; (2) ease of use and learning curve, or the need for clearer setup instructions and guidance; (3) physical design and the environmental fit, accessibility, and ergonomics including preferences for larger fonts, higher contrast, and adjustable display angles; (4) cognitive and emotional support for users; and (5) trust, safety and the caregiver's role and support for shared use reflecting the desire for connected tools and training resources. Themes are summarized with illustrative quotes from conversations.

Theme 1: Innovation and Perceived Value

Participants viewed the HiDO system as an innovative solution to improve medication adherence and caregiver support. They valued the automation and accountability features, which simplified routines or reduced caregiver burden: "great technology for someone with memory issues." Some participants reflected satisfaction with pillboxes and found the device complex, while others felt it created accountability to take medications.

Theme 2: Ease of Use and Learning Curve

Participants described the device as "self-explanatory" and "easy once set up," yet several admitted to feeling "overwhelmed at first" or "intimidated by all the steps." Participants recommended simplifying the touchscreen interface with larger fonts, slower response time, and multimodal feedback (eg, auditory or visual cues). Most users achieved proficiency after repeated use, with one participant summarizing, "There's a learning curve, but it's simple once you get the hang of it."

Theme 3: Physical Design and Environmental Fit

Participants consistently described the device as bulky and difficult to integrate into home environments. Size, need for continuous power, and aesthetic incongruence were perceived as barriers. Many suggested a smaller or wall-mounted design, enhanced portability, and customizable color or appearance to reduce stigma, with participants noting, "I'd put it in my kitchen if it looked more like an appliance."

Theme 4: Cognitive and Emotional Support for Users

The device's reminder and monitoring capabilities provided reassurance and supported autonomy for some users. Participants valued multimodal alerts and personalized prompts and suggested these could be enhanced. Emotional themes centered on feeling empowered and less dependent on caregivers, with one participant summarizing, "It helps you feel you're still in control of your medications." Usability was seen as optimal for mild cognitive impairment but potentially limited for users with advancing dementia and suggested progressive usability that evolves with cognitive decline.

Theme 5: Trust, Safety, and the Role of Caregivers

Facial recognition and dispensing safeguards enhanced perceived safety, but users also expressed apprehension about malfunction or data misuse. The presence of caregivers was viewed as critical, especially for setup, refilling, and troubleshooting. As one caregiver noted, "You can't rely on the phone ping; you need something that tells me if they didn't take it." Participants highlighted the tension between independence and monitoring.

Discussion

Implication of Our Usability Evaluation

Our study assessed the usability and functionality of the HCS with 35 dyads, including setup and use capability, system usability, and qualitative feedback. Two cohorts with similar participants were included in a pooled analysis. On average, the overall time from reminder recognition to medication dispensation was 1.41 minutes (n=35), which was below the prespecified 5-minute threshold for device setup. Task performance data suggest the device was able to be set up and engaged with by the user population across age groups. There were noted differences by age and attempt, suggesting improvements when making repeated attempts, but the sample size was not designed for subgroup analysis. There were low instances of critical errors across the study, indicating the built-in safeguards were performing as designed. The noncritical errors (greater than or equal to 1) helped identify areas that need further work and modifications in product design, especially onboarding user experience and operating manual design.

The overall SUS ratings exceeded the threshold score of 68, typically considered above average, although scores varied between cohort 1 (79) and cohort 2 (63.3). Within age group variations are important to note for future research, but the sample size of 35 participant dyads was not designed to address subgroup analyses. The difference between the two cohorts may reflect iterative improvements in study implementation rather than inherent usability differences. Cohort 1 participants were the first users to engage in the HCS in this study, and likely had greater staff engagement to ensure the protocol was being followed and to address any unforeseen challenges. This could have contributed to slightly longer completion times in cohort 1. Cohort 2 may have benefited from refinements in user instructions and onboarding. Although both cohorts achieved above-average SUS scores for usability, the lower SUS scores in cohort 2 may also reflect slightly higher staff engagement with the setup and onboarding activities in cohort 1, which could have established a different rapport during the process than in cohort 2. SUS scores also represented valuable insights into usability for in-home SMDs with patients who are cognitively impaired. It adds value to the field that our data demonstrate an SMD like the HCS is reported as easy to learn and use, and participants felt confident using it, but further work is required to build in simple, clear, and precise operating and use instructions to meet the users' needs.

Qualitatively, participants recognized the HCS's potential to improve medication safety and reduce caregiver stress. Adoption was moderated by perceived complexity, physical design, and the degree of human connection integrated into the technology. Findings underscore that usability for populations with cognitive

XSL•FO
RenderX

impairment requires iterative design emphasizing simplicity, adaptability, and trust.

Accounting for the between-cohort differences, findings from this study make a significant contribution to the role of SMDs in supporting the challenges of medication adherence in people with dementia and cognitive impairment. Medication adherence tools have undergone substantial transformation since the 1950s, evolving across 4 generations. Early solutions (Generation 1) relied entirely on manual methods such as pill bottles and organizers, placing the full responsibility on patients and caregivers. Generation 2 introduced digital aids, including smart caps and mobile apps, which provided reminders and basic tracking but remained limited by their dependence on user input. Generation 3 technologies advanced to scheduled dispensers with remote monitoring features, yet they remained insufficient for individuals with cognitive decline, particularly those with Alzheimer disease. Current Generation 4 solutions seek to alleviate user burden by automating manual tasks and incorporating advanced monitoring and intervention features.

Principal Findings

The HCS represents a novel advancement within this fourth generation, extending usability to one of the most vulnerable patient groups—people living with dementia. This population faces unique challenges, including impaired cognitive recall, difficulties with complex device setup, and heavy reliance on caregivers. Findings from this study underscore the potential of the HCS to address these barriers. Participants emphasized the perceived usefulness of an automated medication management system, alleviating reliance on caregivers and reducing burden on patients by accessing habit memory. The automated reminders and facial recognition were noted as valuable for simplifying access, while participants also identified areas for improvement such as device size, display accessibility, and clearer setup support. These insights highlight both the feasibility and the refinement opportunities of a fully automated adherence system in real-world home settings.

Strengths and Limitations

This study has a few important limitations. Recruitment focused on patients who were already being treated in a clinical care setting, which may have limited the diversity of the participants to the available demographics of the Rush Medical Center. While efforts were made to include a diverse sample, the population for both patient and caregiver was two-thirds White and one-third Black, without broader racial and ethnic representation. The participant cohort was more likely to be educated, with most participants holding a bachelor's degree or higher. Because of these factors, our cohort may not represent all older adults taking multiple medications. However, as the primary outcome of this study was to demonstrate the feasibility of HCS to determine usability changes and enhancements in setup and use, a random and representative sample was not feasible or critical to achieve these initial goals. Two important strengths were noted. First, we conducted the study with patient and caregiver dyads in two separate but comparable cohorts, providing a larger sample and a broader dataset for analysis. Second, we incorporated qualitative methods, which enabled dyads to share valuable insights that could improve the HCS device for future implementation.

Conclusions

Demonstrating feasible use in people living with dementia, the HCS has the potential to improve the standard of care for medication adherence more broadly. Unlike prior generations of adherence tools, the HCS integrates features that account for both cognitive and caregiving demands, addressing a critical innovation gap specifically in a patient population with limited options for automated medication dispensing. Addressing usability and functionality of the HCS with patient and caregiver dyads advances the potential for more effective medication management in people living with dementia. Results of this study provide the foundation for future studies to measure medication management compliance, impact on disease progression, prolonged quality of life, and more effective communication between patient, caregiver, and clinical care team.

Acknowledgments

We gratefully acknowledge the contribution of the participants who agreed to participate and share their feedback.

Data Availability

The datasets generated or analyzed during this study are available upon reasonable request and in accordance with data sharing policies and with respect for intellectual property and proprietary data constraints. A request for data can be placed by emailing the corresponding author.

Funding

This study received funding from the National Institutes of Health, National Institute on Aging (grant R43AG077737). The National Institutes of Health did not have any input on the design, development, implementation, and reporting of the findings from the study.

Abstract

Background: Nurses are required to perform multiple tasks concurrently, which leads to multitasking situations, and they have to continuously determine which tasks should be prioritized. This is particularly challenging for novice nurses. Although IT-based systems supporting prioritization have begun to emerge, research on the types of information required when prioritization is processed computationally is scant. Despite the clear need for a supportive information system to assist nursing task prioritization, such systems are not yet sufficiently developed.

Objective: This study aimed to explore the appropriate granularity and structure of information that should be provided to computational systems to support decision-making based on the influencing factors of nursing task prioritization.

Methods: Semistructured interviews were conducted with 10 nurses working in general wards to examine the factors they consider when determining task prioritization during clinical practice. Data were analyzed using an inductive, semantic approach based on a thematic analysis framework.

Results: Three themes and nine categories including (1) medical condition assessment factors (signs of acute physiological changes and indicators of clinical status and conditions), (2) patient-related nursing care factors (physical status, psychological condition, and personal characteristics; care needs during hospitalization; and treatment goals and care preferences), and (3) organizational and operational work factors (temporally structured tasks, requiring collaboration partners for task execution, environmental factors affecting task performance, and institutional- and ward-level policies) were identified.

Conclusions: Analysis of computational tractability of the identified factors indicated that medical condition assessment factors are relatively quantifiable. In contrast, patient-centered care and organizational and operational work factors rely on contextual and experiential judgment, limiting standardization and formalization. Regarding such ambiguous and context-dependent elements, flexible information-processing approaches, such as large language models, in addition to conventional rule-based methods, may be effective. Furthermore, the appropriate level of information granularity should be determined by the nature of the prioritization outputs required in actual nursing practice rather than the degree of abstraction itself.

Introduction

Background

Clinical nurses care for multiple patients while concurrently performing a wide range of patient-specific nursing tasks. Consequently, multiple tasks frequently overlap within the same time frame, a phenomenon commonly defined as multitasking—the concurrent execution of 2 or more tasks [1,2]. Multitasking is considered among the most prevalent stressors in nurses' daily practice [3] and has been reported to occur in

XSL•FO
RenderX

approximately 26% - 50% of nursing activities [1,2,4]. Frequent multitasking is associated with task interruptions [5], which in turn increase cognitive and mental workload, leading to deviations from standard procedures, task errors, and increased risk of burnout [6-10].

Such challenges extend beyond interruptions, persisting throughout nursing care delivery. Particularly, when multiple tasks must be performed concurrently, nurses must determine the tasks that should be prioritized. In Japan, nursing students typically care for only one patient during clinical training, limiting their exposure to multitasking situations. Consequently, novice nurses often struggle to prioritize care after entering clinical practice [11-13]. Although prioritization challenges affect all nurses, they tend to be pronounced in early professional practice.

Nursing prioritization is the ordering of nursing problems by urgency and/or importance [12]. However, in clinical practice, prioritization is not determined by a single criterion; rather, it is influenced by multiple factors, including patient acuity and care intensity, availability of resources, organizational and personal values, nursing theories and models, and nurses' proficiency [12,14]. Additionally, prioritization is influenced by multiple mechanisms, including the Maslow effect (prioritization of life-sustaining and physical care), the outcome effect (immediate visibility of intervention outcomes), the time-cost effect (short or more predictable tasks), the collective adaptation effect (tasks emphasized within the team), and the audit effect (tasks confirmed by physicians or managers) [15]. These findings indicate that nursing prioritization is complex, shaped by multiple, overlapping cognitive and organizational factors rather than a single criterion.

Previous studies have introduced educational interventions using simulations and virtual reality to enhance prioritization skills [16-18]; however, their effectiveness has not been consistently demonstrated. Although real-time role modeling by educators or senior nurses is effective [19], such approaches rely heavily on individual interpretation and experiential learning, limiting their applicability as clinical decision support. In contrast, IT-based approaches, such as rule-based methods that identify relevant factors using logistic regression and construct decision trees for prioritization, have also been proposed [20]. While useful in specific applications such as staff scheduling [21], these approaches face significant challenges owing to implicit, context-dependent conditions that are difficult to formalize mathematically [22]. Even in relatively stable task environments, adapting rule-based methods to real-world clinical practice remains challenging. Although previous studies have attempted to identify and organize detailed nursing elements into rule-based frameworks, the diversity and context-dependence of practice hinder the representation of all relevant factors as explicit conditions. Moreover, only a few studies have systematically examined how factors influencing nursing prioritization can be structured for computational processing, including the level of information granularity and structure of representation that enable such processing [12,14,15,20]. Thus, despite the clear need for a supportive information system to assist nursing task prioritization in clinical practice, such systems remain insufficiently developed. This gap can be addressed by acquiring a clearer understanding of how nurses' prioritization decisions can be represented in a form suitable for computational handling.

Aim

This study aims to explore how nursing prioritization factors can be represented in terms of information granularity and structure when computational processing is assumed. To this end, thematic analysis was used to identify and organize the influencing factors of nurses' prioritization decisions. By elucidating the information structures suitable for computational handling, this study provides foundational insights for developing information systems that support nursing prioritization.

Methods

Study Overview

In this qualitative study, semi-structured interviews and a thematic analysis were conducted. This study was conducted in accordance with the Consolidated Criteria for Reporting Qualitative Research checklist.

Setting and Sampling

Participants were recruited between September and November 2024 from general wards of a national university hospital with a nurse-to-patient ratio of at least 1:7. As factors influencing nursing prioritization may differ by ward type and years of nursing experience, both novice and experienced nurses working in general wards were included. Novice nurses included those with 2 or fewer years of clinical experience, whereas experienced nurses included those with 5 or more years of experience and at least 1 year of service in their current ward. Both wards used the partnership nursing system as their nursing care delivery model. Potential participants were identified through the researchers' professional networks in collaboration with ward nurse managers, and purposive sampling was used. All candidates received an explanation of the study purpose and procedures, including audio recording; those who agreed to participate provided written informed consent.

Data Collection

The interviews were conducted once, face-to-face in Japanese by a single researcher (KI, registered nurse; male) with experience in qualitative research, and took place in the participants' wards. Individual, semistructured interviews were conducted, with primary questions focusing on factors influencing task prioritization in nursing practice; these questions were generated through a pilot study. Follow-up questions were asked as appropriate based on the participants' responses. The order and content of the questions were flexibly adjusted. Multimedia Appendix 1 provides an interview guide. Data collection was concluded when no new categories were generated. The interviewer and participants had previous professional contact through prior research activities. Field notes were taken during the interviews to supplement contextual understanding.

XSL•FO
RenderX

Data Analysis

This study aims to identify the factors influencing nursing task prioritization and elucidate context-dependent, multifaceted patterns of meaning. Therefore, an inductive and semantic approach to thematic analysis, as proposed by Braun and Clarke [23], was used to extract meaning from the data.

The analysis involved the following steps. First, the audio-recorded interviews were transcribed verbatim, and the transcripts were read repeatedly to achieve familiarization with the data. Subsequently, the researcher (KI) independently generated the initial codes inductively by focusing on meaningful units within the data. Similarities among the generated codes were examined, and themes and categories were identified. The identified themes and categories were reviewed collaboratively with another researcher (MT; female), and iterative refinement, including merging and differentiating themes, was conducted until consensus was reached. Finally, each theme and category was clearly defined and named to capture its essential meaning.

To enhance the credibility of the analysis, interpretations were discussed among researchers from different academic backgrounds. To reduce bias from the researcher's professional nursing background, ongoing reflexive discussions were held throughout the analytical process, and guidance was sought from an expert in thematic analysis. To further ensure credibility, transcripts were returned to the participants, and some participants confirmed that the content was accurate. Considering participant burden, feedback on the final analytical results was not requested. All analyses were conducted in Japanese, and the findings were translated into English. The researchers reviewed the translations to ensure accuracy. The data were analyzed using Microsoft Excel (version 2511).

Ethical Considerations

This study was approved by the Kyoto University Graduate School and Faculty of Medicine Ethics Committee (approval 4460). Participation in the study was voluntary. Recorded audio data were processed on devices with appropriate security measures, and participant privacy was protected through pseudonymization during the generation of analysis datasets. All participants were provided with a detailed explanation of the study, and written informed consent was obtained prior to participation. Participants were also informed of their right to withdraw consent at any time. No compensation was provided for participation in the study.

Results

Participant Characteristics

Table 1 presents details of the study participants. The participating wards included cardiology and thoracic surgery; 4 experienced and 6 novice nurses were recruited from the cardiology and thoracic surgery wards, respectively, resulting in 10 interviews. The mean interview length was 52.0 (SD 9.6) minutes. No participants declined to participate or withdrew from the study.

Table . Demographic profile of the participants.

Participants	Groups	Sex	Years of experience		Ward type
			Nursing	Ward	
1	Veteran	Male	9th year	5th year	Cardiology
2	Veteran	Male	15th year	3rd year	Cardiology
3	Veteran	Female	6th year	6th year	Cardiology
4	Veteran	Female	13th year	3rd year	Cardiology
5	Novice	Female	1st year	1st year	Thoracic surgery
6	Novice	Female	2nd year	1st year	Thoracic surgery
7	Novice	Female	2nd year	2nd year	Thoracic surgery
8	Novice	Female	2nd year	2nd year	Thoracic surgery
9	Novice	Female	2nd year	2nd year	Thoracic surgery
10	Novice	Female	2nd year	2nd year	Thoracic surgery

Overall Theme

Overview

Table 2 summarizes the factors influencing task prioritization by the general ward nurses. Three overarching themes including (1) medical condition assessment factors, (2) patient-related nursing care factors, and (3) organizational and operational work factors were identified. These themes comprised 9 categories.

XSL•FO
RenderX

Table . Themes, categories, and codes identified through thematic analysis.

Themes and categories	Codes
Theme A: medical condition assessment factors	
A-1: signs of acute physiological changes	Deterioration of hemodynamic status (eg, onset of arrhythmia and sudden decrease in blood pressure), worsening of respiratory status (eg, sudden decrease in SpO_2)
A-2: indicators of clinical status and conditions	Medical interventions (surgery, medication therapy, medical procedures, and diagnostic tests), laboratory data, vital signs, clinical findings, clinical symptoms, indwelling devices, oxygen therapy, medication therapy, fluid balance, progress notes, changes in condition during hospitalization
Theme B: patient-related nursing care factors	
B-1: physical status, psychological condition, and personal characteristics	Activities of daily living, presence of fall risk, physiological function (ability to expectorate), presence of dementia, presence of agitation, communication ability, personality traits
B-2: care needs during hospitalization	Illness stage, infection presence, intrahospital transfer, assistance with personal grooming, assistance with medication management, response to nurse call systems
B-3: treatment goals and care preferences	Discharge preparation, do not resuscitate orders, understanding of end-of-life preferences
Theme C: organizational and operational work factors	
C-1: temporally structured tasks	Time-specific tasks, non–time-specific tasks, unscheduled tasks, sequence-dependent tasks
C-2: required collaboration partners for task execution	Doctor, nurse, allied health professionals, family
C-3: environmental factors affecting task performance	Physicians' availability, nursing staff resources, temporal working conditions, task complexity, clinical procedures volume, number of assigned patients, location of assigned patients, presence of primary patients
C-4: institutional- and ward-level policies	Within the hospital, within the ward

Theme A: Medical Condition Assessment Factors

Overview

This theme represents factors that nurses consider when evaluating patient acuity and prioritizing tasks based on signs of acute physiological changes and clinical indicators. Nurses assessed and integrated information ranging from life-threatening changes to indicators requiring continuous monitoring to guide prioritization decisions. This theme comprises the following 2 categories.

A-1: Signs of Acute Physiological Changes

This category reflects situations in which nurses detect acute and marked changes in physiological indicators, such as the onset of arrhythmias, sudden decreases in blood pressure, or abrupt drops in oxygen saturation, and recognize these changes as signals of clinical deterioration requiring immediate attention. Such indicators strongly influence nurses' decisions to prioritize specific nursing tasks.

> *If an arrhythmia appears on the ECG or the oxygen saturation drops, I think I would prioritize going to see the patient.* [Participant 1, veteran]

> *If there's a significant drop in blood pressure, I feel that it takes priority over scheduled tasks.* [Participant 6, novice]

A-2: Indicators of Clinical Status and Conditions

This category encompasses information reflecting the patient's current condition, including laboratory data, vital signs, and clinical findings and symptoms, as well as factors related to ongoing medical management, such as medical interventions, indwelling devices, medication therapy, and oxygen therapy. The findings showed that nurses comprehensively integrate these diverse indicators to assess patient stability and care needs and to adjust task prioritization accordingly.

> *Patients who have just undergone surgery, those on the first postoperative day, those on mechanical ventilation, those receiving oxygen therapy, or those with unstable vital signs—I tend to prioritize seeing those patients first.* [Participant 8, novice]

> *Patients with higher severity often have multiple infusions, drains, or chest tubes in place, and sometimes temporary pacing leads as well. I assess those factors because their circulatory status can become quite unstable.* [Participant 2, veteran]

Theme B: Patient-Related Nursing Care Factors

Overview

This theme reflects how nurses prioritize nursing tasks based on patient-specific factors including physical status, psychological condition, and personal characteristics; care needs during hospitalization; and treatment goals and care preferences.

XSL•FO
RenderX

Nurses consider not only patients' medical conditions but also their functional status, psychological state, and understanding of and attitudes toward treatment when prioritizing tasks according to the clinical situation. This theme comprises the following 3 categories.

B-1: Physical Status, Psychological Condition, and Personal Characteristics

This category reflects evaluations based on individual patient characteristics, including physical and physiological functions, such as activities of daily living and the ability to expectorate, as well as psychological characteristics, such as cognitive function, presence of agitation, communication ability, and personality traits. The findings showed that nurses adjusted task prioritization and care approach according to the necessity of care, intervention complexity, and monitoring requirements based on these characteristics.

> *About patients with dementia, there is often a greater need for assistance with ADLs, and in terms of building trust or communication, I tend to go to them first. If I am late, even patients with dementia can feel anxious, stressed, or irritated, so I try to attend to them early.* [Participant 4, veteran]

> *Because they cannot express themselves verbally, I think they should be prioritized in case something urgent happens.* [Participant 6, novice]

B-2: Care Needs During Hospitalization

This category indicates that prioritization was determined based on care needs arising from patients' medical conditions and daily living during hospitalization. Nurses considered clinical assessments such as illness stage and presence of infection, alongside patients' expressed needs related to daily living support, including hospital transfer, personal grooming, and medication management. Furthermore, responses to nurse call systems were prioritized, as they were recognized as directly influencing patients' sense of security and the establishment of trust (Textbox 1).

Textbox 1. Representative quotes related to Category B-2

"In the hyperacute phase, that is the highest priority. For acute and terminal phases, it may depend on the individual's condition. Even among terminal patients, there are those whose condition is relatively stable and those who are much closer to death, and in those cases, they may be prioritized at the same level as hyperacute patients. Patients in a stable phase would come later" [Participant 4, veteran].

"When patients ask to go shopping or to be taken to the post office, I try not to postpone it too much. It's also about the relationship—if you make them wait too long, they become anxious, so I try to be mindful not to keep them waiting for too long" [Participant 3, veteran].

"For nurse call responses, I basically go as soon as it rings, unless there is a very compelling reason not to. In principle, I will respond immediately" [Participant 9, novice].

B-3: Treatment Goals and Care Preferences

This category indicates that factors related to patients' values and decision-making, such as their treatment goals and care preferences, influenced prioritization. Information related to treatment direction, including discharge preparation, do-not-resuscitate orders, and understanding of end-of-life preferences, was shown to be a key factor influencing nurses' decisions regarding care timing and approach (Textbox 2).

Textbox 2. Representative quotes related to Category B-3

"I think we start gathering information early on about how the patient wants to live after discharge, but we also check how they feel at that moment, given their current condition" [Participant 1, veteran].

"For terminal patients, it depends on the severity. If it's really down to just a few days or even that day, then the priority becomes very high. But it also changes depending on whether a DNR has been established or not" [Participant 6, novice].

"For patients receiving best supportive care, if they express how they want to proceed from here, I try to listen to that, and if I can make time during the day, I go to see them" [Participant 7, novice].

Theme C: Organizational and Operational Work Factors

Overview

This theme focuses on organizational and operational conditions under which tasks are performed, highlighting structural and environmental factors influencing planning, execution, and prioritization. Beyond clinical assessments and patient-related factors, nurses adjusted priorities realistically and flexibly by considering temporally structured tasks, required collaboration partners for task execution, environmental factors affecting task performance, and institutional- and ward-level policies. This theme comprises the following 4 categories.

C-1: Temporally Structured Tasks

This category reflects task characteristics with temporal constraints, including tasks with predefined timing or sequence of execution, and those requiring situational adjustment. Nurses differentiated tasks that must be performed at specific times, such as medication administration, flexibly timed tasks, and unscheduled tasks. They prioritized tasks based on overall workflow, while also planning tasks that required a specific execution sequence according to their impact on subsequent activities (Textbox 3).

XSL•FO
RenderX

Textbox 3. Representative quotes related to Category C-1

"I make sure to go at 9 o'clock for patients who have scheduled oral medications, since the administration time is fixed" [Participant 5, novice].

"For tasks that are already scheduled, such as hygiene care or wound care, I adjust my schedule so that they can be completed in the morning" [Participant 3, veteran].

"I often have to hurry to make sure blood glucose measurements are done in time before meals" [Participant 10, novice].

C-2: Required Collaboration Partners for Task Execution

This category reflects the individuals with whom nurses coordinate care as part of their duties, including doctors, other nurses, allied health professionals, and families involved in clinical decision-making or task execution.

> *For procedures, when a physician has a fixed schedule—such as outpatient clinics or surgeries—and there is no flexibility around that timing, we adjust other tasks so that we can carry them out accordingly.* [Participant 4, veteran]
>
> *For admissions, we often do them together as a pair, because there are records to complete and one person may need to explain things while the other documents, so admissions are often handled by two nurses.* [Participant 4, veteran or novice]

C-3: Environmental Factors Affecting Task Performance

This category indicates that the human, physical, and temporal environments surrounding nurses influence task execution and prioritization. Nurses adjusted their work based on human resource constraints such as physician availability, nursing staff resources, and shift schedules, and environmental factors, including clinical procedure volume, task complexity, and patient numbers and locations. These factors resulted in variations in task prioritization depending on the day of the week or time of day. In situations where staffing capacity allowed greater flexibility, tasks that were usually deprioritized were sometimes addressed.

> *On weekends, since there are fewer examinations, the ward tends to be calmer, so we try to focus on things like giving bed baths to patients who require full assistance or shampooing patients who haven't been able to get it done.* [Participant 6, novice]
>
> *When I have fewer assigned patients and a new admission comes in, I try to use that time to provide orientation for the patient, such as explaining the ward routines.* [Participant 10, novice]

C-4: Institutional- and Ward-Level Policies

This category indicates that institutional- and unit-level policies and operational rules influence how nursing tasks are performed, including the timing of care delivery and decisions regarding task prioritization.

> *Visiting hours start at 2:00 p.m., and since that is a hospital-wide rule, we provide guidance or education to family members after they arrive.* [Participant 1, veteran]
>
> *For medications such as immunosuppressants, blood concentration levels are important, so we make sure they are administered at the designated time. We try to administer them as early as possible and confirm adherence—this is something like a ward-level rule.* [Participant 8, novice]

Discussion

Principal Findings

Overview

This study identifies 3 themes and 9 categories influencing nurses' task prioritization in general wards. Theme A represents medical urgency and acuity, theme B reflects patient individuality and values, and theme C encompasses organizational and operational constraints. Consistent with previous studies, the findings suggest that nurses' prioritization is a dynamic process integrating multiple elements according to the situational context [12,14,15]. Regarding differences in information structure across themes, the elements in theme A are relatively amenable to simple classification (eg, binary or categorical) or quantification, whereas aspects of themes B and C rely on situational interpretation and experiential judgment, complicating uniform representation.

Theme A: Medical Condition Assessment Factors

The elements in theme A were largely consistent with previously reported criteria for medical urgency and acuity. Regarding A-1, previous studies have shown signs of acute physiological changes such as dyspnea, chest pain, airway obstruction, stroke, and massive hemorrhage to require immediate, high-priority intervention [14,24-26]. Similarly, the indicators of clinical status and conditions in A-2 were aligned with those reported in earlier research, including medical interventions, laboratory data, vital signs, oxygen therapy, medication therapy, indwelling devices, clinical symptoms, and progress notes [14,15,27]. In contrast, elements such as clinical findings and fluid balance were uniquely identified. These factors may previously have been subsumed under broader concepts such as "physiological needs" or "patient assessment," and therefore not explicitly defined as discrete elements [15,27]. Particularly, fluid balance appears to be a context-dependent factor influenced by the specific clinical setting of a cardiology ward. This finding highlights a key challenge: as elements are identified in greater detail, context-specific judgment criteria increase, potentially complicating comprehensive organization and standardization.

Theme B: Patient-Related Nursing Care Factors

In theme B, judgment elements based on patient individuality and values were identified. Regarding B-1, physical status, psychological condition, and personal characteristics such as activities of daily living, dementia, agitation, and personality

XSL•FO
RenderX

traits have also been reported in previous studies [14,25,28,29]. While some studies emphasize that psychological support should be prioritized [14], others highlight that such care is often left unfinished because of time constraints and difficulties in evaluating outcomes [15]. Although these factors can guide prioritization, their weighting likely depends heavily on individual nurses' values and clinical experience [12]. Furthermore, previous research shows that early-career nurses tend to emphasize psychosocial needs, whereas experienced nurses tend to deprioritize them or consider them the responsibility of other professions [28]. Physiological functions such as the ability to expectorate (ie, clear sputum from the airway) and communication were newly identified in this study and are likely influenced by the thoracic surgery ward study setting. Regarding B-2, care needs during hospitalization, such as the presence of infection and responses to nurse call requests, have been reported in previous studies [15,24]. In contrast, factors including illness stage, intrahospital transfers, assistance with personal grooming, and medication management were newly identified in this study. These elements reflect patient-specific needs and, compared with the medical factors in theme A, may be less likely to become explicit in the prioritization decision-making process. Regarding B-3, treatment goals and care preferences, previous studies show that discharge support and planning are often incomplete [15]. In contrast, this study identifies discharge preparation as a prioritized element. This difference is attributable to the target hospital, where the partnership nursing system has been implemented, suggesting that a care delivery model with relatively sufficient human resources may influence nurses' prioritization decisions. These findings primarily reflect what should be prioritized based on patient-specific considerations.

Theme C: Organizational and Operational Work Factors

In theme C, judgment elements based on organizational and operational constraints were identified. In contrast to theme B, these factors primarily constrain what can be feasibly performed in practice. Regarding C-1, temporally structured tasks were consistent with previous studies, showing that, during physical emergencies, routine tasks are interrupted to provide immediate care [28], corresponding to "unscheduled tasks" in this study. In contrast, few previous studies have clearly distinguished between time-specified, non–time-specified, and sequence-dependent tasks based on time constraints or execution order. Although this represents a highly detailed classification, it reflects the level of granularity required for computational processing. The elements related to C-2, which required collaborators for task execution (doctors, nurses, allied health professionals, and family members), were newly identified in this study. Although these elements may not directly determine task priority, they represent key influencing conditions for task feasibility. Regarding C-3, environmental factors affecting task performance, such as human resources, task difficulty, procedure volume, and number of assigned patients, have also been reported in previous studies [12,14,27-30]. In contrast, factors including physician availability, day of the week, location of assigned patients, and whether the patient was assigned as a primary patient were specific to this study. Differences in the implementation of examinations and rehabilitation depending on the day of the week may influence the structure of prioritization, suggesting that prioritization depends on institutional characteristics. Regarding C-4, institutional- and ward-level policies, previous studies show that ward philosophy and the nursing theories or models adopted influence prioritization decisions [12,15,24,27]. Given that nursing practices are performed within specific environments, context-dependent judgment criteria were identified. The elements identified in C-2, C-3, and C-4 are suggested to serve both mediating and moderating roles in task prioritization. Specifically, they mediate the formation of prioritization judgments while also moderating the strength and direction of these effects. For example, nursing practice is not uniform; the priority assigned to the same task varies across settings, such as hospitals and wards, long-term care facilities, and home care. Furthermore, the range of feasible tasks is constrained by factors such as interprofessional collaboration and staffing conditions, which in turn alter the scope of tasks that can be prioritized. Taken together, these findings suggest that the elements identified in themes B and C can be understood as different dimensions of contextual judgment, encompassing both patient-specific and organizational factors that shape prioritization decisions.

Building on these functional roles, the following discussion further conceptualizes organizational context as a broader mechanism underlying task prioritization. Although this study does not address the attributes of the requester, previous research shows that in nonhospital settings, requests from managerial staff are more likely to be prioritized [12,28]. In contrast, in general hospital wards, nurses primarily assume leadership in task execution. This contrast suggests that the influence of requester attributes is contingent on organizational context, particularly differences in roles, authority structures, and chains of command. These findings suggest that ward characteristics function as a foundational mechanism structuring task prioritization processes. Specifically, such characteristics encompass not only explicit operational rules, such as visiting hours, but also the configuration of stakeholders and their power dynamics. Through their interaction, these factors shape nurses' subjective judgment in practice. Furthermore, as previous studies have shown, nurses tend to prioritize physicians' expectations due to the nature of their roles, indicating that task prioritization is conducted with close attention to established chains of command [26]. Additionally, previous studies indicate that nurses' subjective assessments—such as the time required to complete a task and the predictability of intervention outcomes—as well as value-based considerations, including the prioritization of physician expectations and tasks that emphasize human dignity, also influence prioritization decisions [15,26]. Taken together, these findings suggest that task prioritization is shaped by a complex interplay of organizational, contextual, and individual factors that are difficult to fully formalize, including nursing theories and judgments based on individual values and professional experience.

Characteristics of the Extracted Factors and Their Computational Tractability

This study explores which information structures are amenable to computational processing, based on the elements identified

XSL•FO
RenderX

through thematic analysis, and conceptualizes mechanisms for supporting nursing task prioritization.

Regarding information processing approaches for prioritization, both rule-based methods, such as integer linear programming, and non–rule-based approaches, such as large language models (LLMs), can be considered. ILP enables the derivation of optimal solutions through the explicit formulation of objective functions and constraints; however, it is limited in adequately representing the ambiguous and context-dependent elements inherent in real-world clinical practice. Additionally, its high computational cost and the need for recalculation in dynamically changing environments pose practical challenges for real-world implementation. In contrast, LLMs can process information that includes implicit judgments and ambiguous expressions that are not explicitly defined by rules. This characteristic suggests their potential usefulness in handling the tacit knowledge and context-sensitive decision-making in nursing practice. Nevertheless, LLMs present challenges, including the opacity of their reasoning processes and concerns regarding explainability, safety, and reliability when applied to medical information.

In routine clinical practice, nurses' decision-making is typically grounded in higher-level, abstract categorical understanding, while drawing on more concrete, code-level information. In contrast, from the perspective of computational information processing, even code-level data can be handled in a formalized manner. However, the codes identified in this study do not fully encompass all factors influencing nurses' decisions. Particularly for highly context-dependent elements, explicit structuring remains a challenge. Specifically, the elements within theme A (medical condition assessment factors) are relatively capable of simple classification (eg, binary or categorical) or quantification, whereas aspects of theme B (patient-related nursing care factors) and theme C (organizational and operational work factors) require situational interpretation and experiential judgment. Consequently, these elements cannot be easily represented within a uniform information structure. This structural heterogeneity highlights the difficulty of defining a single, standardized level of granularity or representation for information used in prioritization. Together, the key challenges identified in this study can be summarized as how to address the long-tail structure of decision-making factors and how to determine the appropriate level of granularity for information used in prioritization. As a complementary approach to these challenges, integrating category-level information through retrieval-augmented generation using LLMs may enable the partial incorporation of contextual variability and judgmental nuances that are difficult to capture using conventional rule-based or mathematical optimization methods. Consequently, while defining information at a highly detailed level may limit the comprehensiveness of captured judgment factors, excessive abstraction may render the information too vague for LLMs to interpret in a manner consistent with the intended decision-making process. Therefore, the granularity of information should be determined by the nature of the prioritization outputs required in clinical practice rather than its level of detail.

The focus of this study—prioritization of nursing tasks—can be situated within the framework proposed by Barrett and Jones [31], which conceptualizes 3 types of nurse-artificial intelligence interaction: task augmentation, task automation, and hybrid. Specifically, this study is positioned as an attempt toward task automation [31]. We posit that achieving full automation requires that all elements involved in prioritization decisions be represented in a structured and computable form. However, our findings indicate that the factors underlying task prioritization can be broadly categorized into those that are amenable to quantification and structuring and those that rely on unstructured information such as natural language. This distinction is consistent with the framework proposed by Autor et al [32], in which routine tasks are more susceptible to substitution by computer technologies, whereas nonroutine tasks tend to be complemented rather than replaced. In this context, elements that can be structured may be processed using rule-based approaches, whereas elements that resist structuring may require interpretation through generative artificial intelligence or may be difficult to incorporate into computational processes altogether. These unstructured elements are characterized by their reliance on context-dependent judgment, and their structuring becomes even more challenging when incorporating not only clinical information but also patient preferences and needs. The difficulty of structuring such elements reflects the inherent ambiguity of task characteristics in the nursing domain, suggesting that it is not feasible to fully structure all relevant information. Therefore, the findings of this study highlight the importance of designing and implementing technologies under the assumption that complete structuring is unattainable. Similar to the indispensable role of free-text fields in electronic health records, our results underscore the need for system designs that accommodate both structured and unstructured information.

Limitations

This study has several limitations. First, the codes identified as influencing prioritization may not comprehensively capture all the elements that affect nurses' decision-making. Second, the relative influence of each factor was not quantitatively evaluated; therefore, the relative importance and potential interactions among factors remain unclear. Third, the findings were derived from a specific context and population, and the results may not be generalizable to settings with different ward characteristics, organizational structures, or nursing systems.

Future Directions

Overview

The system envisioned in this study is designed to support the prioritization of nursing tasks and to partially automate the associated information-gathering processes. Such a system may be implemented via a smartphone-based interface that presents the next task to be performed and allows nurses to record task completion through simple interactions. It may be used both before the start of a shift to provide an overview of the day's workload and continuously during the shift to accommodate changes in clinical conditions. The future research required for the development and implementation of this system is outlined below.

XSL•FO
RenderX

Technical Validation of Prioritization Criteria

To translate the findings into rule-based information processing approaches such as ILP, further examination regarding which codes should be incorporated into prioritization systems, the appropriate level of granularity, and how the weighting of each code should be determined is required. Additionally, it is necessary to investigate which levels of abstraction (eg, code or category) and what types of information are most effective when presenting prioritized recommendations to nurses in clinical practice.

Design of Supportive Information System

Previous research shows that nurses tend to undertake nonnursing tasks and that such tendencies are associated with an increased likelihood of nursing tasks being left undone (NTLU) [33]. Moreover, experiences of NTLU have been reported to be strongly associated with job dissatisfaction than performing nonnursing tasks [33]. Importantly, NTLU often involves intrinsically meaningful activities, such as comfort or talk with patients, which are prone to deprioritization under time pressure [28,33]. This phenomenon may be partly explained by the mere-urgency effect, whereby urgent tasks are prioritized over those that are more important but less time-critical, thereby hindering appropriate prioritization [34].

Accordingly, the design of support information systems should not simply aim to mechanistically determine or present task priorities. As suggested by prior research proposing a 7-stage normative framework for prioritizing nursing activities, they should support nurses in making informed decisions while preserving professional values and the core aspects of nursing practice [35]. In other words, instead of immediately reprioritizing nonurgent interruptions, decision support systems should facilitate judgments that consider job satisfaction, nursing care quality, and sustainability of "nursing as a profession."

Conclusions

Although there is a clear need for a supportive information system for nursing task prioritization, such systems remain insufficiently developed. Accordingly, this study explored how factors influencing nursing prioritization can be represented in terms of information granularity and structure.

Thematic analysis was used to identify and organize the factors guiding nurses' prioritization decisions. The results indicate that nurses' prioritization constitutes a multilayered decision-making process comprising three qualitatively distinct themes: (1) objectively observable elements such as medical urgency and acuity, (2) context-dependent factors grounded in patient individuality and values, and (3) environmental factors including time constraints, staffing resources, and organizational policies.

Theme A (medical condition assessment factors) was relatively amenable to quantification. In contrast, themes B (patient-related nursing care factors) and C (organizational and operational work factors) required context-sensitive and experiential judgment. While these elements enable flexible, patient- and institution-specific decision-making, they complicate standardization and formalization. Accordingly, for such ambiguous and context-dependent elements, flexible information-processing approaches, such as LLMs, may be effective in complementing conventional rule-based methods. Furthermore, the appropriate level of information granularity should be determined by the nature of the prioritization outputs required in actual nursing practice, rather than by the degree of abstraction alone.

Funding

This work was supported by the Japan Science and Technology Agency Support for Pioneering Research Initiated by the Next Generation (grant JPMJSP2110) and the next Crossministerial Strategic Innovation Promotion Program on "Integrated Health Care System" (grant JPJ012425).

Data Availability

The datasets generated or analyzed during this study are not publicly available due to ethical and privacy restrictions, as they contain interview data that may include personally identifiable information, but are available from the corresponding author on reasonable request.

Authors' Contributions

KI conceptualized and designed the study, developed the interview guide, conducted the interviews, performed the primary data analysis, and drafted the manuscript. MT provided methodological guidance and contributed to data analysis. KK, CL, GY, and YM contributed to study conceptualization and design, data interpretation, and critical revision of the manuscript. TK supervised the study. All authors read and approved the final manuscript.

Abstract

Background: Chronic obstructive pulmonary disease (COPD) affects more than 16 million US adults, many of whom experience high rates of acute care revisits (emergency department and hospital) after initial hospitalization. These frequent exacerbations, often due to failures in transitions of care (TOC), lead to lung function decline and premature mortality. While effective interventions exist to reduce readmissions, wide-scale implementation of COPD TOC programs remains limited. The National Institutes of Health–funded Reducing Respiratory Emergency Visits Using Implementation Science Interventions Tailored to Settings (REVISITS) study was designed to address this implementation gap by developing and implementing bundled COPD TOC programs across diverse US hospitals.

Objective: This study aimed to conduct pre-implementation contextual assessments at US hospitals to guide the development of site-specific, evidence-based COPD TOC programs.

Methods: We conducted pre-implementation contextual assessments using a novel semi-structured interview format that integrated the Consolidated Framework for Implementation Research (CFIR) with human-centered design approaches (ethnographic interviewing) to capture real-world experiences of COPD care across inpatient, outpatient, and home settings. We used a sequential explanatory mixed methods design in which pre-interview survey data completed by site leads informed and shaped the subsequent semi-structured interviews. Site leads, clinicians, organizational leaders, patients, and caregivers were interviewed. Interviews explored baseline COPD TOC practices, local resources, opportunities for improvement, as well as participant priorities from a menu of 12 evidence-based interventions (eg, pulmonary rehabilitation, patient navigation, and inhaler teaching). Rapid analysis methods identified intervention priorities across participant groups, along with perceived barriers and facilitators to implementation. Findings were shared with site leads to help guide their development of tailored COPD TOC programs.

Results: Among 194 participants from 21 sites (42 site leads, 29 organizational leaders, 105 clinicians, and 18 patients or caregivers), the highest priority interventions identified during interviews were post–emergency department follow-up visits, education (inhaler technique, disease management, and action plan), and pulmonary rehabilitation. Reported barriers included clinician-level challenges (limited training, staffing, and time), patient-level challenges (social needs and physical burden of COPD), and system-level challenges (lack of standardization, limited resources, and cost). Key facilitators included the presence of dedicated staff and the availability of pre-existing programs or infrastructure. The 3 most commonly chosen interventions for implementation were patient education (eg, inhaler education and COPD action plans), medication reconciliation, and post-discharge care (eg, post-discharge visits and pulmonary rehabilitation).

Conclusions: This study demonstrates how the integration of implementation science and human-centered design approaches can yield valuable insights, beyond what either field could obtain separately, during the pre-implementation phase of COPD TOC program implementation development. Contextual assessments that capture diverse views are instrumental in designing feasible and relevant interventions. Future work will explore how pre-implementation insights relate to post-implementation outcomes across participating sites.

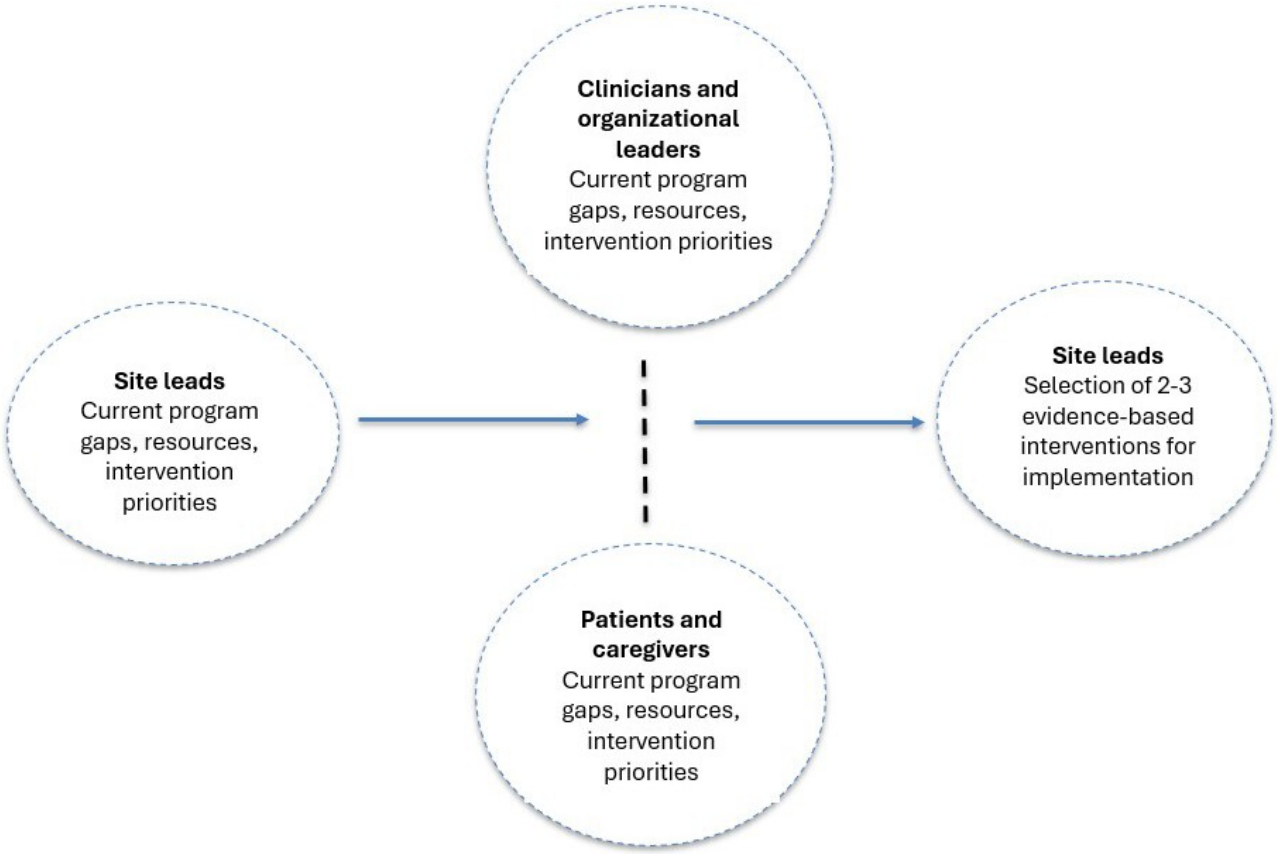
KEYWORDS

chronic obstructive pulmonary disease; COPD; readmission; revisits; transitions of care

Introduction

Chronic obstructive pulmonary disease (COPD) affects more than 16 million US adults, many of whom experience high rates of acute care revisits (emergency department [ED] and hospital) after initial COPD hospitalizations [1-5]. These frequent exacerbations, often due to failures in transitions of care (TOC), lead to lung function decline and premature mortality [6]. In response, the Centers for Medicare and Medicaid Services launched the Hospital Readmission Reduction Program (HRRP), which includes COPD readmissions as a targeted outcome [7]. Additionally, the Centers for Medicare and Medicaid Services introduced the Bundled Payments for Care Improvement (BPCI) initiative, a voluntary program designed to encourage coordinated care and reduce costs associated with hospital readmissions [7-9]. These policies motivated many US hospitals to pursue interventions aimed at reducing COPD readmissions to avoid financial penalties. However, beyond a few published reports of successful TOC interventions, there is limited clarity regarding what constitutes a successful COPD TOC program [10-14]. To date, no systematic evaluation has been conducted on the types or consistency of care transition interventions used within or across hospitals since the implementation of the HRRP. As a result, wide-scale implementation of COPD TOC programs remains limited by fundamental gaps in effectiveness and implementation data [15-17].

The Reduce Respiratory Emergency Visits Using Implementation Science Interventions Tailored to Settings (REVISITS) study was designed to address these gaps by developing, implementing, and evaluating bundled COPD TOC programs across diverse US hospitals [18]. Before sites launched their tailored COPD TOC programs (comprised of 2‐3 evidence-based interventions), we conducted pre-implementation contextual assessments to identify baseline COPD TOC practices, local resources, and opportunities for improvement. These contextual assessments were intended to inform site-specific program development and promote successful implementation and sustainability.



Methods

Study Design and Setting

The Reduce REVISITS study used a sequential explanatory mixed methods design [19]. Site leads first completed a pre-interview survey to identify preliminary priorities, site characteristics, and contextual factors. These survey responses were then used to inform and tailor the subsequent semi-structured interviews, during which participants elaborated on and clarified their survey responses. This sequential approach allowed the qualitative interviews to build on the quantitative survey data, providing deeper insight into site-level priorities and implementation considerations. Using a structured, stepwise discovery process, we conducted pre-implementation contextual assessments at each participating site. These assessments were designed to help sites develop COPD TOC programs tailored to their specific needs and environment. Specifically, the assessments aimed to characterize each site's local context, evaluate readiness for change, and identify desirable evidence-based COPD interventions for inclusion in the site's TOC program (Figure 1).

XSL•FO
RenderX

Figure 1. Pre-implementation contextual assessment approach used in the Reduce Respiratory Emergency Visits Using Implementation Science Interventions Tailored to Settings (REVISITS) study, a sequential explanatory mixed methods study conducted across 21 US hospitals to inform the design of chronic obstructive pulmonary disease transition of care programs. The figure outlines the stepwise discovery process integrating human-centered design and implementation science methods, including pre-interview surveys, multiparticipant interviews, rapid analysis, and site-specific implementation planning.

Hospitals were recruited into this initial phase of the study from the Hospital Medicine Reengineering Network [20] and through the Society of Hospital Medicine [21]. The study aimed to enroll at least 20 hospitals to complete this phase to ensure sufficient power for the randomized trial in the following phase [18].

Each participating hospital designated 2 site leads responsible for leading local study-related COPD TOC intervention implementation efforts. The process began with site leads completing a brief survey (Multimedia Appendix 1), followed by in-depth interviews. During the interviews, site leads described the current state of COPD care at their organization, identified potential barriers and facilitators to implementation, and prioritized interventions for inclusion in their site's TOC program. Site leads then identified additional key participants, including clinicians and organizational leaders, whose input would further inform the COPD TOC program implementation. Site leads were also encouraged to distribute flyers and engage in efforts to recruit patients hospitalized with a COPD exacerbation in the past year and their caregivers to the study.

Data Collection Tools and Procedures

We developed data collection tools by human-centered design (HCD) ethnographic interviewing techniques, such as journey mapping, projective images, and concept ranking [22,23], with implementation science (IS) methodology, specifically constructs from the Consolidated Framework for Implementation Research (CFIR) [24-28].

Qualitative data collection was guided by a pragmatic research paradigm, which emphasizes generating actionable, contextually grounded insights to support real-world implementation planning. This paradigm aligned with the study's objective to identify practical barriers, facilitators, and priorities that could directly inform the design of site-specific COPD TOC programs.

Site leads first completed a pre-interview survey on their site's current practices and resources that informed the patient or caregiver, clinician, and organizational leader interviews. All participants were interviewed using semi-structured guides. During interviews, participants interacted with a structured slide deck to prompt reflection and discussion. For example, patients were presented with 11 projective images and asked to select 2 that represented their experiences with COPD, while clinicians ranked 12 evidence-based interventions by priority. Interviews were conducted by members of the study team trained in qualitative interviewing, including individuals with backgrounds in medicine (VGP), HCD (KE), health services research (MA and LT), behavioral science (HP and FG), and IS (LD). We acknowledge that these professional backgrounds may influence data collection and interpretation. To mitigate bias, interviewers used consistent probes and documented reflections during and after interviews. Each interview was attended by at least 2 members of the study team (MA, LT, KE, HP, and FG). One team member conducted the interview while the second took detailed notes, facilitating cross-validation and supporting subsequent analysis. No interviewers had previous relationships

XSL•FO
RenderX

with any participants. Interviewers introduced themselves by name and study role at the start of each interview and emphasized that participation was voluntary and confidential.

Site leads at each participating hospital assisted with identifying eligible potential participants and provided the study team with contact information for these individuals. Site leads also distributed study flyers to recruit patients hospitalized for a COPD exacerbation in the previous year and their caregivers. The study team used a standardized recruitment protocol across sites, which included initial email or phone outreach, confirmation of interest, and scheduling of interviews. To ensure consistency, all recruitment communications followed a uniform script.

All interviews were conducted virtually via Zoom (Zoom Communications) or a recorded telephone call. For patients and caregivers with limited technology access, study materials were mailed, and phone interviews were offered as an alternative to Zoom. No in-person interviews were conducted.

Data Types and Quantitative or Qualitative Approaches

Using a sequential explanatory mixed methods approach, we collected both qualitative and quantitative data. Quantitative data included structured ratings and rankings (eg, intervention priorities and readiness scores) and were summarized using descriptive statistics (means and medians) to assess inter- and intrasite variation in priorities and context. Qualitative data were analyzed using a qualitative descriptive design to summarize participants' experiences and perspectives. This approach aligns with the pragmatic paradigm and the study's objective to rapidly generate actionable insights rather than interpret lived experience from a philosophical standpoint. We adopted a rapid qualitative analysis approach, which allowed data to be synthesized and reported to site leads in time to inform the development of COPD TOC programs.

Consistent with a sequential explanatory mixed methods design, quantitative survey data were first used to shape and tailor the subsequent qualitative interviews. Integration occurred at multiple points: (1) during data collection, where pre-interview survey responses informed interview probes and areas for follow-up; (2) during analysis, where quantitative intervention rankings were compared with qualitative descriptions of barriers and facilitators; and (3) during interpretation, where findings across data sources were synthesized to develop site-specific contextual needs. This integrated understanding directly informed the site-specific implementation planning discussions.

Rapid Analysis and Summary Development

Interview data from site leads, organizational leaders, clinicians, patients, and caregivers were collected and analyzed by the study team (MA) using a rapid analysis approach. This analysis resulted in the formation of a "priority summary table," which ranked interventions based on the number of participants who identified them as high priorities, and a "resource table," which listed available resources that could support implementation of priority interventions. These materials were compiled to inform intervention planning for each site.

Implementation Planning Discussions and Reports

Post analysis, site-specific findings, and intervention-specific evidence summaries were presented to site leads during facilitated implementation planning discussions led by the principal investigator (VGP). Based on this information, site leads were asked to select 2 - 3 interventions to implement as part of their site's COPD TOC program. Following these discussions, the study team (MA and LT) created tailored "site implementation reports" that site leads could use when planning implementation of their selected interventions. These reports included key takeaways from interview data, such as barriers and facilitators to implementation, priority and resource summary tables, and notes from the implementation planning discussion. Each report also included a "workbook" component to guide sites in planning implementation steps and collecting baseline quantitative data (Multimedia Appendix 2).

Ethical Considerations

This study was reviewed and approved by the University of Chicago Institutional Review Board (IRB; IRB20-0373). All participants provided oral informed consent before participation in semi-structured interviews conducted via Zoom or recorded phone call. Site leads at each participating hospital assisted in identifying eligible stakeholders and shared contact information with the study team, who then contacted potential participants directly.

All research activities were conducted by trained study personnel following a standardized, written protocol. Participant confidentiality was rigorously maintained: all site-level data were fully deidentified, hospital data were stored in REDCap (Research Electronic Data Capture; Vanderbilt University), and interview data were housed on a secure, HIPAA (Health Insurance Portability and Accountability Act)–compliant shared drive managed by the University of Chicago Center for Research Informatics. Study ID numbers were used in place of personal identifiers. Identifiable contact information collected for recruitment and compensation was stored separately from study data and will be destroyed, along with audio files, after study completion.

Participants received compensation approved by the IRB. Patients and caregivers received a US $25 gift card, and clinicians and organizational leaders received a US $10 gift card. Site leads who supported implementation at participating hospitals received an honorarium of US $3500 per year of participation. Raw data will not be shared outside the study investigators, research personnel, and approved external collaborators covered under the University of Chicago IRB.

Results

Site Characteristics

In total, 21 hospital sites were enrolled in the first phase of the Reduce REVISITS study. Approximately two-thirds (13/21) were academic hospitals, and one-third (8/21) were community hospitals. There was considerable geographic diversity among enrolled sites, with the Midwestern (7/21), Northeastern (6/21), and Southern (6/21) regions of the United States roughly equally

XSL•FO
RenderX

represented. However, only 2 sites were enrolled from the Western region (Table 1).

Table . Characteristics of the 21 US hospital sites enrolled in the pre-implementation phase of the Reduce REVISITS[a] study, including hospital type and region.

Characteristic	Sites (n=21), n (%)
Academic	13 (61.9)
Community	8 (38.1)
Northeast	6 (28.5)
Midwest	7 (33.3)
South	6 (28.5)
West	2 (9.5)

[a]REVISITS: Respiratory Emergency Visits Using Implementation Science Interventions Tailored to Settings.

Across the 21 sites, a total of 194 participants were interviewed. Among these participants, 176 were hospital-affiliated individuals (site leads [n=42], organizational leaders [n=29], and clinicians [n=105]), and 18 were patients or caregivers (n=16 and 2, respectively).

Participant Characteristics

Overall, participant demographics varied by participant group (Table 2, Supplementary Table S1 in Multimedia Appendix 3). Hospital-affiliated individuals tended to be younger than patients and caregivers. When obtaining demographic information, we asked participants what gender they currently identify with, and gender distribution varied by participant group. Although side leads were roughly split between males and females (22 females and 20 males), most organizational leaders (21/29) were male, while most clinicians (70/105) and patients and caregivers (13/18) were female. Racial diversity was limited and also varied by participant group. Most notably, there were significant socioeconomic and educational disparities. Most hospital-affiliated individuals (149/176) reported household incomes higher than US $100,000, whereas approximately two-thirds (11/18) of patients and caregivers reported an average household income of less than US $40,000. The majority of site leads, organizational leaders, and clinicians (140/176) held a master's degree or higher, whereas most patients and caregivers (14/18) had not attained a bachelor's degree.

[a]REVISITS: Respiratory Emergency Visits Using Implementation Science Interventions Tailored to Settings.

Interventions Identified as Priorities by Interview Participants

Across all 194 participants, the most frequently prioritized interventions were post–hospital or ED follow-up visits (90/194, 46%), inhaler education (78/194, 40%), and COPD education (66/194, 34%). Pulmonary rehabilitation was similarly prioritized (66/194, 34%), followed by COPD action plan (61/194, 31%), and patient navigation (60/194, 31%). The least frequently prioritized interventions included remote monitoring and reporting, advanced care planning, and spirometry. High-priority interventions were similar across hospital-affiliated and patient participants, although hospital-affiliated participants more strongly prioritized post–hospital or ED follow-up visits (84/176 hospital-affiliated vs 6/18 patient participants), inhaler education (73/176 hospital-affiliated vs 5/18 patient participants), and COPD action plan (58/176 hospital-affiliated vs 3/18 patient participants).

There was general agreement across participant groups about both the most and least prioritized interventions (Table 3). For example, post–hospital or ED follow-up visit, COPD education, and COPD action plan were frequently selected as top priorities, while remote monitoring and reporting, advanced care planning, and spirometry were less favored. However, there was more participant variation for interventions that were only moderately prioritized. For example, pulmonary rehabilitation was prioritized more often by site leads and patients or caregivers than by organizational leaders and clinicians. The COPD action plan was the top-ranked intervention among clinicians, although it was not equally prioritized by other groups (Table 5).

[a]REVISITS: Respiratory Emergency Visits Using Implementation Science Interventions Tailored to Settings.

[b]ED: emergency department.

[c]COPD: chronic obstructive pulmonary disease.

Participant-Identified Barriers and Facilitators

During interviews, site leads, organizational leaders, and clinicians identified a range of barriers and facilitators related to COPD TOC interventions (Table 4). Barriers occurred at the clinician, patient, and systems levels. Clinician-level barriers included a lack of staff, bandwidth, time, and lack of clinician education. Patient-level barriers included social determinants (eg, transportation, socioeconomic status, and technology literacy) as well as physical limitations (eg, poor vision and mobility issues). System-level barriers included a lack of standardization, inadequate resources (eg, placebo inhalers), shifts in care delivery (eg, nebulizer use), and cost-related issues (eg, pulmonary rehabilitation reimbursement and hiring patient navigators).

XSL•FO
RenderX

Table . Qualitative themes describing clinician-level, patient-level, and system-level barriers and facilitators to implementing chronic obstructive pulmonary disease transitions of care interventions, based on multiparticipant interviews conducted at 21 US hospitals during the pre-implementation phase of the Reduce REVISITS[a] study.

TOC[b] interventions	Representative CFIR[c] domains and subdomains with quotes	
	Barriers	Facilitators
Inhaler education	• Inner Setting: Work Infrastructure "We unfortunately don't have those dummy inhalers [to] educate [patients]." -RT[d] • Individuals: Innovation Deliverers "I have no idea how patients get inhaler education. It's not from me. I don't really know how to give that education." -SL[e]	• Inner Setting: Work Infrastructure "We have a respiratory therapist whose job is education, and she is an asset." -SL • Individuals: Innovation Deliverer "Previous to [the pulmonary navigator], I was just going, 'Puff, puff,' to both of them. And he taught me how to use it." -Patient
COPD[f] education	• Inner Setting: Work Infrastructure "It's really hard to have the time to sit with the patient and discuss [education] in the hospital." -Physician • Individuals: Innovation Recipients "My eyes aren't real good right now. So my glasses still ain't letting me read real good." -Patient	• Inner Setting: Work Infrastructure "[The nurse-led education service] get this consult, and then they have a team of nurses that basically meet with the patient and family one-on-one." -RN[g] • Individuals: Innovation Deliverer "The most valuable part [of treatment was] [the pulmonary navigators]'s directions on how to deal with all of it." -Patient
COPD action plan	• Innovation: Innovation Design "Some patients [are] discharged without a clear COPD action plan. Often it should be tucked in as part of their [after visit summary], but they leave with a 30-page document." -Physician • Inner Setting: Work Infrastructure "Just having enough staff to take care of patients is a problem. So whether the [COPD action plan] would be able to happen, I think it probably wouldn't." -Care Coordinator	• Innovation: Innovation Complexity "I feel like we see [the COPD action plan as] the low-hanging fruit one that's relatively easy to do." -Physician • Innovation: Relative Advantage "I have [a COPD action plan] on my refrigerator. [When] you're in the beginning of the yellow, then you might think, 'Oh, okay. It's okay. It'll get better.' But really, that's the starting of it go into the red." -Patient
Smoking cessation and/or treatment	• Inner Setting: Work Infrastructure "Whether they hand them a brochure or sit with the patient and have a 10-minute conversation, it's very dependent on the therapist." -RT • Individuals: Innovation Recipient "I used some of the patches, but they didn't really work because when I came home [from the hospital], my insurance wouldn't pay for them." -Patient	• Inner Setting: Available Resources "There's a smoking cessation clinic. Patients can get nicotine patches or resources to stop smoking." -Physician • Inner Setting: Work Infrastructure Deliverers "I'm trying to free up some full-time equivalents so that I can create some tobacco treatment specialists to go to the bedside." -OL[h]
Medication reconciliation	• Inner Setting: Work Infrastructure "[Medication reconciliation]'s owned by nursing and physicians here just because we simply don't have the pharmacy bandwidth to own that process." -Pharmacist • Outer Setting: Policies and Laws "It can be an hours-long process of trying to get approval for [the inhaler] or finding the right [one] that's on formulary." -SL	• Inner Setting: Information Technology "Our outpatient pharmacy just went online with Epic so that our nursing staff and physicians can see where in the process meds to beds are." -Pharmacist • Individuals: Innovation Deliverers "The transition-of-care pharmacist is extremely helpful. The pharmacists have a keen eye for what somebody's insurance will cover and what they won't." -OL

XSL•FO
RenderX

TOC[b] interventions	Representative CFIR[c] domains and subdomains with quotes	
	Barriers	Facilitators
Advanced care planning	• Inner Setting; Work Infrastructure "Our palliative service is really involved, but they are already over-maxed." -Physician • Individuals: Capability "There comes a point where it would be nice if there were professional people that were telling him this rather than his son telling him that the trajectory is not necessarily positive. I'm reluctant to bring it up with him because it increases his anxiety." -Caregiver	• Inner Setting: Information Technology Infrastructure "And then for the high risk [patients], we get that alert for [a] care conference screening, [which] sometimes [includes] discussing palliative care." -Care Coordinator • Inner Setting: Work Infrastructure "We do have a pretty robust advanced care planning initiative. [We have] people who are specifically hired to do advanced care planning for a good chunk of our inpatients." -SL
Post-ED[i] follow-up	• Inner Setting: Work Infrastructure "[Trying to get patients an appointment is] a very labor-intensive process. One of our biggest frustrations, I would say, as hospitalists trying to discharge patients is that we have no help in making these follow-up appointments." -SL • Outer Setting: Local Conditions "I got a insurance but they don't pay for transportation and stuff like that, I have to catch the bus, get on the train, and run from the train station to [the hospital], and I have to stop and rest because I get short of breath." -Patient	• Inner Setting: Available Resources "We have a transition of care clinic, which is pretty great. If you put in the order, they're good about going bedside to the patient, handing them information related to their discharge diagnosis and then the actual appointment in hand." -Physician • Inner Setting: Work Infrastructure "There's been a very small improvement in [clinician availability] because we've hired two pulmonologists that actually do clinics now." -SL
Pulmonary rehabilitation	• Outer Setting: Financing "There are only two to three pulmonary rehab facilities in [the region]. And it's very difficult for patients to get to, and it is because the Centers for Medicare and Medicaid Services reimbursement for pulmonary rehab is abysmally low." -Physician • Individuals: Innovation Recipients "I think [pulmonary rehab] was very good for me [in the past]. I think would be good for me now too [but] I don't want to ask my son because it's like you're there for two hours and then to travel is another hour." -Patient	• Outer Setting: Partnerships and Connections "To try address [transportation barriers], we are looking at tele pulmonary rehab programs that are currently being offered by external vendors." -Physician • Inner Setting: Information Technology "Pulmonary rehab [is] going to be included in the new COPD discharge order set that's going to roll out later this month." -SL
Patient navigation	• Innovation: Innovation Cost "But unfortunately, we only have one [nurse navigator]. We're hoping that [the system] [will] hire more nurse navigators, but they have not because, unfortunately, they have not proven their return on investment." -OL • Outer Setting: Policies and Laws "Yeah. I wish I had one of these little portable oxygen machine that I could tote on my shoulders. It's all up to my insurance company." -Patient	• Individuals: Innovation Deliverer "So in my role [as a navigator], I do catch a lot when I go to rounds. We do COPD education. If there are discharge needs, then I take care of that. Then [I do] a follow-up phone call at least 48 hours after they're discharged." -RT • Individuals: Innovation Deliverer "[The pulmonary navigator] is the most valuable person I've met [because of] his knowledge and his ability to translate medical terms into laypeople's terms so that I can understand it and was not frightened by any of the approach or the medication." -Patient
Spirometry		

XSL•FO
RenderX

TOC[b] interventions	Representative CFIR[c] domains and subdomains with quotes	
	Barriers	Facilitators
	• Inner Setting: Work Infrastructure "With COVID though, with the lab being shut down for quite a while, the backlog of people who needed pulmonary function testings got so large that we're booking three months out." -Physician • Individuals: Innovation Recipients "But in my opinion, patients are not really aggressive about using spirometry because it's a little aggravating and it's easily forgotten." -Care Coordinator	• Inner Setting: Work Infrastructure "We kind of piloted [an outreach program] on a very small scale. Once we identified our COPD population, [we] just pulled some [patients who] did not have spirometry and reached out [to schedule pulmonary function testings]. We learned that you can cold-call patients, and that patients do respond and come in." -Physician • Inner Setting: IT Infrastructure "[In the portal they ask] patients to fill out a questionnaire, and then based on the results of the questionnaire, it lets them self-schedule to get their spirometry done." -Physician
Remote monitoring and reporting	• Inner Setting: Work Infrastructure "We do have this remote monitoring system but as I mentioned, it's just not utilized. And then there's only so many kits that we have." -SL • Individuals: Innovation Recipients "I think a lot of the elderly patients find the tablet and entering all this to be a little overwhelming. They don't want to deal with it." -Care Coordinator	• Inner Setting: Work Infrastructure "I do know that we started an at-home monitoring system during COVID. Originally, it was designed just to be kind of post-COVID hospitalizations, but then the hospital expanded it to heart failure and COPD." -Physician • Individuals: Innovation Recipients "But I bought myself an oximeter because you can't see the numbers of your oxygen unless you've got a machine to show you the numbers. I'm the guy that wants to know when I can't breathe, what's my number now?" -Patient

[a]REVISITS: Respiratory Emergency Visits Using Implementation Science Interventions Tailored to Settings.

[b]TOC: transitions of care.

[c]CFIR: Consolidated Framework for Implementation Research.

[d]RT: respiratory therapist.

[e]SL: site lead.

[f]COPD: chronic obstructive pulmonary disease.

[g]RN: registered nurse.

[h]OL: organizational leader.

[i]ED: emergency department.

The most prominent facilitators included having a dedicated staff or dedicated team (eg, COPD educator, pulmonary navigator, nurse education team, and TOC pharmacist), existing infrastructure (eg, transition of care clinic, smoking cessation clinic, and electronic health record), and ongoing quality improvement (QI) initiatives and protocols (eg, advanced care planning initiative, virtual pulmonary rehabilitation, and telehealth program).

Patient perspectives often aligned with those of clinicians, especially regarding challenges with follow-up visits and pulmonary rehabilitation. Both groups cited lack of clinician availability and transportation as key barriers. At one site, both groups emphasized the benefit of a dedicated pulmonary navigator. However, there was some disagreement around the utility of printed materials. Some patients and clinicians questioned their usefulness (eg, due to poor eyesight or redundancy), while others endorsed them, particularly the COPD action plan, which some patients kept visible at home and some clinicians described as efficient. These differing perspectives were discussed during intervention selection with site leads.

Interventions Selected for Implementation by Site Leads

Inhaler education was the most frequently selected intervention for implementation, chosen by nearly all sites (20/21). Other commonly selected interventions included posthospital or ED follow-up visits (13/21) and COPD action plan (12/21). Fewer sites chose to implement medication reconciliation (9/21), pulmonary rehabilitation (6/21), patient navigation (6/21), COPD education (4/21), and advanced care planning (4/21). No sites chose advanced care planning, spirometry, and remote monitoring and reporting. While some participants listed spirometry and remote monitoring and reporting as priorities, site leads were discouraged from selecting these interventions as they could not be randomized to virtual or in-person delivery. Site leads were encouraged by the study team to include these

XSL•FO
RenderX

as supplementary interventions if they also selected 2 eligible interventions compatible with the study design.

Overall, intervention selections aligned with the priorities expressed by site participants (Tables 3 and 5). In total, 5 of the 6 interventions ranked as priorities were chosen for implementation. An exception is COPD education, which was ranked high as a priority but was less frequently selected for implementation.

Table . Interventions ranked as high priority by 194 multistakeholder interview participants (site leads, clinicians, organizational leaders, and patients or caregivers) across 21 US hospitals in the pre-implementation phase of the Reduce REVISITS[a] study. Values represent the number and percentage of participants within each participant type who identified the intervention as a high priority.

Intervention	All (n=194), n (%)	Site leads (n=42), n (%)	Organizational leaders (n=29), n (%)	Clinician (n=105), n (%)	Patients+caregivers (n=18), n (%)

[a]REVISITS: Respiratory Emergency Visits Using Implementation Science Interventions Tailored to Settings.

[b]ED: emergency department.

[c]COPD: chronic obstructive pulmonary disease.

Discussion

Principal Findings

This study integrated HCD and IS methods to conduct multiparticipant pre-implementation contextual assessments at 21 hospitals. The most frequently prioritized interventions were mostly related to post-discharge care (eg, post-discharge follow-up visits, pulmonary rehabilitation, and post-discharge patient navigation) and patient education (eg, inhaler education, general COPD education, and COPD action plan). Barriers to implementation occurred at the patient level (social and physical challenges), clinician level (resources: time, staffing, and training), and system (lack of standardization and/or resources to support COPD TOC programs). Key facilitators included harnessing available resources and activities, such as having dedicated staff, using existing infrastructure, and partnering with ongoing QI initiatives. Importantly, intervention selections by site leads generally aligned with the priorities identified by other participants at the same site, suggesting strong participant engagement and feasibility.

These findings align with previous studies identifying education, medication management, and structured follow-up as central components of effective COPD TOC programs. This study extends the existing literature by demonstrating the value of integrating HCD with IS methods as a structured, replicable approach for translating contextual data into actionable implementation decisions during the pre-implementation phase. The integration of HCD and IS enabled the identification of both universal priorities and site-specific constraints that directly informed intervention selection and implementation planning. The inclusion of patients and caregivers allowed the identification of accessibility barriers that are often overlooked when relying solely on clinician or administrative perspectives. Additionally, the use of rapid analytic techniques enabled timely translation of qualitative data into site-specific reports, demonstrating a pragmatic approach for supporting real-world implementation planning in multisite QI initiatives.

Variation in intervention prioritization across participant groups highlights the importance of including multiple perspectives in intervention planning. Site leads' reliance on existing staff and infrastructure as facilitators also aligns with IS frameworks emphasizing adaptability, compatibility, and resource fit [24-28]. These findings underscore the value of blending HCD and IS in identifying contextual barriers and facilitators.

This study has several limitations. While there was considerable geographic diversity among sites, there was limited

XSL•FO
RenderX

representation of hospitals in the Western region of the United States compared with the other regions, and community hospitals were slightly less represented compared with academic hospitals; notably, no Veterans Affairs hospitals enrolled. Patient and caregiver recruitment was limited due to reliance on site leads for recruitment and low technology access among patients. Additionally, the use of snowball sampling may have overrepresented clinicians already engaged in QI, and nearly half of the clinician participants were physicians, potentially limiting perspectives from other health professionals. Due to time constraints, such that data analysis was needed to move to the implementation phase, we used a rapid analytic approach to summarize site-specific interview data. We implemented several quality assurance strategies, including standardized note-taking templates, a uniform analytic process, and principal investigator (PI) review of all transcripts, to preserve analytic rigor. However, no formal coding of transcripts was conducted, and the majority of the analysis was performed by a single analyst, which may introduce interpretive bias.

Another important potential source of bias is regarding the COPD TOC interventions. While the study team used rigorous methods to identify evidence-based COPT TOC interventions, including reviewing the literature (PubMed and Google Scholar), reviewing scoping and systematic reviews [29-31], and team-based expertise (eg, PI was lead or senior author on evidence reports) [16,17], it is possible that interventions were missed. However, participants could prioritize any intervention when completing the interviews. In addition, bias related to the intervention chosen may have been introduced during the final site lead interview or discussion. The information regarding summaries of the evidence supporting COPD TOC interventions was presented by the study PI during these implementation planning discussions, and hence, this summary and any additional input from the PI may have influenced intervention selection. For example, inhaler education has been an area of previous research led by the PI, which may have influenced site lead decision-making. However, concern for this limitation is mitigated by the additional data that inhaler education was consistently identified as a top priority across participant groups during the interviews before this session with the PI, and the PI was not present for any of the participant interviews. This suggests that prioritization of inhaler education and other interventions largely reflected the participants' perspectives rather than investigator influence. Additionally, although COPD education was frequently identified as a priority by participants, it was selected less often by site leads. This may reflect the study team's guidance to prioritize specific, measurable education-related interventions or the tendency for site leads to bundle multiple education components together. However, most interventions were chosen by site leads by integrating prespecified priorities in conjunction with site-level feasibility.

Conclusion

Integrating HCD and IS methods during the pre-implementation phase can enhance the relevance and feasibility and possibly the sustainability of hospital-based COPD TOC interventions. Perspectives from patients, clinicians, and organizational leaders help identify both universal priorities and site-specific constraints, enabling tailored program design. These findings illustrate a replicable and scalable model for designing contextually grounded TOC programs in COPD and other chronic conditions. Future work will assess whether these pre-implementation insights predict implementation fidelity, reach, and sustainability as well as patient outcomes across sites in subsequent phases of the Reduce REVISITS study.

Acknowledgments

The authors would like to thank all sites and participants in the Reduce REVISITS (Respiratory Emergency Visits Using Implementation Science Interventions Tailored to Settings) study.

The Reduce REVISITS study team would like to acknowledge and honor Jean Rommes, our dedicated Patient Advocate, who passed away before publication of this manuscript. Jean would have been a co-author had she been able to complete the authorship forms prior to passing. In lieu of co-authorship we wanted to highlight the very important role she played with this study as a member of our study team. Jean provided essential insight into patient experiences and needs during the development and implementation of this research program and dissemination of its findings, and her perspective meaningfully shaped our approach to evaluating and implementing COPD transitions of care.

Funding

This work was supported by the National Heart, Lung, and Blood Institute of the National Institutes of Health (R01HL146644 and K24HL163408). The funder had no involvement in the study design, data collection, analysis, interpretation, or writing of the manuscript.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to the data being qualitative but are available from the corresponding author on reasonable request.

Abstract

Background: The existing intravenous systemic anticancer therapy (SACT) pathway in pharmacies is operationally inefficient. Manual, paper-based workflows render the system prone to human error, and the need for time-consuming manual verification diverts pharmacy staff time. The introduction of an automated workflow solution for the intravenous SACT pathway could optimize treatment timeliness and improve oncological outcomes for patients, aligning with the National Health Service Long Term Plan for improved cancer care.

Objective: This observational analysis aimed to assess the change in time, cost, and errors following the implementation of the Becton Dickinson (BD) Cato Pharmacy system in an aseptic unit producing intravenous SACT at Watford General Hospital.

Methods: Data on compounding process times were collected manually by pharmacy staff before and after the implementation of the intravenous compounding software (BD Cato). The data were analyzed to estimate annual time savings, opportunity cost savings, and error reduction.

Results: The intravenous compounding software produced a time saving of 18 (SD 9) minutes per drug, equating to 1034 hours saved per year (1034/2591, 39.9% reduction). If this time were repurposed to producing more intravenous SACT, Watford General Hospital could increase production by 66% (2298/3482) annually (2298 additional intravenous SACT). This represents an average cost saving of £11.29 (£1=US $1.273) per drug, equating to an annual opportunity cost saving of £39,246. The intravenous compounding software also decreased observed errors by 86% (43/50), a reduction of 43 errors over 2 months (approximately 258 fewer errors annually). Staff also preferred the intravenous compounding software to the manual system.

Conclusions: Implementing intravenous compounding software can save time, reduce costs, and lower errors in intravenous SACT preparation. This could improve timely treatment access for patients with cancer.

Introduction

The National Health Service (NHS) Long Term Plan includes targets for the NHS in the United Kingdom, including better care for cancer [1]. NHS England made a case for transforming pharmacy aseptic services, including reducing medical waste to reduce NHS costs [2], and reducing medication errors [3]. As medication errors are approximately 5 times more likely to occur for intravenous medications [4] and can cause significant patient harm [5], there is increasing pressure on aseptic units to reduce this error risk [2,6].

In 2022, the British Oncology Pharmacy Association found that 91% of respondents experienced same-day treatment delays due to delays within their pharmacy's service [7]. Delays in preparation within the pharmacy aseptic unit accounted for 69% of these pharmacy-related delays to intravenous systemic anticancer therapy (SACT) administration. Similarly, 76% of respondents had their treatment rescheduled at least once in 6 months [7]. Two main causes resulting in the rescheduling of treatment were known staffing issues (33%) and aseptic unit capacity (35%). This indicates that the current pathway for the preparation of intravenous medicines in full-capacity aseptic units is struggling to manage these demands.

The traditional pathway for the production of intravenous SACT involves a lengthy process, characterized by a manual paper-based workflow, which is slow, susceptible to errors, and lacks traceability. There is also a heavy reliance on manual verification and supervision to ensure a quality-assured process, which requires substantial pharmacy staff time. As the number of patients requiring first-line chemotherapy is estimated to increase each year [8], an alternative automated solution is required to improve efficiency, increase capacity, reduce costs, and reduce the risk of errors [2,9]. Becton Dickinson (BD) has developed a medication workflow software solution, BD Cato, which offers a potential solution to help organizations address these challenges.

A study from 2021 found that using the BD Cato software in East Tallinn Central Hospital, Estonia, reduced compounding time by 35% and doubled medication production capabilities over the course of the study [10]. BD Cato Pharmacy has also been found to detect errors in 7.89% of prepared cancer drugs, which would not have otherwise been detected using traditional compounding methods [11]. Therefore, the BD Cato Pharmacy software has the potential to save time (and potentially save costs) and to reduce errors, thus helping to meet policy targets.

The aim of this economic analysis was to assess the observed change in time, cost, and error rates associated with the implementation of the BD Cato Pharmacy system within an aseptic unit producing intravenous SACT at Watford General Hospital (WGH), England.

Methods

The Intravenous Compounding Software

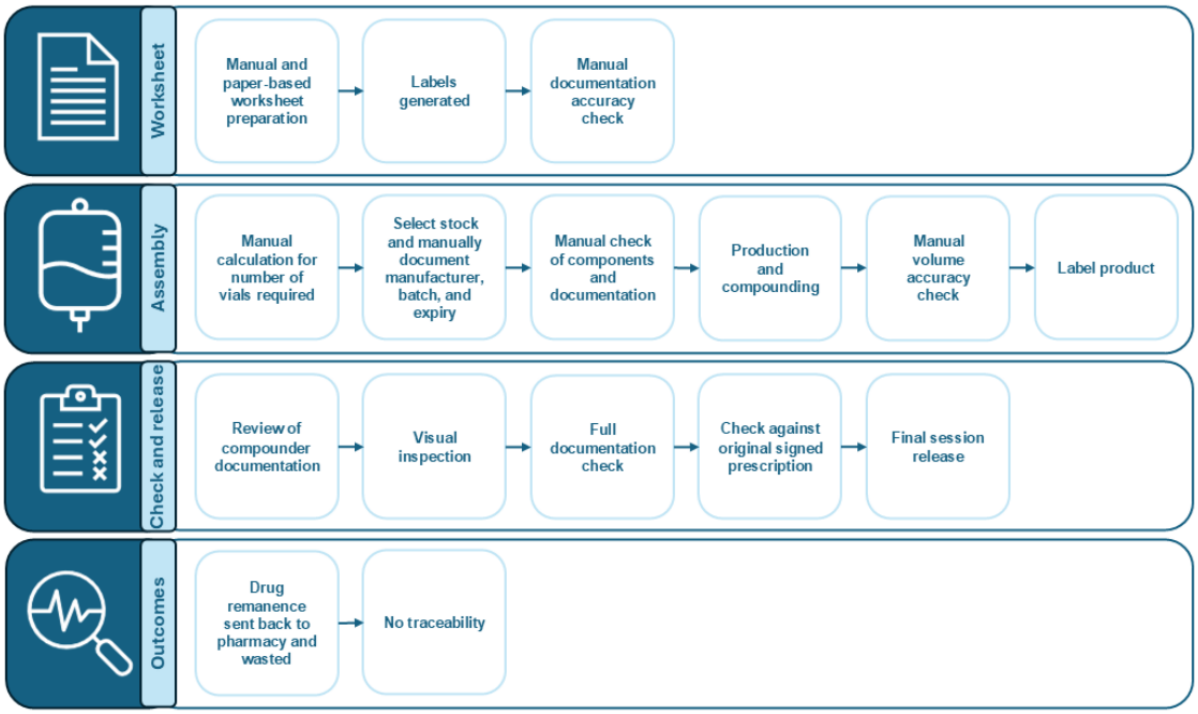
BD Cato is a medication workflow solution software that standardizes prescription, compounding, and administration processes along the medication pathway.

BD Cato Pharmacy is the module within this workflow related to the compounding process and provides functionality for the gravimetric and volumetric preparation of prescribed intravenous medication, such as chemotherapy, parenteral nutrition, pain medication, and antibiotics. It supports barcode scanning of vials and other components for electronic verification and documentation, automated calculations, step-by-step on-screen workflow guidance, gravimetric preparation using an electronic scale, image capture of preparation steps via a camera, hard stops when deviations have been detected, inventory and remainder management functionality, and production planning and report generation.

Figure 1 demonstrates the pathway for the preparation of intravenous SACT without the use of BD Cato. Figure 2 demonstrates the pathway for the preparation of intravenous SACT with the use of BD Cato.

XSL•FO
RenderX

Figure 1. Current pathway for the preparation of intravenous medications for cancer.



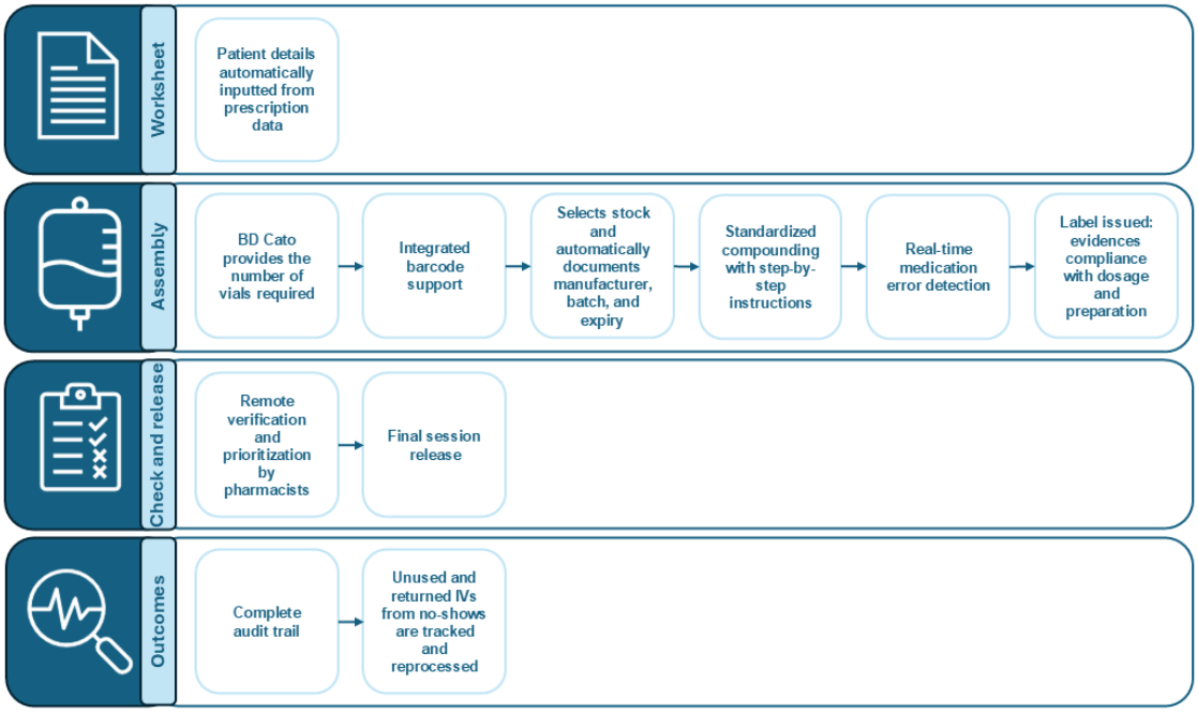


Figure 2. The Becton Dickinson (BD) Cato Pharmacy pathway for the preparation of intravenous (IV) systemic anticancer therapy for cancer in this study.

Study Design

This was a single-center before-and-after observational study. Data collection was carried out in the pharmacy department at WGH, which had decided to adopt the BD Cato system, and was interested in understanding the impact on time, costs, and error rates. The period for data collection before the introduction of the intravenous compounding software was approximately 10 weeks, between March 2021 and May 2021. The period for data collection after the introduction of the intravenous compounding software was approximately 8 weeks, between December 2023 and January 2024.

A data collection sheet was produced in collaboration with a qualified pharmacist at WGH to record the metrics shown in Textbox 1.

Pharmacy staff at WGH were asked to manually complete data collection sheets for every intravenous SACT that was compounded within the period before and after the implementation of the intravenous compounding software.

XSL•FO
RenderX

Before and after the implementation of the intravenous compounding software, manual data collection methods were used, whereby pharmacy staff were asked to record the time it took them to complete different aspects of the manufacturing process on a paper form. These were collated and analyzed by the York Health Economics Consortium.

The time to compound and reconstitute intravenous SACT and the number and types of errors before the study were unknown. This made sample size calculation difficult to determine. A period of 8 to 10 weeks was chosen to allow sufficient numbers of intravenous SACT compounding data to be collected and to be able to accurately measure the time taken for the compounding of different classes of intravenous SACT. It also provided time to record any errors that occurred during the data collection periods.

Textbox 1. Summary of primary metrics and parameters captured during the data collection process.

Metrics recorded in the data collection sheet

- The intravenous systemic anticancer therapy drug name being compounded
- The time taken for each task
  - Worksheet completion
  - Worksheet checking
  - Assembly
  - Assembly checking
  - Compounding
  - Labeling
  - Check and release
- Any identified errors
  - Wrong stability entered
  - Wrong diluent or fluid
  - Wrong volume drawn in compounding
  - Missing assembly item
  - Wrong batch number (assembly)
  - Wrong protocol
  - Wrong vial size chosen
  - Wrong volume entered
  - Wrong dose inputted
  - Wrong dosage form
  - Wrong or no ward
  - Missing or wrong infusion time
  - Other (please state)

Data from the data collection sheets were manually input into Google Sheets to clean and store the data and perform basic data analysis. Once data collection was complete, the data were exported, and analysis was performed in Microsoft Excel.

The primary outcome of the study was the impact of the intravenous compounding software on the time taken to compound intravenous SACT. The secondary outcomes were the impact of the intravenous compounding software on direct costs and the number of errors made during the compounding of intravenous SACT.

In addition to the quantitative analysis, 2 surveys were distributed among pharmacy staff members: 1 before the implementation of the intravenous compounding software and 1 after the implementation of the intravenous compounding software (18 months apart). The objective was to assess staff perception of the BD Cato workflow compared to the previous manual process with regard to safety, accuracy, efficiency, visibility of production status, work satisfaction, and overall preference. It was also used to evaluate staff satisfaction with the introduction of the new system.

Ethical Considerations

This study did not require ethics approval as the analysis was based on a system to automate pharmacy processes and did not involve human participants. Deidentified data on pharmacy processes were retrieved from WGH via staff surveys. West

Hertfordshire Teaching Hospitals NHS Trust provided access and permission to reuse the dataset for this study.

Results

Overview

Preimplementation and postimplementation data for 12 drug types were available from the intravenous compounding software. These drugs are presented in Table 1. Within the preimplementation data, there were an additional 3 drug types that were not present in the postimplementation data: brentuximab, cisplatin, and cytarabine. Within the postimplementation data, there were an additional 5 drug types that were not present in the preimplementation data: bleomycin, carfilzomib, tebentafusp, tocilizumab, and vinblastine. The preimplementation data comprised 408 total preparations, and the postimplementation data comprised 345 total preparations. Average time savings per drug, average time savings per drug per year, and average staff cost savings per drug were calculated. The activities involved in compounding were grouped into production, verification, and check and release. Production consisted of worksheet creation, assembly, compounding, and labeling tasks. Verification consisted of worksheet checking and assembly checking tasks. Check and release consisted of an accuracy and final release check to ensure the medication has been prepared correctly and is suitable for administration.

XSL•FO
RenderX

Time Outcome Results

Time outcomes were examined by calculating the difference between the time taken to complete each activity type in the drug compounding process before and after the implementation of the intravenous compounding software.

Table 1 presents the average time savings per drug compounded in minutes after the introduction of the intravenous compounding software. It presents a nondrug-specific weighted average time saving for each activity group, which included drugs only in the preimplementation phase, drugs only in the postimplementation phase, and drugs included in both data collection phases. It also presents the average time savings for each of the 12 drugs that had both preimplementation and postimplementation data.

Table 1 also presents the average time savings per year in hours. These values were calculated by multiplying the average time saved per drug by the number of each drug compounded per year. This is split into an average nondrug-specific time saving per year and individual time savings per drug per year.

Table 1 shows an average nondrug-specific time saving of 18 (SD 0.55) minutes per drug when using the intravenous compounding software. Time savings were observed for production, verification, and check and release tasks for all drugs, except for check and release for bendamustine and obinutuzumab. However, this did not influence the total average time saved, as all drugs demonstrated a total average time saving. The greatest time saving was observed for production (worksheet, assembly, compounding, and labeling tasks) and for polatuzumab and vincristine P.

Table 1 also shows an average nondrug-specific time saving of 1034 hours per year when using the intravenous compounding software. This represents a 39.9% (1034/2591) reduction in compounding time. This was calculated by multiplying the weighted average time saved per drug (hours) by the 3476 drugs compounded annually by WGH. The greatest time saving for an individual drug was for bortezomib. The individual drug-specific time savings per year were calculated using the number of each drug produced annually at WGH.

Table 2 presents the average time savings per drug per day.

Table 2. Average time saved per drug per day (minutes).

Day	Production, mean (SD)	Verification, mean (SD)	Check and release, mean (SD)	Total, mean (SD)
Monday	16 (0.60)	6 (0.36)	1 (0.33)	24 (1.28)
Tuesday	13 (0.57)	5 (0.20)	0 (0.34)	19 (1.10)
Wednesday	8 (0.57)	7 (0.54)	2 (0.35)	17 (1.45)
Thursday	6 (0.47)	5 (0.18)	0 (0.26)	10 (0.92)
Friday	9 (0.56)	5 (0.21)	1 (0.35)	15 (1.13)

Table 2 shows that when using the intravenous compounding software, there were observed time savings on every day of the week. These time savings could not be weighted as data on the number of drugs compounded each day were not available.

Opportunity Cost Savings

Opportunity cost savings were calculated by multiplying the average time saved by the average staff cost per hour for each task. The average staff cost per hour was based on the staff bands responsible for each task, taken from the Personal Social Services Research Unit [12]. Correspondence with WGH established that production tasks were carried out by staff in bands 3, 4, and 5; verification tasks by staff in bands 5, 6, and 7; and check and release tasks by staff in bands 7 and 8.

The average cost saving per drug and the average cost saving per year are presented in Table 3. This is split into a weighted average nondrug-specific cost saving, which included drugs only in the preimplementation phase, drugs only included in the postimplementation phase, and drugs included in both data collection phases. It also presents individual cost savings per drug for drugs that had both preimplementation and postimplementation data.

[a]The average time multiplied by the amount of activity (SD could not be calculated).

Table 3 shows a weighted average nondrug-specific total cost saving of £11.29 (£1=US $1.273) per drug. Table 3 also shows a weighted average nondrug-specific total cost saving of £39,246 per year. The use of the intravenous compounding software was observed as cost saving for all production tasks, all verification tasks, and most check and release tasks, excluding bendamustine, cyclophosphamide, and obinutuzumab, which were cost incurring. Nevertheless, this did not have an impact on the total cost savings of these drugs, as all drugs resulted in a total opportunity cost saving. The greatest opportunity cost savings per year were observed for production tasks and for bortezomib.

Error Outcome Results

The reduction in the number of observed errors from the use of the intravenous compounding software was calculated by finding the difference between the number of errors reported before and after its introduction. These results are presented in Table 4. While the intravenous compounding software anticipates potential errors to proactively implement mitigations and prevent process inefficiencies, this analysis focused solely on observed errors that directly resulted in process inefficiencies.

XSL•FO
RenderX

Table 4. Number of errors saved.

[a]BD: Becton Dickinson.

Table 4 shows that the intravenous compounding software decreased the risk of observed errors by 86% (43/50). There was a reduction of 43 observed errors over a 2-month period, which equates to reducing approximately 258 observed errors per year. The greatest reduction in errors was for missing assembly items. The intravenous compounding software reduced errors through barcode scanning, automatic documentation, vial size suggestion, and guided workflows, preventing staff from proceeding to the next step until the current step was correctly completed. There were 9 reported cases of the intravenous compounding software losing signal, which required staff to log out and log back in to continue preparation. While these were not reported as errors, as they did not result in loss of data or require a workflow step to be repeated, they resulted in an increase in time taken to prepare the drug, which is accounted for in the time and opportunity cost saving analysis.

Staff Survey Results

The preimplementation survey had a response rate of 93% (13/14), and the postimplementation survey had a response rate of 100% (8/8). A total of 88% (7/8) of postimplementation respondents preferred to compound a product using the intravenous compounding software and perceived it as being safer, more accurate, and more efficient compared to a manual workflow. In total, 100% (8/8) of respondents believed that the intravenous compounding software facilitates the tracking of sterile products during the compounding process. Regarding work satisfaction, none of the respondents found work dissatisfying using the intravenous compounding software, compared to 8% (1/13) of respondents who found work dissatisfying using the previous manual workflow.

Before receiving training on the use of the intravenous compounding software, preimplementation staff were asked an open-ended question about what they considered to be its potential advantages. The most common response was improvement in process efficiency, with 1 respondent stating that freeing up time would allow more focus on clinical roles related to oncology. The second most common responses were reduction of errors and improved accuracy. Traceability, removing the need for paperwork, waste reduction, and cost savings were also perceived as advantages. One respondent also perceived that the new system would upskill staff in the use of technology.

Staff in the preimplementation survey were also asked an open-ended question on what they would consider the likely challenges or disadvantages of introducing the intravenous compounding software. The most common response was related to overcoming resistance to change and having to adopt new ways of working due to familiarity with old processes and procedures. The second most common response was training requirements, with some respondents acknowledging that it can be a challenge for staff that are lacking in IT skills to adapt to new technology. Other perceived challenges were the need for a downtime plan and new types of errors that could be introduced.

Discussion

Principal Findings

In this observational study, the use of an intravenous compounding software reduced time, costs, and errors during the production of intravenous SACT at WGH. It was estimated that the use of the intravenous compounding software would save 1034 hours of pharmacy staff time per year. If this time were all repurposed toward the production of intravenous SACT, an additional 2298 drugs could be compounded at WGH each year. This is an increase of approximately 66.11% (2298/3476) from the number of intravenous SACT currently being produced by WGH per year (n=3476). If half of the time saved (517 hours)

XSL•FO
RenderX

was repurposed toward the production of intravenous SACT, an additional 1149 drugs could be compounded at WGH each year. It was observed that the use of an intravenous compounding software reduced the time to produce, verify, and check and release intravenous SACT by 39.9% (1034/2591). These results are in line with previous research that also found that the intravenous compounding software produced a 35% reduction in compounding time [10].

On the basis of the time saved and the average staff cost to the NHS, the observed time saved using the intravenous compounding software can be valued at £39,246 per year. This figure can be viewed as an opportunity cost saving, as the time saved could be reinvested into producing more intravenous SACT without incurring additional labor costs. The opportunity cost of an intervention is what is foregone as a consequence of adopting a new intervention [13].

There was some heterogeneity in the observed time savings between different drugs, partly driven by the number of steps in the manual manufacturing process for certain drugs. Bendamustine, in particular, is a complex product to make and typically involves more vials to reconstitute and larger volumes to be measured and then transferred to the infusion bag. As there are more steps in the process, the pharmacist review contains more photos of the steps in the compounding process for the releasing officer to review, and therefore, it would take longer to complete.

The greatest time savings per drug were on a Monday, and the least time savings per drug were on a Thursday. One explanation for this is that different levels of staff may work on different days throughout the week. Another explanation is that the number and types of drugs compounded per day may differ; for example, drugs that are slower to prepare may be compounded on a specific day.

The use of an intravenous compounding software was also shown to decrease the occurrence of errors requiring activity to be redone by 86% (43/50), with the potential to reduce 258 errors per year at WGH. This is in line with previous research that also reported the error-reducing capabilities of BD Cato Pharmacy [11]. It is of interest that there were 0 diluent errors before implementation. This is at odds with a survey carried out by the Institute for Safe Medication Practices, which found that more than half of pharmacists and pharmacist technicians who responded could identify with certainty which drugs, diluents, and volumes were used when verifying compounded sterile preparations [14]. WGH solely used volumetric preparation before implementation, but after implementation, a mix of both volumetric and gravimetric preparations was used, with most products made gravimetrically.

Therefore, the introduction of an intravenous compounding software could contribute toward meeting NHS targets that are currently unmet. For example, the British Oncology Pharmacy Association survey found that one of the main causes of same-day treatment delays was delays within the pharmacy aseptic unit (69%), and one of the main causes of rescheduled treatments was limited aseptic unit capacity (35%) [7]. Therefore, if more intravenous SACT can be compounded more quickly using an intravenous compounding software within aseptic units, same-day treatment delays and rescheduled treatments could be reduced. This could also help to manage the predicted increase in treatments required in the coming years [8].

The implementation of the intravenous compounding software was well received by staff who completed the postimplementation survey. The preimplementation open-ended question on perceived challenges highlights the importance of getting staff on board with the change at an early stage and taking steps to overcome resistance. Sufficient time and resources should also be allocated to training to support the effective use of the system and help overcome the concerns and resistance that staff have.

Limitations

This analysis has several limitations. Because the data were collected manually, there is an increased risk of human error when completing the data collection sheet, as well as potential inconsistencies in how individuals report different data items.

There are also potential confounding variables that may have influenced the findings of the study. Data were collected at 2 different time points, with preimplementation data collected in 2021 and postimplementation data collected in 2023 to 2024. Factors that may have influenced the data collection process between 2021 and 2023 to 2024 include changes in protocols or procedures, changes in staff (including staff competency), and changes in resources other than the intravenous compounding software. Similarly, data were collected over short periods, which might not capture long-term effects or trends. Longitudinal effects or outcomes might differ from these short-term findings.

A similar limitation applies to the staff survey. Preimplementation survey responses were collected in 2021, while postimplementation survey responses were collected between 2022 and 2024. Due to staff turnover, respondents may differ before and after the implementation of the intravenous compounding software. It is also uncertain whether all respondents had experience with compounding using the previous manual process.

The study was not intended to be a return on investment analysis. The time saved has been quantified in financial terms to provide a context for the benefits of automation. Consequently, the investment required for the installation and maintenance of the system was not taken into consideration when savings were calculated. Similarly, no calculation was made of the investment WGH would have required to achieve comparable productivity gains had it retained the previous manual workflow.

In response to the limitations of this study, future research could address the following areas. The economic impact of BD Cato Pharmacy across other aseptic units within the NHS, and for different types of drugs (eg, intravenous antibiotics or nutrition), should be investigated. This would be beneficial to assess the broader applicability of the results. In addition, future research could investigate the cost impact of managing drug remnants and drug waste using BD Cato Pharmacy's remnants functionality.

XSL•FO
RenderX

Conclusions

The aim of this economic analysis was to assess the observed change in time, cost, and error rates associated with the implementation of an intravenous compounding software system within an aseptic unit producing intravenous SACT at WGH. BD Cato Pharmacy has the capability to reduce time, costs, and errors and offers a practical and scalable solution to address key areas within the NHS, such as improving efficiency and increasing capacity. The system's ability to proactively implement mitigations helps to provide necessary transparency for medication management. The system requires some IT infrastructure to operate, including hardware (barcode scanners, label printers, a printer, keyboards, a PC with Windows 10, scales, and visual documentation hardware) and software (SQL server with 4 central processing unit cores and 16 GB memory random-access memory, Microsoft .NET Framework [version 4.8.0], and DirectX [version 9.0]).

Funding

The study was funded by Becton Dickinson.

Data Availability

All data generated or analyzed during this study are included in this published paper. The datasets generated or analyzed are available from the corresponding author upon reasonable request.

Authors' Contributions

The study design was conceptualized by NH and BU. TM and HS collected the data. BU conducted the analysis and drafted the manuscript. All authors contributed to the critical revision of the manuscript for important intellectual content and provided final approval of the version to be published.

Conflicts of Interest

The York Health Economics consortium was paid by Beckton Dickinson to conduct the analysis and draft the manuscript.

Abstract

Background: Hospitals face increasing pressure to accelerate digital transformation. Modifiable off-the-shelf technologies (MOTs) combine standardized products with limited adaptability, offering promising opportunities for rapid digitalization. However, implementing MOTs in complex hospital settings involves multiple barriers, facilitators, and organizational dynamics that require deeper investigation.

Objective: This study identifies barriers and facilitators in the implementation of MOTs in hospitals and explores how organizational dynamics, conceptualized as tensions, emerge throughout this process.

Methods: Guided by a constructivist-interpretivist paradigm, the study followed a collaborative action research approach. A qualitative multimethod design was used, including observations, workshops, and focus groups with clinical and project management staff. Data were analyzed using deductive-inductive qualitative content analysis following Kuckartz's approach.

Results: We analyzed 12 deidentified researcher protocols from 5 observations, 3 workshops, and 4 focus groups. Across these activities, 129 individuals from various wards and departments participated. Barriers and facilitators were clustered into 6 categories representing inhibiting and enabling conditions of MOT implementation. Barriers included product limitations (22.6%, 88/390), misaligned implementation process (4.4%, 17/390), absence of available individuals (3.8%, 15/390), structural challenges (2.8%, 11/390), and resource constraints (2.8%, 11/390). Facilitators included orchestrated implementation process (13.8%, 54/390), product alignment (14.4%, 56/390), effective coordination and communication (9.2%, 36/390), presence of available individuals (6.7%, 26/390), available resources (3.1%, 12/390), and structural assets (1.8%, 7/390). These categories were conceptualized into 3 organizational tensions: limited relative advantage of generic systems, structured participation challenges in complex settings, and constrained engagement despite motivation due to limited resources.

XSL•FO
RenderX

Conclusions: Tensions in MOT implementation reflect organizational misfits that go beyond concrete barriers or facilitators and instead require systemic and agile organizational structures. The analysis introduces the concept of user:ability as an organizational capacity for enabling engagement with MOTs. We derive 3 tailored strategies to mitigate the tensions: ensuring relative advantage through IT integration and learning; empowering user participation through digital transformation and communication; and enabling clinician engagement through dedicated resources and systematic implementation. This study advances prior work by deepening the understanding of implementation determinants into organizational tensions and offering actionable strategies to address them. It also illustrates how collaborative, agile research approaches can illuminate complex organizational dynamics and support hospitals during transformative change.

Introduction

A growing body of literature in information systems, health services, and implementation science highlights the potential of digital health technologies (DHTs) to improve health care delivery and outcomes [1-4]. Empirical studies demonstrate that DHTs, such as electronic medication systems, can enhance patient safety, care coordination, and clinical workflow efficiency [5-10].

In Germany, this recognition has been reinforced by major political initiatives. The Krankenhauszukunftsgesetz (Hospital Future Act; KHZG) created a strong regulatory impetus by tying substantial federal and state funding to the adoption of specific digital infrastructures [11]. Intended to improve care quality and efficiency, the KHZG mandates core digital solutions for German hospitals and penalizes nonimplementation with reductions of up to 2% of inpatient reimbursement, thereby enforcing rapid adoption [12,13]. Yet, while the KHZG accelerates digital adoption, DHTs remain subject to stringent safety and performance regulations, which can inadvertently slow innovation, delay responsiveness to emerging user needs, and limit design flexibility [14,15].

In this context, we conceptualize the DHTs examined in this study as modifiable off-the-shelf technologies (MOTs), drawing on modifiable off-the-shelf software or packaged software [16,17]. MOTs are prebuilt, licensed products that allow limited customization but are not developed in-house for a specific organizational use case. In this study, MOTs encompass a range of implementations: from a completed end user–initiated development scaled into the clinic, to system-wide infrastructures, and Software-as-a-Medical-Device, such as digital medication support systems [18], to applications closely integrated with hardware components, such as mobile ward rounds with iPads (Apple Inc). While MOTs promise rapid deployment and regulatory compliance, their limited adaptability often constrains alignment with heterogeneous clinical workflows and evolving organizational needs [19,20]. These dynamics can foster resistance and undermine organizational fit [20,21], particularly in large academic hospitals, where complexity heightens the risk of “unbridled adoption” [22]. In this context, the generic design of MOTs, developed for broad markets rather than the situated needs of specific clinical practices, often reduces usability because it lacks sensitivity to local workflows and limits opportunities for contextualized, implementation-level design [23]. As a result, successful implementation requires a stronger focus on end users during and after implementation, ensuring that users can use the system safely and efficiently through adequate training and sustained support [24].

Implementation science offers structured approaches to analyze these dynamics by examining the conditions under which adoption succeeds or fails. At its core is the examination of barriers and facilitators: barriers are factors that hinder or prevent uptake, while facilitators are enabling conditions within a specific context that promote adoption [25].

Previous research has identified barriers at multiple levels, including technological barriers such as interoperability [26,27] and system complexity [27,28]; individual-level barriers such as limited digital literacy [29] and low acceptance [29,30]; organizational barriers such as the lack of integration of digital technologies into existing workflows [30,31] and limited resources [29,31]; as well as structural barriers, including the lack of stakeholder involvement [26] and insufficient funding [32].

Beyond well-documented barriers, recent research points to deeper organizational dynamics, such as tensions and paradoxes, that are not easily resolved and require ongoing management [33]. Examples include conflicts between the push for standardization and the need for clinical autonomy; the pursuit of digital efficiency and the value of hands-on care; and the promise of technology and the reality of added burden, reflecting organization-technology misfits [33-35]. Building on Strong and Volkoff [19], misfits arise when technology and organizational practices fail to align. They appear in 6 domains: functionality, data, usability, role, control, and organizational culture. Each can surface either as a deficiency (missing features or capabilities) or as an imposition (an inherent technological characteristic needed for seamless integration) [19]. If left unmanaged, organization-technology misfits can impede adoption by fostering resistance, neglect, or misuse of otherwise beneficial technologies [33-35].

To address barriers, tensions, and misfits, implementation science applies evidence-based theoretical models and frameworks [21,36-40]. However, these are often insufficiently applied in practice [41], contributing to a persistent knowledge

XSL•FO
RenderX

translation gap [42]. Action research can help bridge this gap by generating insights that are simultaneously actionable for organizations and generalizable for theory building [43]. Tailored implementation strategies [44] remain essential, as MOT implementation must account for technical and organizational factors alongside competing demands from regulations, limited resources, and staff needs.

Building on the outlined challenges and literature, we posit a set of assumptions that guide our study. As MOTs offer limited opportunities for participation in design, we expect usability and functionality misfits to emerge during implementation. Building on this premise, we suggest that effective MOT implementation requires tailored strategies to address contextual needs during implementation, as the limited modifiability of MOTs restricts contextual adaptation. We further argue that structural characteristics of hospitals can reinforce these misfits and intensify tensions during implementation.

These propositions lead to the following research question: What are the barriers and facilitators in the implementation of MOTs, and what organizational dynamics emerge during this process within complex hospital contexts?

Methods

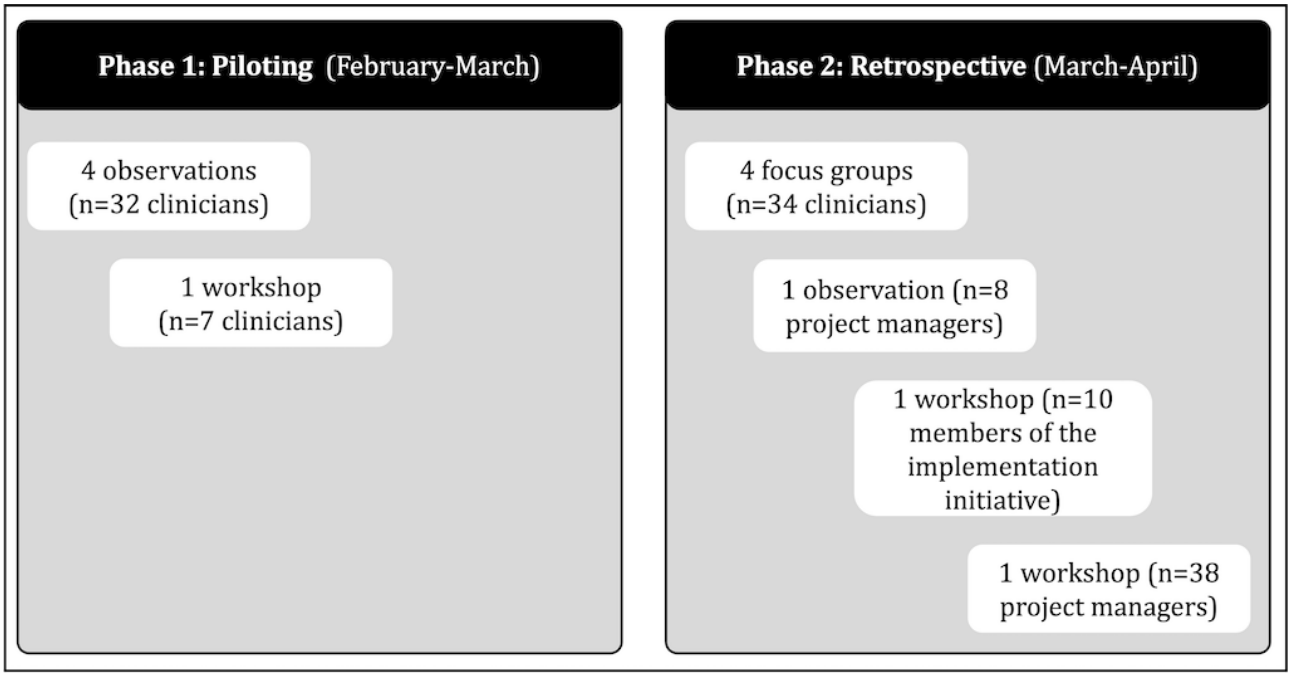
Study Design

This study followed a qualitative, multimethod, collaborative participatory action research design within a constructivist-interpretivist paradigm. The design aimed to explore how clinical and project management staff experienced the implementation of MOTs in a complex tertiary hospital environment [45,46]. Action research was conducted in iterative Plan-Act-Observe-Reflect cycles [47,48], integrating observations, focus groups, and participatory workshops in a convergent triangulation design. Following the action research paradigm, female implementation researchers with backgrounds in clinical medicine, human factors, and information systems acted as the action researchers, whereas female members of the Chief Medical Information Office and the operational project management unit represented the client system. Participants' accounts were treated as first-order data and interpreted by the researchers to develop second-order concepts [49]. As some team members were involved in coordinating implementation activities, their dual roles not only provided valuable contextual insight but also introduced the possibility of bias. Reflexivity was supported through systematic field notes, joint data collection, and regular team discussions, and analytic distance was strengthened by involving 2 researchers (BK and DF), who had not participated in data collection, in leading the analysis. The study was reported in accordance with the Standards for Reporting Qualitative Research (SRQR; see Multimedia Appendix 1) and the Consolidated Criteria for Reporting Qualitative Research (COREQ; see Multimedia Appendix 2) [50,51].

Before data collection, participants were informed about the study's purpose, the researchers' roles, and the goals of the initiative. No formal relationships were established in advance. Researchers were introduced in line with their collaborative roles as action researchers (AN, CG, EH, and LM) and clients (AW, CdP, JCB, and GK) [47]. Professional backgrounds and interest in implementation processes were disclosed, whereas the research questions were not shared.

Setting

The study was conducted at Charité – Universitätsmedizin Berlin, a large German university hospital employing over 23,000 staff and operating more than 3000 beds across more than 100 clinics and departments [52].



The research was embedded in the hospital's digital transformation initiative funded under the German Hospital Future Act (KHZG), which promotes the implementation of DHTs across German hospitals.

Recruitment and data collection occurred from February to April 2025 across 2 implementation phases: (1) a pilot phase observing pre- and early implementation activities and (2) an evaluation phase retrospectively assessing experiences across wards and departments. Together, these stages provided rich insights into the implementation process (Figure 1). Data were collected in inpatient wards, emergency and outpatient clinics, and administrative project management offices.

Access to the field was established by the initiative's lead via email, drawing on existing professional relationships to promote trust and encourage engagement, as well as through presentations of the initiative in various internal organizational committees. To contextualize these implementation activities, the next section describes the portfolio of digital technologies introduced under the KHZG initiative and examined in this study.

Figure 1. Data collection procedure for a qualitative study on modifiable off-the-shelf technology implementation at a large German academic hospital, illustrating a 2-stage process (pilot and evaluation phases) conducted from February to April 2025 across clinical and administrative settings.

The Implementation Portfolio

The research was conducted within the framework of the Hospital Future Act, a political mandate that allocates targeted funding to accelerate hospitals' digital transformation. Hospitals apply for these funds and must comply with national standards for DHTs to be eligible for support [11]. In line with the requirements of the KHZG and the hospital's overarching digital strategy [53], which emphasizes interoperability, user-centered design, and improved care, a dedicated implementation initiative was launched. Its objective was to introduce 10 preselected MOTs that fulfill KHZG criteria and contribute to the operationalization of the telematics infrastructure, Germany's secure and interoperable digital health network [54]. These technologies, formally approved as part of the hospital's digital transformation program, were implemented across inpatient and outpatient departments to enhance clinical documentation, resource management, device integration, and interprofessional communication. Patient-facing or consumer-oriented applications were not included because they were not part of the active implementation portfolio during the study period and thus did not constitute the exposure of interest. The study aimed to investigate the experiences, practices, and challenges of clinical personnel as active users of KHZG-funded MOTs, rather than to evaluate patient experiences or patient-technology interactions. The portfolio comprised both mandatory and optional solutions (see Table 1). Aligning with the action research approach [47], the initiative was iteratively refined in response to contextual factors, including high workloads and limited resources, as well as ongoing adjustments to evolving KHZG regulations.

Table 1. Overview of mandatory and optional modifiable off-the-shelf technologies included in the implementation portfolio of a digital transformation initiative at a large German university hospital (February-April 2025). Technologies were implemented in inpatient and outpatient clinical areas as part of the KHZG[a]-funded program and represent the digital tools to which clinical staff were exposed during the study.

Technology	Description	Requirement type
Electronic Sick Leave Certificate [55]	Online transmission of sick leave certificates via the telematics infrastructure.	Mandatory
Nationwide electronic health record (elektronische Patientenakte) [56]	Integration and implementation of a unified IT system for medical report writing across the hospital.	Mandatory
ePrescription Implementation [57]	Digital creation and transmission of prescriptions via the telematics infrastructure.	Mandatory
Digital Medication Management (inpatient) [58]	Digital documentation of medication on regular wards and some outpatient clinics; work on emergency and intensive care units in progress.	Mandatory
KIM (Communication in Medicine) – KIM Email [59]	Secure, encrypted email service within the telematics infrastructure for medical communication.	Optional
Operating Room Solutions (Digital Implant Passport) [60][b]	Clinical information system–integrated software module for implant documentation.	Optional
Mobile Ward Round [61]	An iPad app allowing access to critical clinical systems/features to support clinical ward rounds for doctors, nurses, and other staff (Wi-Fi dependent).	Optional
Admission Planning Tool [62][b]	Standardized planning for inpatient admissions.	Optional
Fluid Balance Module [63][b]	Digital documentation of access points, drains, and fluid balances in the clinical information system.	Optional
Digital Whiteboard for Ward Management [64][c]	Digital workflow organization tool for inpatient services in hospital wards and intensive care units.	Optional

[a]KHZG: Krankenhauszukunftsgesetz (Hospital Future Act).

[b]SAP modules were modified by the local IT department.

[c]End user–initiated development.

Participants

Participants were clinical staff (physicians, nurses, and patient coordinators) and nonclinical project management personnel involved in or affected by the digitalization initiative.

Eligibility criteria were (1) employment at Charité in a clinical or project management role and (2) involvement in or exposure to at least one MOT implementation. Recruitment followed a multistage purposeful sampling strategy to ensure maximum variation across disciplines and hierarchical levels [65]:

- Stage 1 (maximum variation sampling): selection of diverse departments (regular ward, emergency, and outpatient settings).
- Stage 2 (emergent purposive sampling): inclusion of additional participants expressing interest during project meetings and presentations.
- Stage 3 (criterion sampling): targeted recruitment of project managers due to their pivotal role in planning and coordination.

Elements of convenience sampling were used when data collection was integrated into existing meeting schedules.

A total of 129 participants were included: 73 clinicians, 46 project managers, and 10 members of the implementation initiative. While participation was generally high, a small number of invited nurses and physicians declined due to time constraints. Exact numbers of refusals and dropouts were not systematically recorded, as participation was integrated into routine clinical and project management activities. Sampling decisions across all stages aimed to capture diverse perspectives from frontline users and institutional implementers. Units of study were 12 researcher protocols: 5 from observations, 4 from focus groups, and 3 from workshops (see Multimedia Appendix 3). While 129 individuals contributed to data collection activities, analytic inferences were drawn from these protocols rather than from individual participants.

Demographic data were not collected because, following Rapoport's [43] view of action research as a collaborative, context-bound process focused on collective practice change, roles and functions in implementation were considered more relevant than individual characteristics, and statistical generalizability was not sought.

Assessments

Primary outcomes were perceived barriers and facilitators to MOT implementation, as well as underlying organizational dynamics that became evident during the process.

Exposures of interest included the characteristics of MOTs (usability, adaptability, and interoperability) and organizational factors (resources, infrastructure, and communication structures).

Potential contextual influences considered during interpretation included differences in departmental resources, professional hierarchies, and workload variation.

All outcomes were derived from qualitative accounts rather than standardized instruments, reflecting participants' lived experiences and professional perspectives.

XSL•FO
RenderX

Data Sources

Overview

An emergent qualitative design [66] guided data collection. Outcomes were assessed using 3 qualitative data sources: focus groups [67], workshops [68], and field observations [69] (see Multimedia Appendix 3). Data collection was conducted across 2 implementation phases and combined real-time engagement with retrospective reflection to capture both situated practices and reflective accounts of barriers, facilitators, and organizational dynamics. Each method contributed distinct perspectives on implementation processes and context-specific determinants.

Field Observations (n=5 Protocols)

Field observations were conducted on-site or online to capture real-time implementation practices, clinical routines, and interactional dynamics within the organizational environment. In phase 1, researchers (AN, CG, LM, AW, JCB, GK, and CdP) conducted 4 departmental observations (each 60-90 minutes; protocols [P] 9-12), focusing on implementation workflows and situated engagement with available MOTs, including how interest in specific solutions emerged or failed to emerge. In phase 2, a 90-minute online observation with project managers provided broader perspectives on cross-departmental coordination processes (P2). Researchers adopted a participant-observer stance, with varying levels of engagement depending on the activity. Observational field notes documented contextual factors, actor interactions, emergent issues, and workflow characteristics [69]. Field observations focused on capturing situated practices and real-time interactions as they occurred in the clinical and organizational context, rather than participants' retrospective accounts or evaluative judgments.

Workshops (n=3 Protocols)

Workshops served as participatory formats to support collective reflection and cocreate implementation strategies. In phase 1, following a ward's expressed interest in an MOT, AN and EH conducted a 2-hour back-casting workshop [70] with senior and assistant physicians, nursing staff, and patient coordinators to envision future workflows and articulate required process changes, starting from a desired future state (P4). In phase 2, a 30-minute workshop with project managers (P6), conducted by CG, AN, and EH, focused on evaluating implementation steps ("do," "don't," "must") and strategies for resource-constrained contexts. A 1-hour internal workshop with implementation initiative members (P7), led by CG and AN, supported reflexive examination of the overall approach. Workshops followed a semistructured but flexible facilitation style to allow participant-led exploration of barriers, facilitators, and implementation needs. They were explicitly future-oriented and designed to support joint sense-making, cocreation, and the development of shared implementation strategies.

Focus Groups (n=4 Protocols)

In phase 2, CG, AN, JCB, CdP, and AW conducted 4 one-hour focus groups with clinicians across diverse professional and hierarchical levels (P1, P3, P5, and P8). Focus groups explored implementation experiences, communication preferences, perceived determinants of adoption, and emergent best practices. Sessions were held on-site or digitally and were researcher-moderated. Focus groups elicited retrospective reflections, complementing the observational insights generated in phase 1. In contrast to workshops and observations, focus groups emphasized retrospective reflection on implementation experiences and facilitated comparison of perspectives across professional roles.

Across all methods, manual note-taking (without audio or video recordings) ensured participant comfort, protected confidentiality, and supported candid dialogue. A structured field note template (see Multimedia Appendix 4) was developed specifically for the study to document setting characteristics, actor interactions, contextual influences, and emerging themes consistently across methods. Only study participants and researchers were present during data collection; no nonparticipating individuals attended. Field notes were primarily compiled by AN and CG and supplemented by LM, CdP, AW, and JCB, enabling iterative refinement of prompts and observational foci in response to field engagement [66].

Study Size

The final study size (n=129 participants across 12 protocols) was determined pragmatically, based on data sufficiency, diversity of perspectives, and information power. This approach aligns with qualitative research conventions rather than statistical power considerations [71]. Breadth and representativeness across roles and departments were prioritized over saturation, given the multimethod, organizational scope of the research.

Data Analysis

All analyses were conducted at the protocol level, with the 12 researcher protocols forming the analytic corpus. Coding frequencies indicate patterns across activities rather than individual-level quantification, consistent with the study's action research design [47].

All protocols were transcribed and analyzed in MAXQDA 2022 (VERBI GmbH) [72] using deductive-inductive qualitative content analysis following Kuckartz and Rädiker [73].

To ensure analytic rigor, all coding activities were conducted by product-independent action researchers who were not part of the client system. AN and CG defined a priori codes from the Consolidated Framework for Implementation Research [21,36], guided by prior knowledge of barriers and facilitators. An independent researcher (BK), who was not involved in data collection, then coded the material in MAXQDA, applying these codes and developing inductive ones specific to the MOT context. BK subsequently assigned these codes to either the first-order category MOT implementation barrier or MOT implementation facilitator, with regular review by AN and CG. AN grouped related codes into 12 second-order categories (6 barriers and 6 facilitators), which were validated in 3 team meetings (AN, CG, and LM). To prevent "data overload," we decided to report only codes with 4 or more coded segments [74]. As Kuckartz and Rädiker [73] do not provide numerical thresholds, these cutoffs were established through analytical reflection to manage data complexity and ensure transparent reporting. This approach aligns with qualitative standards that emphasize conceptual significance over statistical

XSL•FO
RenderX

representativeness. A detailed overview of coding frequencies is provided in Multimedia Appendix 5.

Building on preliminary qualitative findings from the different data collection steps, MOT implementation barriers and facilitators also served as a basis for analyzing organizational tensions and deep-seated dynamics. Together, the 3 data sources provided complementary perspectives on the implementation of MOTs. Field observations captured how available MOTs were encountered in practice and how reasons for adoption or nonadoption emerged in everyday clinical and organizational workflows. Workshops contributed to the structured, future-oriented articulation of implementation pathways, including required process changes and strategies for resource-constrained contexts. Focus groups supported retrospective reflection on individual implementation experiences, preferences, and perceived determinants of adoption. Additionally, findings from the different data collection steps were triangulated to inform the interpretation of recurring patterns and contradictions. Based on access to the coded material, LM and DF, who were not involved in data collection and therefore contributed additional analytical distance, independently examined codes for contradictory demands or competing logics (eg, complexity vs participation, resource constraints vs engagement). Findings were discussed in 3 team meetings with AN and CG.

Integrating findings across methods, perspectives, and study phases, the analysis served as the basis for identifying higher-order organizational tensions. As a result, the final conceptual interpretations and tailored implementation strategies were derived from this integrated, triangulated analytical process.

Triangulation of methods (observations, workshops, and focus groups) and perspectives (clinicians, project managers, and implementation staff) enhanced trustworthiness [75]. Reflexivity was maintained through analytic memos and peer debriefing sessions. Quantitative counting of coded segments (frequencies and percentages) was used descriptively to illustrate emphasis, not to infer significance.

Ethical Considerations

Ethics Approval

The study protocol was reviewed and approved by the Charité – Universitätsmedizin Berlin Ethics Committee (approval number EA4/031/23). As the study involved human participants in the form of clinical and project management staff, institutional ethics oversight was required and obtained.

Informed Consent

Before participation, all individuals received verbal information about the study's aims, procedures, voluntary nature, and their right to withdraw at any time without consequences. Verbal informed consent was obtained before all data collection activities. The ethics committee confirmed that verbal consent was appropriate given the minimal risk, nonclinical nature of the study, and the absence of patient-related data.

Privacy and Confidentiality

To protect participant confidentiality, all field notes and workshop and focus group documentation were deidentified at the point of data collection. No names, professional identification numbers, or other personal identifiers were recorded. Data were stored on secure, password-protected institutional servers accessible only to the research team. Findings are presented exclusively in aggregated or anonymized form.

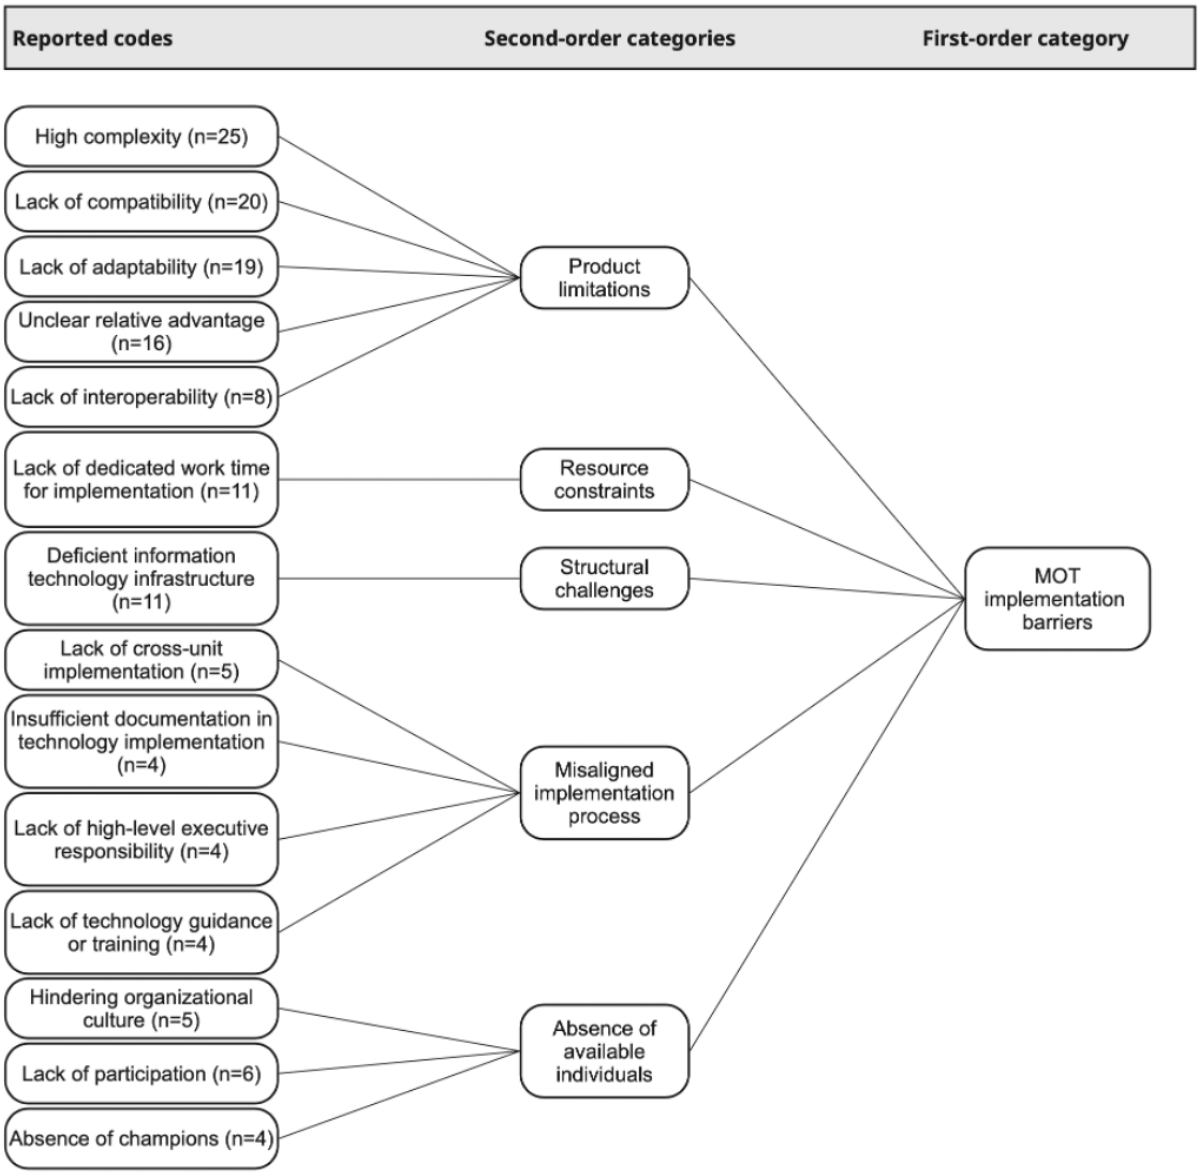
Compensation

Participants did not receive any financial or material compensation for their involvement. Participation was voluntary and occurred during or adjacent to routine professional activities.

Identifiability in Images or Multimedia Appendices

No identifiable individuals are presented in the manuscript or its multimedia appendices. All illustrative figures and multimedia appendices contain only anonymized documents and deidentified field note excerpts. No visual materials include recognizable individuals; therefore, no individual image-based consent forms were required.

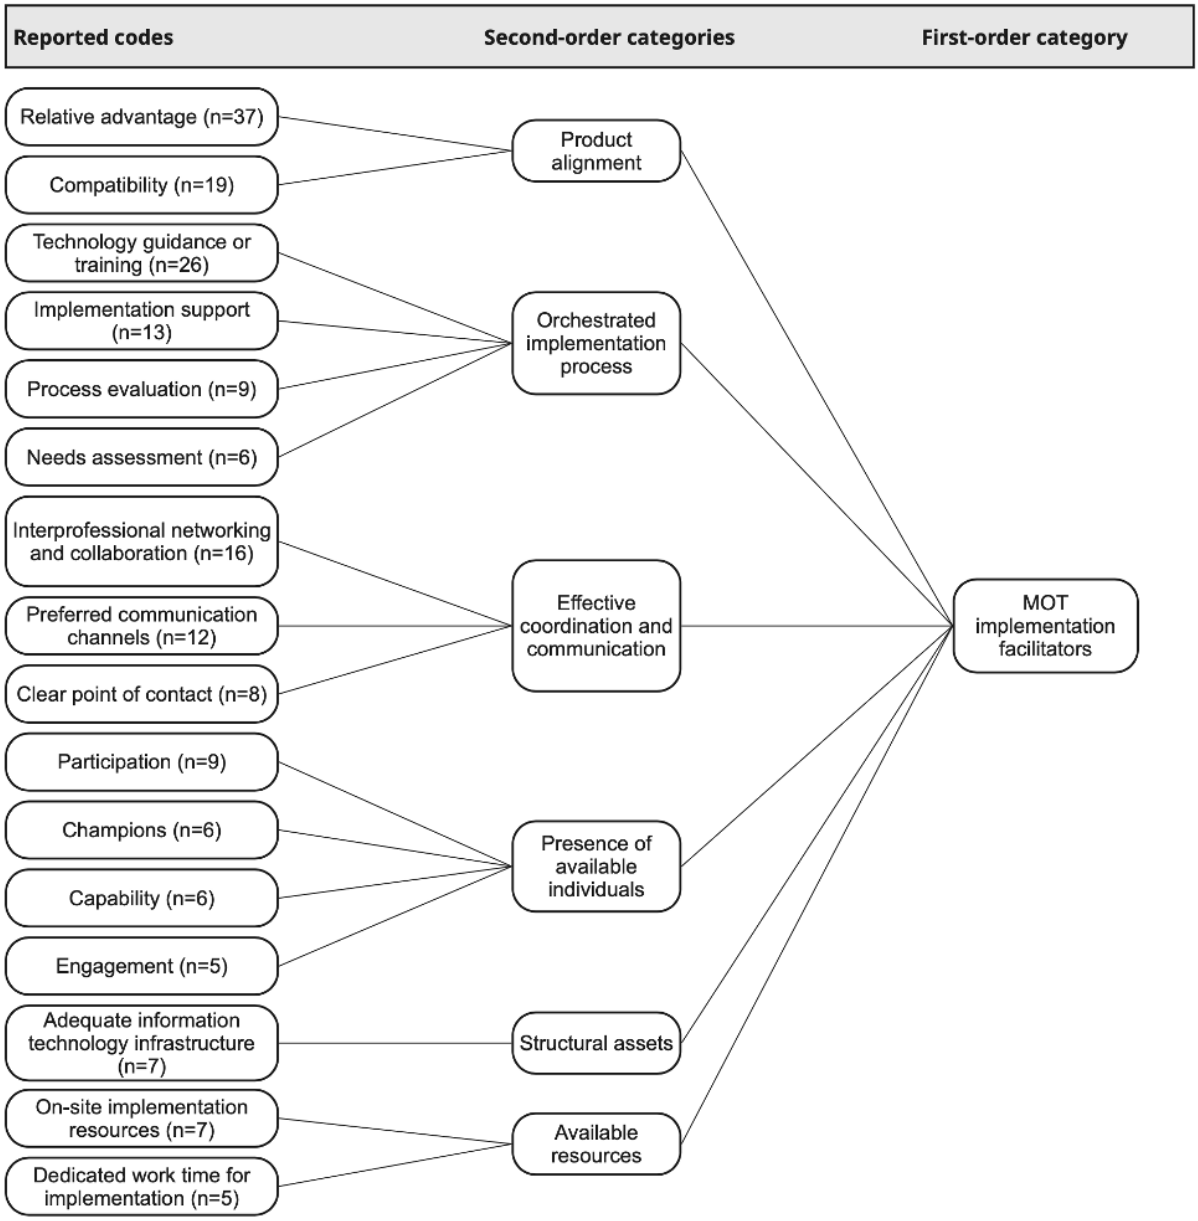
Results



Overview and Analytical Structure

Results are presented in 2 sections: (1) 6 integrated second-order categories combining barriers and facilitators within shared aspects of MOT implementation (see Figures 2 and 3) and (2) organizational dynamics conceptualized as 3 tensions. We defined barriers as factors that hinder or prevent uptake and facilitators as enabling conditions that support uptake [25]. Codes and second-order categories were labeled according to participants' perceptions and our interpretation: barriers were typically described using terms such as lack of, limited, or deficient, whereas facilitators were usually characterized by the perceived presence or availability of a factor.

In total, the coding process identified 390 data segments, comprising 172 barriers and 218 facilitators across the 12 researcher protocols. Frequencies indicate how often themes occurred across protocols and are not intended to represent participant-level prevalence. Multimedia Appendix 5 provides an overview of the distribution of reported and unreported codes, as well as all code frequencies. Representative quotes for all codes can be found in Multimedia Appendix 6. The following sections elaborate on each second-order category, beginning with those related to product characteristics.



XSL•FO
RenderX

Figure 2. Coding scheme of modifiable off-the-shelf technology (MOT) implementation barriers. Reported codes were aggregated into 5 second-order categories—product limitations, resource constraints, structural challenges, misaligned implementation processes, and absence of available individuals—which together constitute the overarching category of MOT implementation barriers.

XSL•FO
RenderX

Figure 3. Coding scheme of modifiable off-the-shelf technology (MOT) implementation facilitators. Reported codes were grouped into 6 second-order categories—product alignment, available resources, structural assets, an orchestrated implementation process, the presence of available individuals, and effective coordination and communication—which together constitute the overarching category of MOT implementation facilitators.

Product Limitations and Product Alignment

This category captures how the functional, technical, and workflow-related characteristics of MOTs shaped users' experiences.

Barriers arose when MOTs were difficult to operate, poorly aligned with existing routines, or technically constrained. These challenges were reflected in the lack of compatibility (20/172, 11.6%, barriers; 20/390, 5.1%, coded segments), such as when duplicate documentation or parallel paper processes were required. Lack of adaptability (19/172, 11%, barriers; 19/390, 4.9%, coded segments) captured the limited flexibility of MOTs to accommodate diverse wards, workflows, or professional roles. The added value of MOTs was not always evident, as reflected in unclear relative advantage (16/172, 9.3%, barriers; 16/390, 4.1%, coded segments). Difficulties were further reinforced by missing interfaces and fragmented data flows, represented by a lack of interoperability (8/172, 4.7%, barriers; 8/390, 2.1%, coded segments), which required manual bridging and complicated coordination across units. High complexity (25/172, 14.5%, barriers; 25/390, 6.4%, coded segments) referred to multistep logins, unstable Wi-Fi, and slow system responses that conflicted with fast-paced clinical work, as exemplified by a participant describing the mobile ward round:

> *[Mobile Ward Round] You go into the room to see the first patient, document everything, then go to the second patient, then the iPad is off, you have to enter a code and unlock it again, then log back into the HIS – by the time you've logged in, 3-5 minutes have passed and the others are already with the next patient. Then you want to look at the MRI image*

XSL•FO
RenderX

> *again, but the Wi-Fi cuts out. So, the idea is great, but the application isn't* [P9]

Facilitators emerged when MOTs aligned with clinical routines and offered clear benefits. Relative advantage was the most frequently reported facilitator (37/218, 17%, facilitators; 37/390, 9.5%, coded segments), emphasizing efficiency gains and reduced communication effort. Compatibility (19/218, 8.7%, facilitators; 19/390, 4.9%, coded segments) supported adoption when system functions fit existing workflows or professional expectations.

Together, these patterns indicate that MOT uptake depended on the extent to which technical design, usability, and workflow integration cohered with everyday clinical practice.

Resource Constraints and Available Resources

This category captures how staffing levels, protected time, and available support shaped clinicians' ability to engage in MOT implementation activities.

The most prominent barrier was a lack of dedicated work time for implementation, which accounted for 11 out of 172 (6.4%) barriers and 11 out of 390 (2.8%) coded segments. Participants reported that implementation-related tasks had to be completed alongside routine clinical duties, leaving little opportunity for training, experimentation, or supporting colleagues. As P7 noted: "Enthusiasm is there, but the time resource is missing."

Facilitators emerged when additional resources or protected time were available. On-site implementation resources represented 7 out of 218 (3.2%) facilitators and 7 out of 390 (1.8%) coded segments, and dedicated work time for implementation accounted for 5 out of 218 (2.3%) facilitators and 5 out of 390 (1.3%) coded segments. Participants described that responsive local support and focused time windows enabled them to engage in implementation activities without competing clinical responsibilities and to incorporate MOTs more consistently into everyday practice.

Structural Challenges and Structural Assets

This category reflects how participants experienced the adequacy and reliability of the hospital's technical infrastructure during MOT use and implementation.

Barriers were primarily captured in the code-deficient IT infrastructure, which accounted for 11 out of 172 (6.4%) barriers and 11 out of 390 (2.8%) coded segments. Participants described limited device availability, unstable Wi-Fi, slow system performance, and outdated hardware, all of which interfered with routine work and discouraged sustained use of MOT functions. Furthermore, these gaps sometimes prevented MOTs from being implemented in the first place, as required equipment was delayed or unavailable. As one participant noted: "Procurement of technical infrastructure unclear or very slow and bureaucratic via procurement platform" [P3].

By contrast, facilitators emerged when the infrastructure functioned reliably. Adequate IT infrastructure accounted for 7 out of 218 (3.2%) facilitators and 7 out of 390 (1.8%) coded segments. Participants reported smoother logins, stable network access, and consistent availability of clinical information; these conditions supported the routine use of MOTs and reduced the need for workaround practices.

Misaligned Implementation Process and Orchestrated Implementation Process

This category captures how the structure, coordination, and support of implementation activities influenced clinicians' experiences.

Barriers reflected fragmented processes, unclear responsibilities, and insufficient preparation. Lack of cross-unit implementation (5/172, 2.9%, barriers; 5/390, 1.3%, coded segments) and insufficient documentation in technology implementation (4/172, 2.3%, barriers; 4/390, 1.0%, coded segments) highlighted difficulties in understanding which technologies were already in use and how previous rollouts had unfolded. Several participants reported that oversight for implementation had been delegated to local clinical leaders who, due to existing clinical demands, had limited capacity to take on additional coordination tasks, as reflected in the lack of high-level executive responsibility (4/172, 2.3%, barriers; 4/390, 1.0%, coded segments). Reports of lack of technology guidance or training (4/172, 2.3%, barriers; 4/390, 1.0%, coded segments) further contributed to inconsistent processes and limited practical support.

Facilitators emerged when implementation was structured and actively supported. Technology guidance or training was a frequent facilitator in this domain (26/218, 11.9%, facilitators; 26/390, 6.7%, coded segments), alongside implementation support (13/218, 6.0%, facilitators; 13/390, 3.3%, coded segments), process evaluation (9/218, 4.1%, facilitators; 9/390, 2.3%, coded segments), and needs assessment (6/218, 2.8%, facilitators; 6/390, 1.5%, coded segments). Participants emphasized that accessible, context-specific training formats, visible support from the implementation team, and iterative feedback loops helped align expectations and adapt strategies to local workflows: "Planned iterative approach from the start—reminding people, asking about further interaction" [P7].

Absence of Available Individuals and Presence of Available Individuals

This category reflects how the availability, engagement, and roles of clinical staff and members of the implementation team were experienced by participants during MOT adoption.

Barriers were reported when individuals lacked time, recognition, or opportunity to participate meaningfully. Lack of participation accounted for 6 out of 172 (3.5%) barriers and 6 out of 390 (1.5%) coded segments. Participants described that, although interest often existed, competing clinical duties limited involvement. Hindering organizational culture represented 5 out of 172 (2.9%) barriers and 5 out of 390 (1.3%) coded segments, referring to hierarchical structures and strained working climates that reduced openness to change. The absence of champions accounted for 4 out of 172 (2.3%) barriers and 4 out of 390 (1.0%) coded segments, indicating missing local multipliers who could support peers or coordinate with the project team.

XSL•FO
RenderX

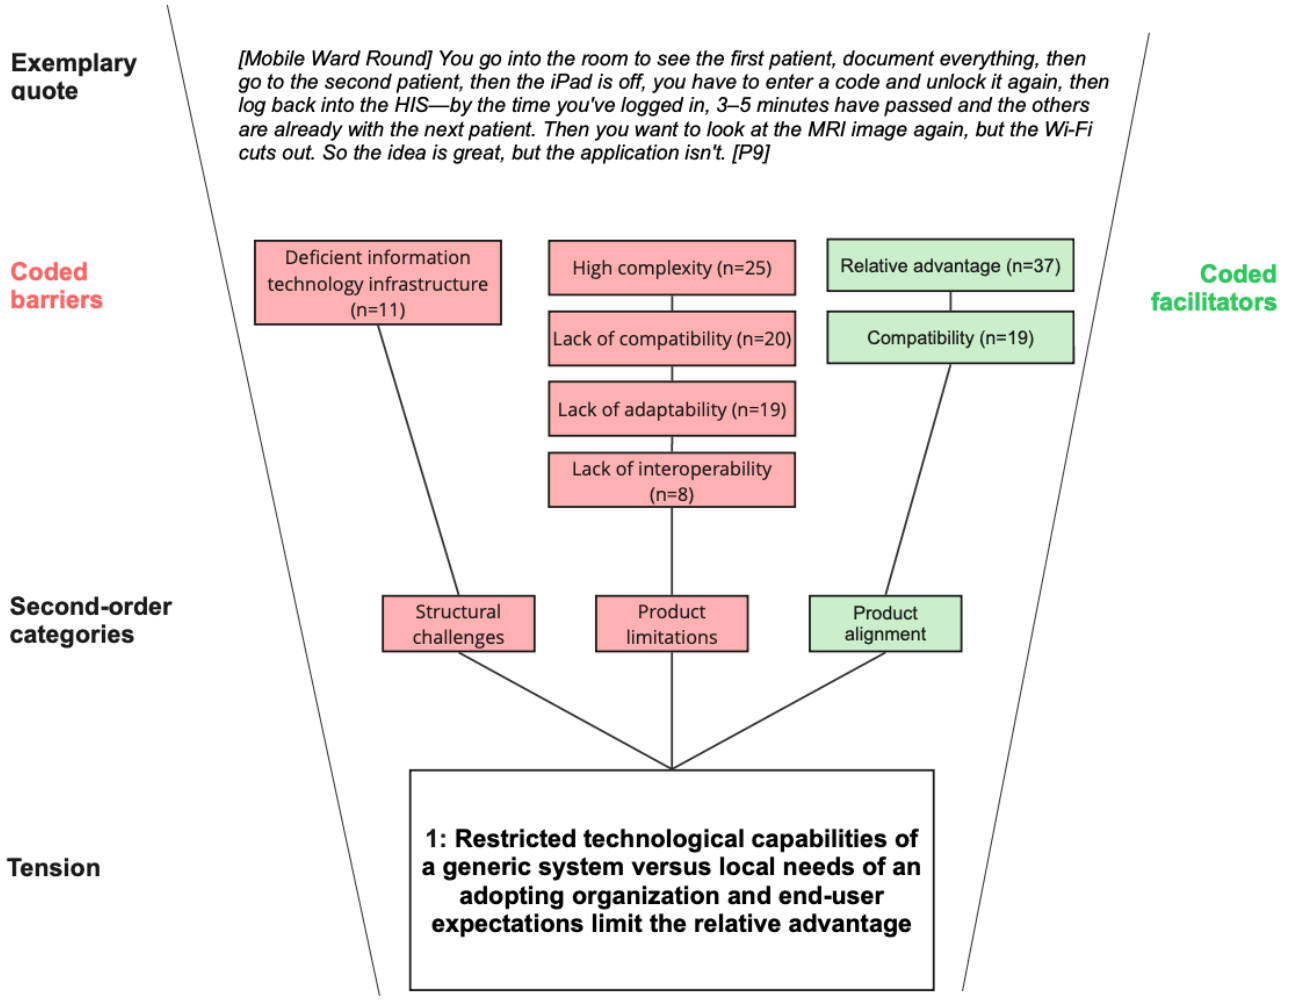
By contrast, facilitators emerged when individuals—whether clinicians or implementation team members—were available and engaged. Participation accounted for 9 out of 218 (4.1%) facilitators and 9 out of 390 (2.3%) coded segments, with staff actively initiating or supporting MOT rollout activities. Presence of champions represented 6 out of 218 (2.8%) facilitators and 6 out of 390 (1.5%) coded segments, capturing designated or informal multipliers who guided colleagues, tested functions, or liaised with the implementation team. Capability accounted for 6 out of 218 (2.8%) facilitators and 6 out of 390 (1.5%) coded segments, with participants highlighting digital competence and willingness to learn. Engagement accounted for 5 out of 218 (2.3%) facilitators and 5 out of 390 (1.3%) coded segments, reflected in proactive contributions to problem solving or workflow adaptation. A participant summarized the importance of identifiable and engaged individuals: "What else do we need from the clinics? Clear, consistent contacts who can serve as multipliers" [P6].

Effective Coordination and Communication

This category captures how interprofessional coordination and communication practices shaped the implementation of MOTs.

Although participants occasionally referred to coordination challenges, no communication-related barrier reached the minimum reporting threshold of 4 coded segments used in this study. Facilitators, however, were more frequently described and were reflected in interprofessional networking and collaboration, preferred communication channels, and a clear point of contact.

Interprofessional networking and collaboration accounted for 16 out of 218 (7.3%) facilitators and 16 out of 390 (4.1%) coded segments. Participants emphasized that structured collaboration between clinical professions and the project team supported implementation activities, as illustrated by one clinician who noted the value of "bringing different professional groups together to plan the implementation" [P6]. Preferred communication channels represented 12 out of 218 (5.5%) facilitators and 12 out of 390 (3.1%) coded segments, highlighting the importance of using familiar and accessible communication formats, such as in-person briefings, emails, or departmental meetings. A clear point of contact accounted for 8 out of 218 (3.7%) facilitators and 8 out of 390 (2.1%) coded segments, emphasizing the role of identifiable, reliable contacts for resolving questions and maintaining continuity during implementation.



Tensions in MOT Implementation Resulting From Existent and Perceived Barriers and Facilitators

Organizational Tensions in MOT Implementation

Across all categories, our analysis revealed deeper, interrelated patterns beyond isolated barriers or facilitators, pointing to underlying organizational tensions that become apparent during MOT implementation and use. We identified 3 organizational tensions that characterize MOT implementation in complex academic hospital settings (see Figures 4-6).

XSL•FO

Tension 1: Restricted Technological Capabilities of a Generic System Versus Local Needs of an Adopting Organization and End User Expectations Limit The Relative Advantage

While users expected a relative advantage from MOT use, product limitations emerged as a major barrier. Lack of interoperability and lack of compatibility led to fragmented data flows and incomplete functional integration, as vendor-driven system designs using preconfigured, standardized interfaces conflicted with the locally required data exchange in everyday care, which is often based on organization-specific terminology and interfaces. This created a tension because standardized system logics prioritized general applicability across diverse settings, whereas local care practices required flexible, context-specific integration of data flows. As a result, users were confronted with constant translation and alignment work to bridge the gap between the generic system architecture and their actual needs.

Closely related, the lack of adaptability and high complexity of MOTs produced usability constraints, forcing workaround practices as MOT use collided with the temporal, relational, and situational logics of clinical practice. This stood in tension with the expectation that digital systems should simplify and streamline clinical work, as MOTs instead introduced additional layers of cognitive and procedural effort. In practice, clinicians had to spend more time navigating complex interfaces or bypassing rigid functions, which diverted attention from patient care.

The emerging technological tension was further exacerbated by structural challenges, another major barrier category, particularly the hospital's deficient IT infrastructure. Ultimately, MOTs were not adopted when their potential efficiency and performance gains were outweighed by these barriers. These included high complexity, limited adaptability, and IT-infrastructural constraints, particularly a lack of interoperability and compatibility. Under such conditions, the relative advantage of MOTs was not apparent to users, which hindered their uptake.

Tension 2: Organizational Complexity and Different Oversight Logics Compromise Desired Structured User Participation

Clinicians emphasized the importance of active involvement before and during MOT implementation through preimplementation needs assessment, implementation support, process evaluation, and the use of preferred communication channels to share information effectively. Likewise, project managers highlighted their need for clear points of contact and designated champions for MOT implementation within departments. While participation was valued and desired by both groups, a hindering organizational culture was reported by clinicians and the implementation team. Clinicians, for example, felt that too much responsibility for MOT implementation was shifted to local clinical leaders, indicating a mismatch between assigned responsibilities and their perceived roles.

Participants perceived misaligned implementation processes—such as lack of technology guidance or training, insufficient documentation in technology implementation, and lack of cross-unit implementation—as barriers to their participation. These challenges may reflect differing oversight logics and governance structures shaped by managerial, economic, and regulatory requirements, such as the KHZG and data protection regulations, which had to be implemented within a short time frame, leaving limited opportunity for thorough planning and preparation. Specifically, rigid, project-bound management, hierarchical structures, and strained working climates reduced openness to participatory formats (eg, needs assessment) and hindered effective coordination and communication. This created a tension between the participatory processes that clinicians valued and the formal structures guiding implementation.

Tension 3: Limited Resources Undermine Individual Enthusiasm and Interest

While some participants expressed enthusiasm and willingness to participate, a major barrier to MOT implementation was resource constraints. Clinicians criticized the lack of dedicated work time they could allocate to implementation and highlighted their need for intensive on-site implementation support from project managers. Project managers, in turn, lacked champions in clinical departments for rollout processes and faced IT staff shortages and tight rollout schedules. This tension arises when clinicians are assigned responsibility as implementation leaders without having the necessary resources or identifying with that role. As a result, hospital managers experience tensions because they must operate under resource constraints while facing a persistent need for dedicated implementation resources.

Furthermore, interprofessional collaboration was recognized as a facilitator of MOT implementation because it was perceived to help align perspectives and create shared ownership. However, in practice, training and support were often organized in monoprofessional silos, meaning that doctors and nurses were trained separately. This reduced opportunities for joint learning and undermined the collaborative momentum required for sustained adoption. These structural and organizational barriers not only slowed implementation processes but also gradually weakened the initial enthusiasm of both clinicians and project managers. This reflects tensions between the demand to be innovative and collaborative and the lack of structures and resources needed to facilitate such collaboration.

Discussion

Principal Findings

This study identified 3 tensions during the implementation of MOTs.

Tension 1 concerned restricted technological capabilities that did not meet local needs and reduced the perceived relative advantage of the MOTs. Key barriers included product limitations, such as limited interoperability, low compatibility, low adaptability, and high complexity, as well as structural challenges that hindered smooth use. Product alignment acted as a facilitator when MOTs fit existing workflows.

XSL•FO
RenderX

Tension 2 arose from organizational complexity and differing oversight logics that compromised structured user participation. Barriers included a misaligned implementation process and the absence of available individuals to coordinate or support activities. Facilitators included an orchestrated implementation process, effective coordination and communication, and the presence of available individuals who could enable cross-unit participation.

Tension 3 reflected limited resources that undermined individual enthusiasm and interest in implementation. Barriers included resource constraints and a recurring absence of available individuals. Facilitators involved available resources, effective coordination and communication, and the presence of available individuals who could help maintain engagement.

The remainder of the "Discussion" section links these tensions and their respective barriers to misfit theory, introduces the concept of user:ability, and examines how 3 tailored strategies that integrate the observed facilitators respond to the organizational tensions in MOT implementation.

Misfits and the Role of User:Ability

Across all 3 tensions, the findings reveal that hospitals operate in a policy environment that seeks to accelerate digitalization while imposing strict timelines and compliance demands. Examples include Germany's KHZG and telematics infrastructure requirements [11,54], EU regulations such as General Data Protection Regulation (GDPR) [76] and the upcoming European Health Data Space [77], and US initiatives like HITECH [78] and the 21st Century Cures Act [79]. In this environment, hospitals often rely on MOTs, even though their standardized architecture restricts adjustments to functions, interfaces, or data flows. Limited involvement of end users during early procurement also contributes to systems that later need upgrades or expensive adjustments, as seen with the electronic health record in Germany [80-82]. These dynamics create fertile ground for organization-technology misfits as described by Strong and Volkoff [19]. Such misfits manifest in fragmented tools, disrupted workflows, higher error risk, and increased resource demands for both clinicians and IT teams [83]. In this study, multiple misfits are reflected in, and help explain, the tensions observed.

Tension 1 is characterized by functionality misfits, data misfits, and usability misfits when systems fail to reflect local workflows or information needs. Consistent with prior research, complex authentication [84], complicated user interface navigation [26], misalignment between systems and workflows [29,85], and limited interoperability [86] contributed to usability, data, and functionality misfits. Together, these factors limited the perceived usefulness of the technologies and thus discouraged adoption while also creating workarounds that made the misfits persistent [29,32,33,87,88]. Structural challenges, such as unreliable Wi-Fi, lack of functional devices [31,84], and difficulties complying with interoperability standards, reinforced these limitations.

Tension 2 reflected role and control misfits. Organizational complexity, unclear responsibilities, and inconsistent oversight made structured participation difficult [35,89]. These patterns mirror earlier studies showing that rigid governance structures and unclear responsibilities impede participation [19,90,91]. In our data, clinicians valued early involvement, whereas project managers emphasized clear contact points and department champions.

Tension 3 reflected role and organizational culture misfits. Clinicians were motivated but lacked time, recognition, and resources to take on implementation responsibilities. Resource constraints limited dedicated work time for both clinicians and project managers, a pattern consistent with the comparatively low IT investment levels in German hospitals [92]. Prior evidence supports that high workload and competing priorities force clinicians to prioritize patient care, limiting their capacity to meaningfully evaluate and adopt MOTs [93-95].

Taken together, these misfit patterns allow a focused reflection on the 3 assumptions from the "Introduction" section. The first assumption, that MOT implementation is shaped by functional and usability misfits, is confirmed but should be broadened. Functionality and usability mattered, but their effects were strengthened by role, control, and cultural misfits, showing that challenges arise from clusters of misfits rather than from product issues alone. The second assumption, that MOT implementation requires capacity-building conditions, is supported but needs refinement. Training, participation opportunities, and protected time are not optional but essential to counteract misfits caused by the limited modifiability of MOTs. However, capacity building alone cannot address structural or cultural misfits when organizations lack available individuals or coordination mechanisms. The third assumption, that structural characteristics intensify misfits, is also supported. Structural conditions not only amplified existing misfits; they also created new roles and cultural misfits by limiting participation, creating inconsistent responsibilities, and reducing available time. Overall, successful MOT implementation requires managing technological, organizational, and cultural misfits together, not only improving product alignment or increasing training.

Based on these findings, we introduce the concept of user:ability. User:ability describes the organizational conditions that enable users to adapt to MOTs effectively. It includes targeted training to clarify relative advantage, structured participation supported by clear communication, and protected time that allows users to engage in implementation tasks. Unlike related concepts such as user participation and user involvement, user:ability does not rely on early co-design, which is usually not possible with MOTs. Instead, it focuses on empowering users during implementation. Strengthening user:ability can help address the 3 tensions by improving perceived relative advantage (resolving tension 1), enabling participation in complex settings (resolving tension 2), and sustaining engagement despite limited resources (resolving tension 3). To operationalize user:ability, the following 3 strategies describe mechanisms to mitigate the tensions identified above, drawing on the facilitators observed in this study and integrating prior evidence.

XSL•FO
RenderX

Strategy 1: Ensuring Relative Advantage Through IT Integration, Product Alignment, and Targeted Learning

Strategy 1 focuses on reducing functionality, data, and usability misfits by strengthening the perceived relative advantage of the technologies through product alignment, IT integration, and targeted learning.

In this study, relative advantage and compatibility emerged as decisive factors for technology adoption, consistent with diffusion of innovations theory and the Consolidated Framework for Implementation Research [21,36,40]. Tailored learning approaches, including training, local implementation support, process evaluation, and microlearning formats, such as short instructional videos and question-and-answer sessions, helped clarify the benefits of MOT adoption and strengthened user confidence and acceptance [31,85,87,96-103]. As MOTs often require repeated upgrades and costly customizations even after rollout, organizations should integrate MOTs into the IT ecosystem with sufficient in-house IT expertise, enabling real-time access and workflow alignment [104].

Strategy 2: Empowering User Participation Through Digital Transformation and Structured Communication

Strategy 2 focuses on reducing role and control misfits by creating structures that enable meaningful participation through clear responsibilities, coordination mechanisms, and consistent communication.

Facilitators such as interprofessional networking and collaboration, clear points of contact, and preferred communication channels promoted knowledge-sharing, joint problem-solving, and shared ownership [31,97,100,101,103]. To strengthen these facilitators, hospitals can align IT and organizational goals through a digital business strategy and improve decision-making and coordination through a participatory process model that promotes aligned leadership, adaptive culture, and effective communication [105,106].

Structured and multimodal communication, including intranet resources, structured training, hybrid meetings, and targeted phone calls, can provide tailored support, clarification, and feedback [107]. These measures help align diverse stakeholders, foster trust, and enable coordination across units, thereby reducing role and control misfits.

Strategy 3: Enabling Clinician Engagement Through Resource Allocation and Systematic Implementation

Strategy 3 focuses on reducing role and cultural misfits by ensuring that individual enthusiasm can translate into sustained engagement through adequate time, support, and recognition.

Hospitals can address these constraints by allocating dedicated resources; providing clear points of contact for clinicians, project teams, and IT support; and structurally embedding clinicians across all phases of implementation [7]. By establishing structured roles such as clinical champions with protected time, for example, 4 hours per week [108], and clear cross-functional points of contact, organizations can sustain engagement, foster ownership, and enhance job satisfaction, supporting effective MOT adoption and evaluation [109-111].

This study contributes to implementation science by moving beyond the common focus on isolated barriers and facilitators. Instead of producing another descriptive list, the analysis integrates the findings into overarching misfits and organizational tensions. This perspective highlights how implementation challenges emerge from structural and relational dynamics rather than from single determinants. The study also introduces the concept of user:ability as an additional contribution. User:ability offers a way to understand how organizations can empower users in settings where technologies allow little adaptation. It shifts the focus from usability to organizational enablement and shows how targeted learning, structured participation, and protected time can help resolve core tensions. This conceptual addition extends existing implementation models by emphasizing the active role organizations play in enabling users to work effectively with MOTs.

While this study focused on barriers to implementing MOTs, the findings should not be interpreted as favoring in-house software development. In-house solutions can involve high development and maintenance costs, limited scalability, and long-term dependence on internal technical expertise and resource commitments [112]. By contrast, off-the-shelf systems benefit from vendor support, regulatory readiness, and standardized functionality, yet implementing them in complex clinical environments frequently requires extensive organizational adaptation to achieve local fit [22,113]. The findings, therefore, do not suggest the superiority of one technological strategy over the other but highlight the need for robust, participatory implementation processes and organizational alignment so that any technology, commercial or locally developed, can be meaningfully integrated into clinical practice.

Limitations

This study has several limitations that may influence interpretation and transferability. First, researchers held dual roles as implementers and evaluators, which is common in action research but may introduce observer bias. This was mitigated through reflexive practices, independent coding, and triangulation. Second, the analysis relies on frequency-based thresholds to structure qualitative data. Although the thresholds were transparently documented and grounded in established guidance for managing data overload, they may restrict the visibility of less frequent but potentially meaningful insights. As the analysis was conducted at the level of researcher protocols, the findings do not allow conclusions about participant-level prevalence or individual differences.

No demographic data were collected, which limits conclusions about individual differences. While this is methodologically acceptable in action research, where the focus is on collective learning and context-specific change [43], it constrains the ability to examine how individual characteristics may have shaped experiences. The findings, therefore, reflect shared group perspectives within the specific organizational context. Participation was voluntary and may have attracted digitally

XSL•FO
RenderX

engaged staff. However, even digitally motivated participants reported substantial barriers, suggesting that the identified tensions reflect systemic conditions rather than the views of a single subgroup. Still, less confident users may be underrepresented.

Some data relied on retrospective accounts, and the short data collection period limited insights into long-term adoption. Moreover, the focus on ready-made solutions may not fully capture upstream influences such as procurement procedures or funding structures. One included technology originated as a local initiative, which only partly aligns with the definition of MOTs but highlights the role of early user involvement.

The study did not include patient-facing technologies and did not collect patient perspectives, limiting insights into how digital transformation affects the care experience. Finally, the study took place in a single, highly resourced university hospital. Transferability is therefore limited, especially to smaller or less digitalized hospitals. Nonetheless, several observed tensions likely resonate across large and complex health care organizations. Future studies should examine these dynamics across hospitals with different structures and digital maturity levels.

Conclusions

This study demonstrates that, in the context of a German university hospital, the successful implementation of MOTs in hospitals depends less on improving usability and more on strengthening user:ability. This reframes digital transformation as an organizational challenge that requires structures that support learning, participation, and engagement when technologies cannot be adapted to local needs.

The 3 strategies derived from the findings provide context-specific guidance for creating such supportive conditions. Their relevance may extend to other large and complex health care institutions, although the implications should be interpreted in light of the single-site setting and the KHZG-funded implementation environment.

More broadly, hospitals must invest in conditions that enable users to work effectively with digital tools. This includes visible benefits for clinicians, coordinated implementation processes for project teams, and strategic resource allocation from hospital leadership.

These insights also extend beyond MOTs. Any digital technology requires alignment between structures, roles, and resources, so the choice between in-house or off-the-shelf solutions is secondary to an organization’s capacity to implement them effectively. Future research should examine how user:ability can be supported across diverse hospital settings to strengthen digital transformation efforts.

Acknowledgments

We gratefully acknowledge the valuable support of Hannah and Lynn during this study. We also extend our sincere thanks to the wards, units, and staff who contributed to data collection, with special appreciation to the nursing management and teams for their commitment and cooperation. GPT-4o (OpenAI) supported improvements to text fluency and grammar. All tool outputs were reviewed and revised by the authors, who take full responsibility for the submitted work.

Data Availability

The datasets generated and analyzed during this study are not publicly available because of data privacy; however, they are available from the corresponding author (LM) upon reasonable request. The qualitative data (field notes, workshop summaries, and focus group materials) generated and analyzed during this study are not publicly available because they contain sensitive information that could compromise participant confidentiality and institutional privacy. This paper includes selected anonymized participant quotations (anchor quotes) that illustrate key themes reported in the findings. No additional data are available for sharing.

Funding

Projects that made the evaluated technologies available for implementation were funded by the European Union through the Hospital Future Act (Krankenhauszukunftsgesetz), by financial support for the provision and maintenance of the telematics infrastructure negotiated between the National Association of Statutory Health Insurance Funds (GKV Spitzenverband) and the German Hospital Federation (Deutsche Krankenhausgesellschaft), and by internal digitalization budgets (regular institutional budgetary resources). Authors from the business units project management and CMIO were funded through the administrative budgets of their respective business units or by the European Union through the Hospital Future Act (Krankenhauszukunftsgesetz). No funder or funding body had any role in the study design, data collection, analysis, interpretation of results, or writing of the manuscript.

Conflicts of Interest

CG, AN, CK, and EH are researchers at the organization that launched and piloted the evaluated initiative, with no financial interests, no role on the JMIR editorial board, and no involvement in developing the technologies. LM is a participant in the BIH Charité Digital Clinician Scientist Program funded by Charité – Universitätsmedizin Berlin and the Berlin Institute of Health at Charité (BIH), and has received research funding from Masimo Inc and Philips. These contributions are independent of this project. DF is employed as a part-time researcher at the organization that launched and piloted the implementation initiative evaluated in this study; has received research funding from the European Commission, the German Federal Ministry of Research, Technology and Space, the German Federal Ministry of Health, the Berlin University Alliance, and the Einstein Foundation; has received support for attending meetings or travel from the German Academic Exchange Service. These contributions are independent of this project; and has no financial interests in the initiative or related products, has not served on the JMIR editorial board, and was not involved in the development of the evaluated technologies. FB has received research funding from the Hans Böckler Foundation, Berlin University Alliance, Charité Foundation, Joint Federal Committee, European Commission, Fresenius Foundation, the German Federal Ministry of Research, Technology and Space, the German Federal Ministry of Health, the German Research Foundation, Honda Research Foundation, and Philips; and has received honoraria from Pfizer and support for attending meetings or travel from the Association of German Anesthetists, DGAI, the German Society of Anesthesiology and Intensive Care Medicine, Masimo, and the Bavarian Academy of Sciences and Humanities. ASP has received research funding from the German Federal Ministry of Education and Research (BMBF), the European Society of Intensive Care Medicine, and the medical technology companies Masimo and Dräger; serves in an advisory capacity to Philips; and is a co-founder and managing director of INCH Health GmbH. BK declares no financial interests, no involvement in JMIR editorial activities, and no role in developing the evaluated technologies. JCB is employed as a project manager at the organization that launched and piloted the implementation initiative evaluated in this study and has no competing financial interests in the initiative or related products. GK is a digitalization manager within the CMIO at the organization that launched and piloted the initiative and declares no competing financial interests. CdP is a digital manager at the organization that launched and piloted the initiative and declares no competing financial interests. AW is employed as a digital manager and nurse at the organization that launched and piloted the initiative and declares no competing financial interests.

Abstract

AI is now embedded in the infrastructure of perioperative care. Risk stratification algorithms, hemodynamic prediction tools, and clinical decision support systems are active in operating rooms at major health systems, and their adoption is accelerating. However, the field has studied model performance and organizational implementation while largely bypassing the moment between them: the real-time encounter in which an anesthesia provider must decide, under active case conditions, what to do with an AI-generated output. We term this the cognitive transaction and argue that it is the fundamental unit of perioperative AI implementation. The perioperative environment presents a specific constellation of conditions that existing human-AI interaction research was not designed to address. Continuous real-time decision demands, extreme time compression, high cognitive load, and consequences that unfold in seconds distinguish the operating room from the clinical contexts where most provider-AI interaction research has been conducted. What we know about AI adoption in radiology, oncology, or ambulatory care does not readily translate to this setting. The cognitive moment in anesthesia has its own structure, its own failure modes, and its own research requirements. This paper examines what those requirements are. We analyze how the operating room functions as a pre-existing human-machine cognitive system into which AI is now being inserted, and why the conditions of that system generate predictable vulnerabilities: miscalibrated trust, automation bias, and cognitive friction produced by interfaces optimized for technical accuracy rather than clinical usability. We argue that these failure modes are not incidental but structural and that they will persist regardless of model performance until the provider-AI interaction is itself treated as a research object. We identify 4 priority research domains. The first concerns the structure of provider-AI disagreement and the methods needed to distinguish automation bias from legitimate clinical insight. The second concerns the longitudinal dynamics of trust calibration across repeated clinical encounters rather than single-session experimental designs. The third concerns interface design for high-acuity workflows, specifically what constitutes a usable AI output for a provider managing a patient in real time. The fourth concerns the need for ecologically valid study designs capable of capturing provider reasoning under actual perioperative conditions rather than retrospective or survey-based proxies. The anesthesia and perioperative research community is positioned to lead this work. The clinical specificity, domain knowledge, and professional stake required to design meaningful studies are all present within the field. Evaluating the cognitive transaction under perioperative conditions, not the computational model in isolation, is both a methodological imperative and a patient safety priority.

Introduction

This paper articulates a human factors research agenda addressing 3 levels of clinical AI integration. The primary target domain is the perioperative surgical environment, a uniquely complex setting characterized by continuous real-time decision demands, extreme time compression, and high cognitive load [1]. Furthermore, unlike insular environments such as an aviation cockpit, the operating room functions as a highly connected socio-spatial network [2]. Introducing AI into this intricate spatial and social architecture requires a dedicated human factors approach to ensure that new technologies align with actual clinical workflows. The insights derived from this environment function less as a direct template for clinical AI generally than as a stress test: if human-AI collaboration can be made to work under the extreme time compression and cognitive load of an active operating room case, the resulting

XSL•FO
RenderX

principles are more likely to hold with even greater confidence in less demanding clinical AI contexts. Finally, this work offers a theoretical contribution by positioning the "cognitive transaction" (the real-time encounter between algorithmic output and clinical judgment) as the fundamental unit of analysis for safe and effective AI deployment.

The Gap Nobody Is Naming

Perioperative health care is generating more data, more rapidly, than any individual clinician can process. The tools being built to close that gap are arriving faster than the science needed to deploy them safely. AI has entered the perioperative environment not as a future possibility but as present infrastructure. Risk stratification algorithms, early warning systems, and clinical decision support modules are increasingly embedded in the electronic health record platforms that anesthesia providers navigate daily.

The research literature evaluating these tools has expanded accordingly, with a growing body of studies reporting model performance and prospective validation results. A parallel implementation science literature has grown alongside it, examining organizational adoption, clinician behavior change, and system-level barriers to uptake. What neither body of literature has systematically studied is the moment between the two.

An anesthesia provider, mid-case, encounters an AI-generated risk output, such as a predicted probability of hemodynamic instability or a hemorrhage risk score embedded in the obstetric record. The number appears, and the provider must decide in seconds, under high cognitive load and with competing attentional demands, what to do with it. Do they act on it, override it, or adjust their existing assessment? The model has done its work; now the human must do theirs.

That cognitive transaction, the encounter between algorithmic output and clinical judgment in real time, is the fundamental unit of perioperative AI implementation. Remarkably, it is also the unit that the field has studied most inconsistently.

This omission does not stem from a lack of interest. Researchers across clinical AI, human factors engineering, and implementation science have recognized that provider-AI interaction shapes outcomes in ways that model performance alone cannot predict. However, the perioperative environment presents a specific constellation of conditions that makes it categorically different from the clinical contexts where most human-AI interaction research has been conducted. These unique conditions include continuous real-time decision demands, extreme physiologic complexity, and consequences that unfold in seconds rather than hours. The cognitive moment in anesthesia has its own structure, its own failure modes, and its own research requirements. Until those requirements are met, the gap between model performance and clinical value will persist regardless of how good the models are.

Why Perioperative AI Is a Distinctive Case

The perioperative environment requires its own analytical framework, not an adaptation of existing clinical AI research conducted elsewhere. Anesthesia providers do not encounter technology as an occasional resource; rather, they operate within it continuously. A single case requires the simultaneous management of a ventilator, infusion pumps, a physiologic monitoring array, and an anesthesia information management system. Each of these components generates real-time data streams, requires ongoing interpretation, and demands an immediate response when conditions deviate from clinical expectations. This is not a new condition introduced by AI. It is the baseline cognitive architecture of the role.

Cook and Woods [3], writing on adaptation to new technology in the operating room, described this environment as one in which human and machine contributions are already interwoven in ways that cannot be disentangled without fundamentally altering the nature of the work. This baseline matters for AI implementation because it means the operating room is not a neutral surface onto which a decision support tool is introduced. It is an existing human-machine cognitive system, already structured by relationships of trust, workload distribution, and situational awareness, into which an AI layer is being inserted [3,4].

The question is not whether providers can tolerate an additional data source. They tolerate many. The question is what happens to the existing cognitive architecture when one of those data sources is probabilistic, opaque, and carries an implicit authority that physiologic monitors do not.

To an anesthesia provider, a pulse oximeter reading of 88% is self-evident. An AI-generated risk probability of 0.73 is not. A pulse oximeter reading speaks directly to a physiologic state that the provider can verify and act upon. An AI risk probability speaks to a statistical relationship between patient characteristics and an outcome, derived from a training cohort the provider did not choose, using features the provider may not be able to inspect, with a CI that is rarely displayed. Every anesthesia provider knows how to respond to one. Almost none have been trained to critically evaluate the other. Treating these 2 outputs as equivalent in design, training, or implementation is a category error with clinical consequences.

The Human-AI Joint Cognitive Systems (HAIJCS) framework, proposed by Xu and Gao [5] and applied to the obstetric anesthesia context by Warner et al [6], offers a conceptual foundation for understanding this distinction. Under HAIJCS, the human provider and the AI system are understood as collaborative cognitive agents, each contributing to shared situational awareness, task execution, and decision-making under the authority of the human. The relevant question is not only whether the model predicts correctly but also whether the human-AI dyad operating together under actual clinical conditions reaches better decisions than either would reach alone and whether the conditions of the operating room allow that dyad to function as designed.

XSL•FO
RenderX

The Joint Cognitive System (JCS) and its HAIJCS extension model the operating room at the level of the system: a standing architecture of shared situational awareness, trust, and control between human and machine agents [4-6]. The cognitive transaction operates at a different grain. It is not a second name for that system-level relationship; it is the discrete event the relationship depends on, and none of the frameworks it draws on treat that event as an object of study in its own right. Trust calibration, as JCS frames it, describes a general disposition the human holds toward the machine over time. Situation awareness, as modeled by Schulz et al [4] in anesthesia, describes an ongoing process of perceiving, comprehending, and projecting system states. The cognitive transaction is neither the disposition nor the process. It is the specific encounter, this output, this patient, this second, in which trust gets tested and situational awareness gets updated. Distributed cognition makes a related claim at the structural level: cognitive work is located across people, tools, and environment rather than inside any single agent [7]. All 3 describe standing conditions of the joint system. None isolates the moment of integration as a unit that can be observed and measured directly. The cognitive transaction is that unit.

Research from aviation and military operations has established that high-workload, time-pressured environments generate predictable patterns in human-automation interaction, including automation bias, complacency, and degraded monitoring of system states during periods of high task demand [8,9]. Perioperative AI introduces an epistemic challenge that those findings were not built to address. The provider must act on a prediction they cannot verify in real time, about a future state that may never materialize, for a patient who may bear little resemblance to the population from which the model learned. Instruments can be independently cross-checked against observable measurements; risk scores cannot be directly verified in the same way. Translating human factors insights from adjacent domains is a necessary starting point, not a sufficient end point. Perioperative AI implementation requires a research agenda built for the operating room, not borrowed from the cockpit.

What the Current Literature Misses

The clinical AI literature has made substantial progress on model development, producing tools that perform well on retrospective datasets. Reviews of perioperative AI consistently demonstrate improvements in predictive accuracy for outcomes including postoperative complications, intraoperative hypotension, and adverse events across multiple patient populations [10]. This is meaningful work, but model development solves only a fraction of the problem.

A striking pattern has emerged from the broader clinical AI literature: AI systems working independently have begun to outperform clinicians using those same systems as decision support tools [11]. Explanations for this range from automation neglect to a fundamental mismatch between how models communicate uncertainty and how clinicians process it in practice. While the authors acknowledge that this evidence is early and drawn largely from controlled settings, it reveals a critical reality. Giving clinicians access to an AI tool does not automatically produce better decisions, and some have argued that the assistive model itself may be fundamentally flawed as a design paradigm [12]. Regardless, the underlying observation stands. The quality of the human-AI interaction, rather than the model's isolated performance, determines whether the combination is synergistic, additive, or subtractive. This interaction has rarely been studied with the rigor applied to the models themselves.

The implementation science literature has done important work naming this problem. Studies on sepsis decision support tools have found alert fatigue, high override rates, and clinician abandonment of models that appeared predictive on paper [13,14]. These deployment failures are not primarily technical; they are cognitive and interpretive. Clinicians cannot inspect the key features driving a prediction or assess if the training cohort matches the patient in front of them. When a model's output conflicts with clinical assessment, clinicians may lack a clear framework for determining which source of information to trust. The result is either uncritical acceptance, which introduces automation bias, or reflexive dismissal, which undermines the tool's purpose [15].

Reviews have summarized technology and human factors that influence clinician-AI interaction, such as data quality, performance, transparency, expertise, cognitive biases, and trust [16]. Perioperative AI researchers have identified similar concerns [10,17]; however, the specific perioperative environment makes failures involving technology and human factors particularly acute. Three features of the perioperative environment explain why that methodological work is both especially difficult and necessary.

First, deliberation time is not merely compressed but functionally eliminated during critical perioperative events. Other clinical AI contexts deploy decision support in real time, including sepsis alerts, opioid risk prediction, and chronic disease management, but providers in those settings retain a meaningful window for reflection, consultation, and staged response [13,14,18]. A perioperative risk output during an evolving hemodynamic event does not allow for reflection, consultation, or staged response. Cognitive psychology research illustrates that time pressure can reduce the quality of activities, modify risk-taking, change underlying cognitive processing, and increase the relative relevance of different information sources [19]; hence, understanding how time pressure influences the clinician-AI interaction in the context of anesthesia and operative events is critically important. Second, human-AI interaction research has rarely accounted for the profound cognitive load of active case management, where fatigue, divided attention, and the dynamic spatial environment of the surgical team dictate whether an alert registers as a signal or mere noise [4,17]. Third, anesthesia providers lack established norms for interacting with probabilistic AI algorithms. Unlike radiologists, who have worked alongside AI-assisted image review tools for years, anesthesia providers are encountering these tools without a shared professional vocabulary for evaluating, trusting, or overriding them [20,21].

XSL•FO
RenderX

This third feature points to a structural explanation for the literature gap. The clinician-researchers best positioned to study the cognitive moment in perioperative AI, those who understand both the perioperative environment and the methodological tools required to study human-AI interaction, exist at an intersection that the field has not yet organized around. Computational researchers lack deep access to perioperative decision-making processes. Implementation scientists lack the anesthesia-specific domain knowledge to recognize what makes perioperative AI distinctive. Meanwhile, the anesthesia providers who navigate these cognitive demands daily have not traditionally received training in human factors or informatics. The gap is not simply a gap in knowledge. It is a gap in who is asking the question.

Toward a Research Agenda for the Cognitive Moment

Rather than proposing a comprehensive framework, this agenda outlines priority research questions grounded in the distinctive features of the perioperative environment. These domains are drawn primarily from risk-stratification and predictive-alert use cases, which currently represent the AI applications most deeply embedded in perioperative workflows. Real-time hemodynamic prediction tools compress the transaction further, leaving less room for the reflective divergence discussed below. Generative systems, which produce free-text recommendations rather than a single score, introduce additional interpretive demands that the disagreement and interface-design frameworks discussed here do not yet address. Whether the cognitive transaction holds the same structure across these AI types, or requires type-specific variants of each research question, is an open question this agenda raises rather than resolves. The most pressing concern is the structure of provider-AI disagreement: when an anesthesia provider and an AI system arrive at different risk assessments for the same patient, what explains the divergence? Current methodologies, largely adapted from radiology and emergency medicine, focus primarily on agreement metrics rather than investigating these underlying sources of conflict [22]. In the operating room, provider divergence from an AI output may reflect automation bias, but it may equally signal critical clinical insight inaccessible to the model, a patient's affect, a subtle physiological pattern recognized over thousands of cases, or unrecorded institutional variables. A perioperative research agenda must disentangle these sources of divergence rather than collapsing them into a binary agreement metric. Capturing this nuance requires mixed methods designs that pair quantitative performance data with structured qualitative inquiry into provider reasoning, an approach largely absent from the current literature. The critical decision method developed by Klein et al [23] offers an established route to this distinction: a structured retrospective interview technique that reconstructs the cues, prior cases, and contextual signals a provider drew on at the moment of divergence, rather than treating the divergence itself as the end point of analysis. It remains one of the most commonly applied cognitive task analysis techniques in clinical decision-making research, spanning surgical and critical care settings [24].

Trust in an AI system is fluid and not a fixed attribute. However, the current clinical AI literature predominantly evaluates trust through cross-sectional surveys or single-encounter experimental designs, yielding a static snapshot. This fails to capture the most vital question for perioperative implementation: How does trust in a specific AI system develop, erode, and recalibrate over repeated clinical encounters? Anesthesia providers who override a model's output and later find it correct will reasonably become skeptical of the model's future reliability. On the other hand, providers who defer to the model and observe a good outcome may default to uncritical reliance. Longitudinal designs that pair momentary, in-the-moment reliance judgments with case-level outcome tracking, sampled repeatedly across a provider's caseload, would let calibration be measured as a trajectory rather than a single point estimate. The relevant construct is not trust in the abstract but calibrated reliance: whether a provider's confidence in a given output corresponds to its actual reliability on a case-by-case basis.

The perioperative AI literature has given little systematic attention to how model outputs should be communicated to providers operating under the cognitive conditions of active case management. Current tools tend to present a risk score or classification optimized for technical legibility rather than clinical usability, prioritizing mathematical accuracy over the ability of a multitasking clinician to quickly and appropriately integrate the information. Human factors research has long established that the design of information presentation shapes clinical behavior just as much as the information itself. Outputs developed without regard for cognitive load, task context, and provider mental models routinely fail at the point of care, even when the underlying algorithm performs well [4,13]. What constitutes a usable, low-friction AI interface for an anesthesia provider mid-case, in terms of format, timing, level of specificity, and fit with existing workflow, remains unanswered. One example of a low-friction output might surface as a color-coded flag integrated directly into the existing vital sign display rather than a separate probability score requiring independent interpretation. Another might be a brief natural language prompt, such as "rising hemorrhage risk, consider early type and screen," delivered at a natural pause in the case rather than immediately when the model updates. Adjudicating between formats requires usability testing under simulated time pressure, not static comprehension surveys. Solving this for the extreme constraints of the operating room will establish baseline principles for AI usability across all clinical environments. Until this is addressed, interface design will continue to be driven by technical conventions rather than clinical evidence.

Ultimately, the field requires research methodologies capable of capturing not only what anesthesia providers think about AI in the abstract but also how they reason about and integrate these outputs within ecologically valid clinical contexts. This should encompass both perceptual and deliberative processes. Expert anesthesia providers often detect physiological deterioration through pattern recognition that precedes conscious reasoning. Recent work pairing physical simulation with eye tracking has begun to capture this in critical care, finding that clinicians' visual attention did not reliably increase even when an AI recommendation was unsafe [25]. Perioperative research

XSL•FO
RenderX

needs the same instrumentation applied to the compressed conditions of an active case. This necessitates moving beyond retrospective analyses and survey-based designs. Instead, research should use realistic clinical simulations incorporating model outputs and evolving patient data to examine the continuous cognitive process of integration, rather than focusing solely on the final binary decision. We must investigate how providers respond to unexpected algorithmic predictors, how the framing of an output shapes clinical action, and precisely when and why human judgment diverges from a model's recommendation. These are not peripheral questions of user experience. They are the empirical foundation on which safe, deployable perioperative AI must be built.

Why This Matters Now

Perioperative AI is not a future abstraction; it is a present reality. Tools for perioperative risk prediction, hemodynamic management, and postoperative complication forecasting are already embedded in clinical workflows at major health systems, and their adoption is accelerating [10]. The window for shaping how these systems are designed, evaluated, and deployed is open now, and it will not remain open indefinitely. Once these tools become embedded in institutional infrastructure, clinical workflows reorganize around them, and the cost of redesign increases substantially. The decisions being made today about what perioperative AI looks like, what it communicates, and how it interacts with provider judgment will permanently shape the cognitive environment of anesthesia practice.

The research agenda proposed here is not a precondition for building these systems; it is a precondition for building them safely and effectively. Models can be designed and deployed without understanding how providers interact with their outputs. In fact, they already have been. The consequence, documented repeatedly in adjacent clinical AI contexts, is a generation of tools that perform well in evaluation but fail in practice. This occurs not because the underlying science was wrong, but because the implementation ignored the human at the other end of the interface [11,13].

Anesthesia providers are not passive recipients of this technology. They are, by the nature of their role, the final cognitive layer between an algorithmic output and a clinical action. That position is not incidental. It is the precise point at which the entire value proposition of perioperative AI either materializes or collapses. A research program that takes this position seriously, that asks what the provider needs to know, what the interface needs to communicate, and what the conditions are under which human and algorithmic judgment combine to produce outcomes better than either alone, is not a niche methodological interest. It is the central scientific problem of perioperative AI implementation.

The anesthesia and perioperative research community is uniquely positioned to lead this work. The clinical specificity required to design meaningful studies, the domain knowledge required to interpret findings, and the professional stake in getting implementation right are all present within the field. Engaging the anesthesia and perioperative community in the development of AI solutions is consistent with calls for the engagement of other specialties, such as primary care, in research and implementation efforts that affect their patient populations. Such engagement helps ensure that AI applications are developed in ways that address the needs of frontline practitioners and ultimately improve patient outcomes [26]. That leadership, however, must be exercised in partnership. The research priorities identified here sit at the intersection of cognitive psychology, health informatics, implementation science, and clinical practice. No single discipline has the tools, the access, and the domain knowledge to address them alone. Anesthesia providers bring irreplaceable expertise in the perioperative environment, cognitive psychologists bring the methodological frameworks for studying human-AI interaction, informaticists bring the technical infrastructure for capturing and analyzing clinical data, and implementation scientists bring the frameworks for translating findings into practice. In practical terms, each stakeholder has a concrete starting point: anesthesia providers can partner with cognitive psychologists to design the simulation studies this agenda calls for; health system informaticists can instrument existing AI tools to capture override rates and response times rather than waiting for purpose-built research infrastructure; and clinical AI developers can treat these research questions as design requirements to address before deployment, rather than as validation exercises conducted afterward. Underlying all of these is a shared recognition that the cognitive transaction at the intersection of algorithmic output and clinical judgment is itself a discrete research object, distinct from the model, the organization, and the provider in isolation. Naming it as such is the first necessary step toward studying it rigorously and designing perioperative AI systems that are not only accurate but also genuinely useful in the operating room.

Abstract

Symptom checkers are apps and websites that assist medical laypeople in diagnosing their symptoms and determining which course of action to take. When evaluating these tools, previous studies primarily used an approach introduced a decade ago that lacked any type of quality control. Numerous studies have criticized this approach, and several empirical studies have sought to improve specific aspects of evaluations. However, even after a decade, a high-quality methodological framework for standardizing the evaluation of symptom checkers is still lacking. This paper synthesizes empirical studies to outline the Symptom Checker Accuracy Reporting Framework (SCARF) and a corresponding checklist for standardizing evaluations based on representative case selection, an externally and internally valid evaluation design, and metrics that increase cross-study comparability. This approach is supported by several open access resources to facilitate implementation. Ultimately, it should enhance the quality and comparability of future evaluations of online and artificial intelligence (AI)–based symptom checkers, diagnostic decision support systems, and large language models to enable meta-analyses and help stakeholders make more informed decisions.

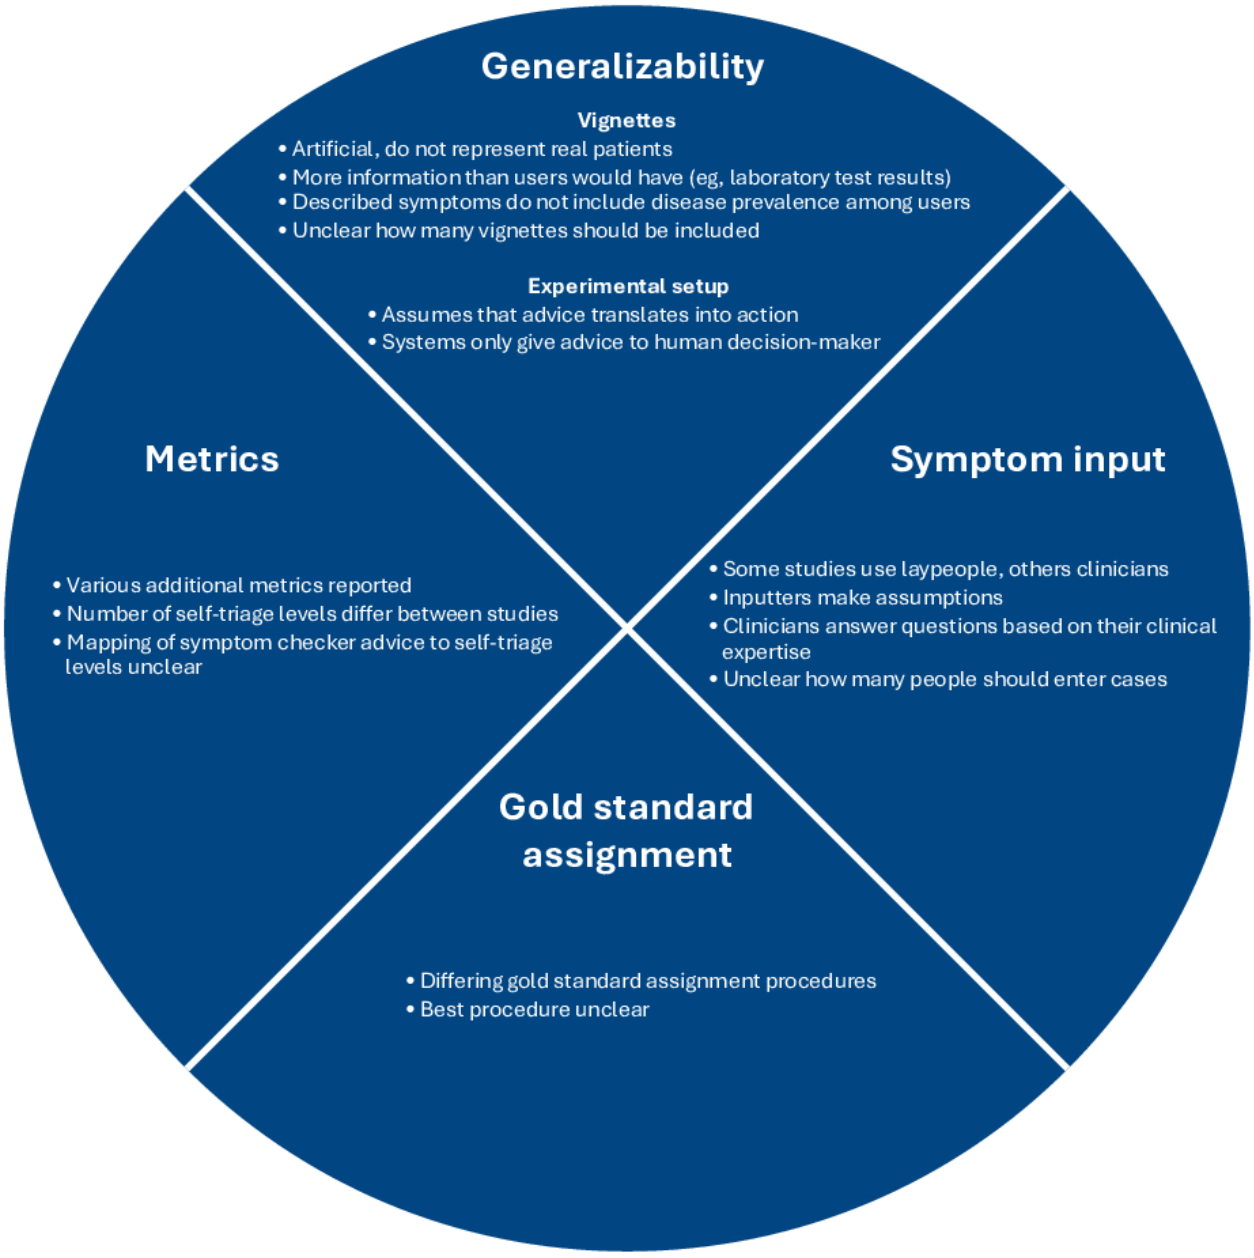
Introduction

Symptom checkers (also called “symptom assessment applications,” “online symptom checkers,” or “self-assessment applications”) are websites or mobile apps in which medical laypeople can enter their symptoms. The apps then provide potential diagnoses and “self-triage” advice. Self-triage advice refers to recommendations given in a precare setting to assist users in determining if, how urgently, and in which institution they should seek care. The first study to systematically analyze the accuracy of these apps was conducted in 2015, and their accuracy has been debated ever since [1]. This seminal study evaluated symptom checkers using 45 medical case vignettes (15 emergency care cases in which users would call the national emergency line or go directly to the emergency department, 15 nonemergency cases in which users would seek primary care, and 15 self-care cases in which users would treat symptoms themselves or wait to see if symptoms improve before seeking care) that were taken from various medical resources, including medical education textbooks. The gold standard solution—that is, the most appropriate action for each case—was determined by 2 physicians who independently rated each case and then discussed disagreements. An unrelated researcher entered all cases into the various symptom checkers, and the authors calculated the proportion of cases correctly solved as the main outcome. This procedure has been used in most subsequent studies, sometimes with slight modifications such as adding more vignettes and triage levels, using lay-friendly phrasing of the vignettes, or including large language models as symptom checkers [2-5]. However, most of these studies acknowledged limitations with this approach and called for improved methods. Systematic reviews that attempted to determine the accuracy of symptom checkers across multiple studies quickly reached the consensus that these methods were often of low quality and that cross-study comparability was limited [6-9]. In recent years, some studies have explicitly formalized this criticism, whereas others have proposed solutions to address it, including several of our own [6,10-14].

In this paper, we do not want to add to this criticism; instead, we present the Symptom Checker Accuracy Reporting Framework (SCARF) and a checklist that can (1) be used to conduct high-quality symptom checker evaluation studies and (2) standardize the evaluation procedure to increase cross-study comparability of symptom checkers and large language models. Because self-triage advice is arguably the most useful



XSL•FO
RenderX

information for medical laypeople, this framework focuses on self-triage accuracy as the main outcome [15].

Limitations and Challenges of Previous Methodologies

Most studies evaluating the triage accuracy of symptom checkers have criticized the existing evaluation approach for being artificial. In particular, the vignettes describe idealized, unambiguous cases, and some include scenarios for which symptom checkers would rarely be consulted (eg, recurrent aphthous stomatitis, which may be unexplainable upon first appearance but is easily recognized once experienced [16]). If the aim is to determine a triage accuracy metric that can be generalized to real-world interactions and scenarios in which symptom checkers are actually used, the inclusion of such cases in evaluations seems questionable. Apart from vignettes, current evaluation approaches have several other shortcomings that we grouped into 4 categories: generalizability, symptom input, gold standard assignment, and metrics (Figure 1). We build on these points to develop our standardized methodological evaluation framework.

Figure 1. Four categories of criticism regarding symptom checker evaluation studies.

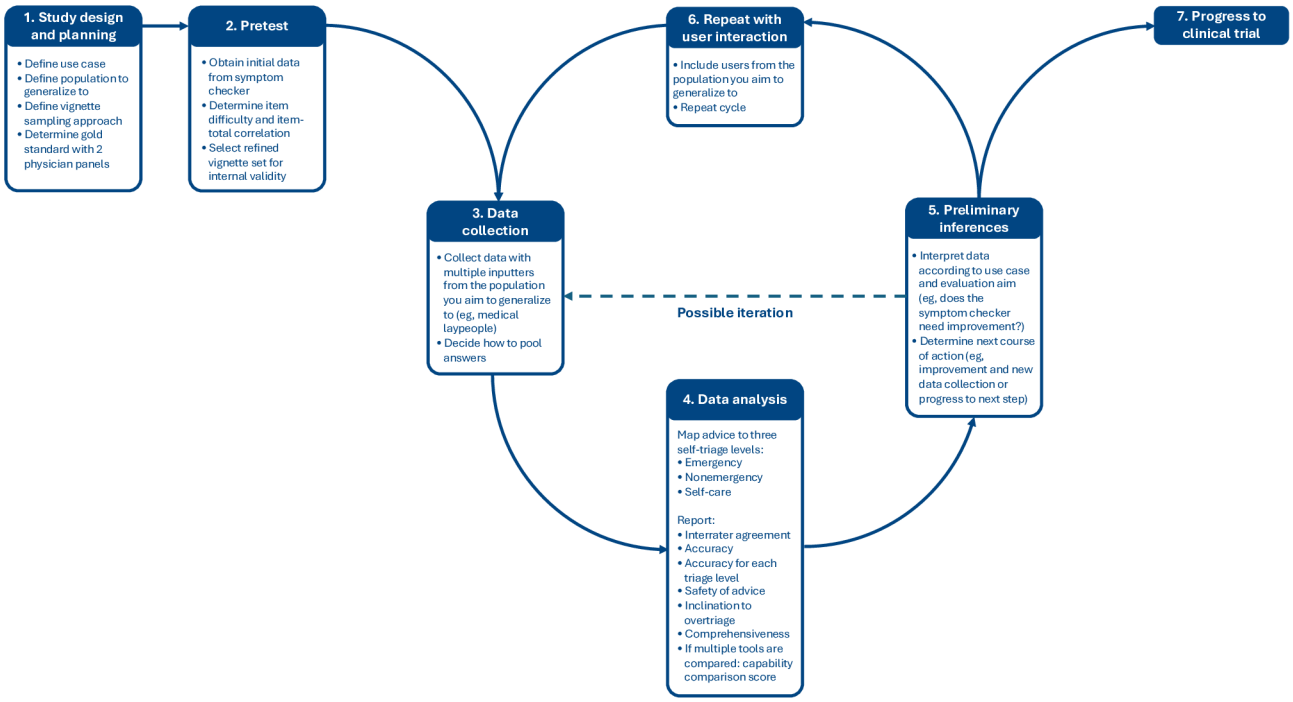
The first point concerns the generalizability of the evaluations. This includes both the vignettes and the experimental setup, which, according to ecological validity theory, should resemble real-world use cases and interactions to yield results that can be generalized [17]. Traditional vignettes have been criticized for a lack of representativeness for several reasons. First, they are often derived from medical education textbooks and are therefore artificial, not representing the unspecific concerns for which patients would use a symptom checker [10,14]. Second, these cases are mostly written post hoc by clinicians who have

XSL•FO
RenderX

access to more specialized information (eg, diagnoses, laboratory test results, and clinical examinations) than a patient consulting a symptom checker [10,13,18]. In other words, thus far, the information in existing vignettes does not reflect the types of problems actual users of symptom checkers face, and it is not clear what that information should be. Third, the cases described in the vignettes do not reflect the natural base rates of emergency or nonemergency versus self-care cases among users [10,13,14]. Fourth, there is no consensus on the number of vignettes that should be included in a vignette set or how to ensure their quality [10]. The experimental setup focuses on symptom checker accuracy and has thus been criticized for implicitly assuming that symptom checker advice directly translates into user actions, even though symptom checkers merely provide advice that users may or may not follow [19-21]. This limitation confines research to assessing only the "technical accuracy" of a symptom checker, without addressing its likely real-world impact. To determine whether technical accuracy translates into improved decision-making by users, symptom checkers ultimately need to be evaluated in user studies.

The second point concerns the procedure for inputting symptoms. Typically, a single person—who may or may not have medical expertise—enters the symptoms. Because not all information that a symptom checker might ask for is included in the vignette, the inputter must make assumptions about the case when asked about it. Thus, clinicians tend to rely on their clinical judgment and expertise, whereas laypeople—the actual users of symptom checkers—use various strategies, ranging from guessing to ignoring the questions they are asked [10,11,22]. It is also unclear how many inputters should be involved in the evaluation to yield valid performance estimates [10]. These issues suggest that the final output is highly dependent on the inputter or inputters, which creates an information bias that limits the internal validity of evaluation studies. This information bias is further compounded by the fact that different symptom checkers allow different input modalities (eg, free text, multiple-choice questions, images, or even laboratory results). These variations introduce an inherent comparability limitation, as the same case may be assessed differently depending on the input options of the tool.

The third point relates to the gold standard assignment used to assign the solution to a case vignette. Different studies use varying procedures: some use a single physician, others use multiple physicians, recordings from clinical encounters (such as telephone triage), or sometimes the authors even determine the gold standard solution themselves [10,12]. This variation not only limits the comparability between studies but also raises questions about the accuracy of the assigned gold standard in some cases.



The final point concerns the metrics used to evaluate symptom checkers. Although most studies report triage accuracy as the proportion of cases solved correctly, some also include additional metrics, such as the tendency to overtriage or undertriage and the safety of the advice [14]. The exact self-triage classifications differ between studies as well: for example, Semigran et al [1] used a 3-tiered approach including "emergencies," "nonemergencies," and "self-care cases," whereas Hill et al [2] extended this classification to include "1-day urgent cases." Furthermore, because different symptom checkers use varying classifications as well, it is unclear how their advice should be mapped to the study's triage categories (eg, whether an urgent care clinic is considered emergency or nonemergency care). These issues ultimately limit cross-study comparability.

Framework

To address these points, we developed an evaluation framework by integrating available empirical studies on methodological improvements. This framework can be found in Figure 2. It can be used for preclinical evaluations to identify symptom checkers that are likely to perform well in clinical trials and real-world evaluations. Once identified, the symptom checker should nonetheless undergo testing in a 3-phase clinical trial similar to pharmaceutical trials [23]. Hence, our framework not only standardizes vignette-based symptom checker evaluations but also makes subsequent clinical trials more cost efficient by identifying tools likely to yield positive outcomes. It can be applied both to evaluations across a broad set of cases as well as to those focusing on specific patient groups (eg, patients receiving rheumatology care), by defining the intended use case and population accordingly.

XSL•FO
RenderX

Figure 2. Integrated preclinical evaluation framework (Symptom Checker Accuracy Reporting Framework; SCARF) for evaluating the self-triage accuracy of symptom checkers and artificial intelligence–based tools.

In the beginning (part 1), evaluators should clearly define the use case they intend to examine, such as “self-triage decisions” or “emergency care decisions.” Next, they should specify the target population to which they wish to generalize. For the self-triage use case, this might include symptom checker users deciding on their next course of action. Then, they should define a vignette sampling approach, which ensures that vignettes are representative of real patient cases and accurately reflect the disease or symptom and triage prevalence relevant to the use case. For example, the approach could sample real patient cases stratified according to the prevalence of symptom types entered into symptom checkers. A systematic sampling procedure to do that is available in the RepVig framework, and for the self-triage use case, a representative vignette set is provided in the framework’s validation study [13]. At this stage, researchers should also assign a gold standard solution to each case and define how the possible outputs of a symptom checker are mapped onto these categories. According to a study by El-Osta et al [12], this should involve 2 physician panels that independently rate the cases in focus groups and resolve any disagreement through discussion until consensus is reached.

Next, evaluators should obtain initial data from some symptom checkers to refine the vignette set according to test-theoretical criteria (part 2) to ensure that vignettes are not only externally but also internally valid. This process involves calculating the item-total correlation and excluding any cases with a negative or zero item-total correlation (to ensure that only cases accurately predicting overall performance are included). Additionally, item difficulty for each vignette should be determined, and cases with an item difficulty of zero may be excluded (to ensure that vignettes add meaningful information and are not impossible to solve). However, if these cases can be solved by physicians and are clinically plausible, even items with an item difficulty of zero may be retained in the vignette set to avoid inflating performance estimates. A procedure for this is outlined in one of our previous studies [24]. The size of the final vignette set should ultimately be determined using a power analysis. However, given that entering a large number of vignettes manually may be infeasible and that there is no empirical evidence on optimal set sizes, we pragmatically recommend a minimum of 45 vignettes. This number has proven feasible and has been applied across multiple studies [1,2,13,25], as it can be developed and entered by a single evaluator within a reasonable time frame, while still providing sufficient variation for a statistical analysis.

Using the refined vignette set, data from all symptom checkers can be collected (part 3). Multiple inputters (at least 2, possibly more) should enter every case into each symptom checker and select a “not sure” option in cases of missing information. To minimize inputter variability, inputters should follow a standardized protocol. For instance, Meczner et al [11] instructed inputters to enter only the symptoms explicitly stated in the vignette, allowing synonyms or broader categories but rejecting new information not included in the vignette. Their publication provides entry instructions that can be used in future studies to standardize input procedures. Once the inputters have obtained the data, their results should then be pooled. This can be achieved using several algorithms, but the best approach appears to be a majority vote, that is, the advice most frequently given to all evaluators [11]. For example, if 2 inputters receive the advice to seek emergency care while 1 inputter receives self-care advice, the recommendation should be coded as “emergency”.

In the next step, the data analysis (part 4), evaluators should map the received advice to a multitiered classification system. To increase comparability across studies and health care systems, we suggest using a 3-tiered classification system—“emergency,” “nonemergency,” and “self-care”—to provide a common reference structure. A potential

XSL•FO
RenderX

"1-day-urgent" category could be classified as "nonemergency." At the same time, we acknowledge that some systems use more granular triage categories; therefore, we suggest conducting sensitivity analyses (eg, treating "1-day-urgent" as "emergency" or as its own category, or analyzing the full set of available tiers) to assess the stability of the results. After mapping each recommendation, evaluators should first report the interrater reliability among all inputters to identify the influence of different inputters, followed by a set of metrics: overall accuracy, accuracy for each triage level, safety of advice, inclination to overtriage, and comprehensiveness [14,26]. These metrics were identified through systematic review of previously reported metrics and can increase comparability across different studies [14,26]. If multiple symptom checkers are evaluated simultaneously, we propose additionally reporting the Capability Comparison Score (developed in a previous study) to determine how symptom checkers perform relative to each other [14,26]. To assist researchers in reporting and visualizing these metrics, the R package *symptomcheckR* is available, where the formulas for calculating all metrics are described as well [26].

In the next step, the results should be interpreted according to the defined use case, and the next course of action should be determined (part 5): if developers aim to validate their tools, they may either decide to improve their tool and test it again (by going back to step 3) using the same setting or continue with the evaluation and test the best-performing tools with users in the loop making self-triage decisions (step 6). In this phase, users should be provided with the symptom checker, and the tool's impact, instead of its "technical accuracy," should be assessed in a new evaluation with sufficient statistical power [21]. This step is included because preclinical vignette studies can only benchmark technical accuracy and do not capture whether laypeople actually make better decisions when using a symptom checker. If results of user studies are also promising, the symptom checker can then be tested in a clinical trial with real patients and their symptoms to assess whether the symptom checker advice also translates to improved decisions by users in the real world (step 7).

Open Questions

Our approach leaves several open questions for future research. First, some of the vignettes (such as the vignettes by Semigran et al [1] and our own [13]) do not include additional information for questions that symptom checkers may ask. Although some vignette sets do include additional information, there is no universal way to collect additional information. Future research could develop a method to supplement this missing information—perhaps using a hybrid approach that combines interviews with patients from whom the case vignettes were derived and synthetic artificial intelligence (AI)–generated supplementary data based on these interviews. Second, it remains unclear whether "accuracy" or a "correct" solution should be the main outcome. Perhaps a binary classification of correct versus incorrect in a task like symptom assessment that is associated with high uncertainty may be less relevant than assessing the impact of the advice—specifically, whether it is safe and appropriate for the individual and whether it increases or decreases health care demands. Third, with the introduction of large language models as an alternative to traditional symptom checkers, output variability plays an even greater role. Future research should address how to manage the variability of generated outputs when provided with identical inputs. Fourth, current evaluations do not specifically include atypical presentations. It remains unclear whether case vignettes are only suitable for typical cases or if vignette sets for atypical cases could also be developed. Although the RepVig framework could be used for developing such a vignette set again, assigning a reliable gold standard solution to atypical cases will be challenging [13]. Finally, our approach is highly tailored to a self-triage use case. Although it standardizes most aspects of an evaluation, diagnostic use cases may require additional details (such as clinical plausibility of the vignettes or a procedure to determine whether a diagnosis matches the gold standard) and outcome metrics (such as cumulative diagnostic scores [27]) that are not covered by our approach.

Outlook

The SCARF (and the corresponding checklist in Multimedia Appendix 1 and Multimedia Appendix 2) presented in this paper addresses all previously raised points of criticism and aims to improve the quality and comparability of future symptom checker evaluations. However, we acknowledge that the presented approach is more resource intensive than the traditional approach introduced by Semigran et al [1] and may not be feasible for every evaluation. To aid researchers in integrating these methods into practice, several open resources are available for the presented use case: for example, representative vignettes are openly accessible and free to use [13], a refined vignette set that satisfies test-theoretical criteria is available as well [24], and all metrics can be easily calculated using the open-source symptomcheckR package [26]. We encourage researchers to build on these resources to improve the quality of future evaluations and enhance cross-study comparability.

Conclusions

In this paper, we summarize the limitations and challenges of previous studies evaluating symptom checkers using vignettes. In recent years, several empirical studies have addressed most of these limitations individually, yet a unified methodological and reporting framework integrating these findings was missing. We present a preclinical framework and the corresponding SCARF checklist upon which future vignette-based symptom checker evaluations can build to address generalizability, input variability, gold standard assignment, and metrics, and we highlight several open access resources that evaluators can use. By adopting this approach, researchers can identify well-performing tools for more cost-efficient clinical trials and can significantly increase the quality and comparability of vignette-based symptom checker evaluation studies, thereby enabling reliable evidence syntheses. This can help move closer to assessing and improving the effectiveness of symptom checkers, diagnostic decision support systems, and large language models.

Abstract

Patient safety classification systems are fundamental to surveillance, organizational learning, research, and governance because they enable adverse events and near misses to be organized into standardized categories for comparison and analysis. However, the increasing complexity of health information technology (HIT)–related patient safety incidents challenges the assumptions underpinning conventional classification approaches, as these incidents often emerge from dynamic, distributed, and evolving sociotechnical interactions rather than discrete, time-bounded events. In this Viewpoint, I argue that many of the challenges associated with classifying HIT-related patient safety incidents arise not simply from limitations of individual classification systems but from the inherent representational logic of classification itself. By viewing classification as a knowledge practice rather than merely a technical tool for organizing incident data, I contend that abstraction, boundary-setting, and standardization inevitably simplify complex sociotechnical processes and constrain how safety problems are represented, interpreted, and acted upon. I discuss 4 recurring representational limitations that characterize the application of patient safety classification systems to HIT-related incidents: fragmentation of sociotechnical interactions, loss of temporality and evolving processes, inadequate representation of scale and propagation across systems, and normalization of "use error" through simplified attribution of responsibility. These limitations can contribute to incomplete organizational learning, misaligned safety interventions, and challenges in interpreting and comparing classified patient safety data across health care settings. Rather than arguing against the continued use of patient safety classification systems, I propose that their strengths and limitations should be recognized simultaneously. Classification remains indispensable for surveillance, learning, and governance, but it should be interpreted as one component of a broader sociotechnical understanding of patient safety. Recognizing the representational limits of classification can support more reflexive interpretation of classification-based evidence and encourage complementary approaches that better capture the complexity of HIT-related patient safety.

Introduction

Classification as Infrastructure in Patient Safety

Classification systems are foundational to patient safety research, surveillance, and institutional learning. By transforming diverse and complex safety incidents into standardized categories, classification enables aggregation, comparison, and analysis across settings and over time. These systems underpin reporting infrastructures, research studies, quality improvement initiatives, and policy conversations, while shaping how patient safety problems are recognized and addressed [1-3].

XSL•FO
RenderX

Diversity of Patient Safety Classification Approaches

Patient safety classification schemes have been developed in a variety of contexts and based on diverse design logics. The International Classification for Patient Safety (ICPS), a World Health Organization (WHO)–created framework, represents a global effort to harmonize safety terminology and incident constructs [3]. Beyond ICPS, there are classification efforts tailored to specific settings or incident types (eg, primary care safety classifications developed through the LINNAEUS [Learning in an International Network About Errors and Understanding Safety] collaboration [4] and medication error taxonomies such as the NCC MERP [National Coordinating Council for Medication Error Reporting and Prevention] taxonomy [3,5,6]). Moreover, structured frameworks, such as human factors taxonomies, provide alternative logics for organizing contributing factors associated with safety events [7-9]. These varied systems share a core commitment: to render unsafe care legible through predefined categories and relationships.

Why Health Information Technology Challenges Classification

The expansion of health information technology (HIT) into clinical work has strained conventional classification logic. HIT-related safety incidents often involve sociotechnical interactions, distributed causality, temporal processes, and emergent behaviors that are not easily reducible to discrete event types and fixed causal categories [10,11]. Although HIT-specific classification efforts (eg, adaptations of Health Information Technology Classification System (HIT-CS) and classifications that integrate technology and device issues) have attempted to capture these phenomena, persistent difficulties in representing HIT-related incidents suggest deeper epistemic limits in how classification systems encode knowledge [1,12].

Although HIT-specific and HIT-adapted classification schemes have been developed to address these challenges, recurring representational difficulties suggest that the problem may not lie solely in the design or implementation of particular frameworks [13]. For example, duplicate medication orders associated with computerized physician order entry (CPOE) systems have been reported as medication-related or HIT-related patient safety incidents, yet such classifications do not fully represent the interacting software, clinical workflow, human, and organizational factors that contributed to their occurrence [14,15].

From Classification Design to Classification Limits

Prior work on HIT-related patient safety has addressed methodological challenges in studying technology-associated incidents and articulated interpretive perspectives on HIT-related risk. Building on this foundation, the present paper shifts attention from how incidents should be classified to what classification systems, by their nature, can and cannot represent. By making these inherent limits explicit, this Viewpoint clarifies the constraints on learning from classified safety data and suggests implications for future research in HIT safety.

Perspective Presented in This Viewpoint

This Viewpoint examines the inherent limits of patient safety classification systems when applied to HIT-related incidents by considering classification as a representational practice rather than simply a technical tool. I argue that 4 recurring representational limitations help explain why patient safety classification systems struggle to adequately represent HIT-related incidents: (1) fragmentation of sociotechnical interactions, (2) loss of temporality and evolving processes, (3) inadequate representation of scale and propagation across systems, and (4) normalization of “use error” through simplified attribution of responsibility. Rather than proposing a new taxonomy or evaluating existing classification systems, this paper examines classification itself as an epistemic practice [16-19]. Importantly, sociotechnical perspectives on HIT safety are well established in the literature, and the present Viewpoint builds on this body of work by examining how classification systems interact with these broader sociotechnical perspectives.

This Viewpoint is intended for patient safety researchers, HIT researchers, patient safety classification developers, health care quality and safety professionals, and policymakers involved in the design, interpretation, and use of patient safety classification systems.

Classification as a Representational Lens: Why Taxonomies Shape Interpretation Rather Than Merely Describe Events

Classification as Knowledge Production

Patient safety classification systems are often presented as neutral tools for organizing information about adverse events and near misses. In practice, however, classification operates as a representational lens that actively shapes how safety problems are understood [1,6,20]. By defining categories and boundaries, classification systems shape what is recognized as an incident, how causality is attributed, and which dimensions of harm are foregrounded or obscured [6,20,21].

The term “system” is used in several ways throughout this paper. Specifically, it may refer to the clinical work system, the HIT system, the incident-reporting system, or the patient safety classification system. Unless otherwise specified, this perspective focuses on classification systems as representational frameworks while recognizing their interaction with broader sociotechnical and reporting systems.

Abstraction and Standardization

At a fundamental level, all classification systems rely on abstraction and standardization. Classification makes complex phenomena easier to analyze by reducing them to predefined units. These units may include event types, contributing factors, or outcomes that can be applied consistently across cases. This abstraction enables aggregation and comparison across cases, supporting patient safety surveillance and learning. At the same time, abstraction necessarily compresses detail, strips away contextual nuance, and stabilizes fluid processes into discrete representational forms [21-23].

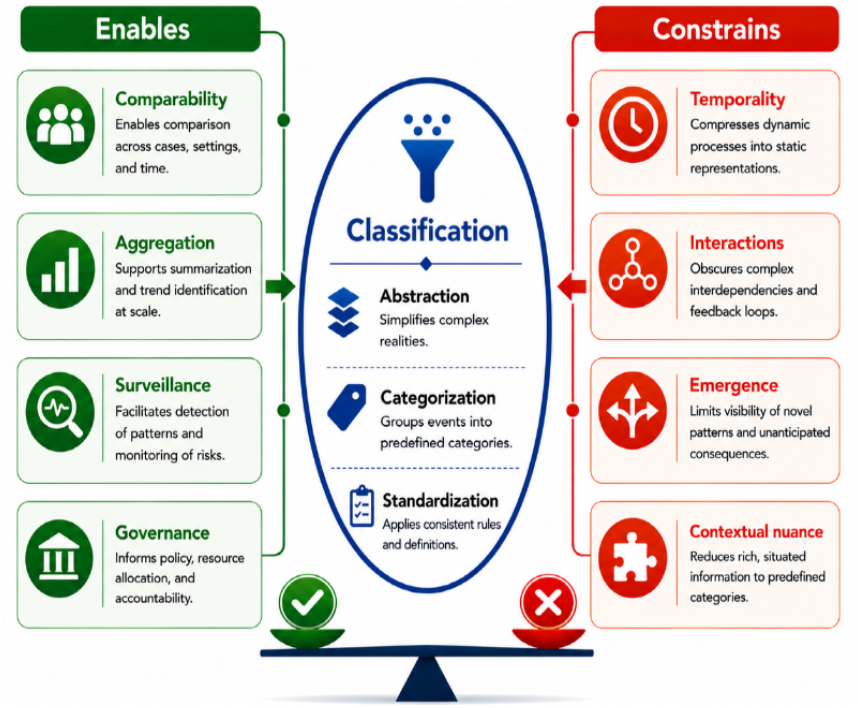
XSL•FO
RenderX

Boundary-Setting and Assumptions About Causality

Classification systems also impose boundaries. They delineate what counts as an "incident," what falls within the scope of patient safety, and where responsibility or causation is presumed to reside. These boundaries are embedded in category definitions, hierarchies, and exclusion criteria [21-24].

Classification, Sensemaking, and Governance

Classification influences not only data organization but also sensemaking and governance. Classified data travel across organizational and institutional contexts, informing research syntheses, quality improvement initiatives, and policy decisions [25,26]. As categories are reused and institutionalized, they can stabilize particular narratives about safety problems while marginalizing others. Over time, this can create feedback loops in which certain types of incidents are repeatedly recognized and addressed, while others remain poorly articulated or invisible [25,27,28].



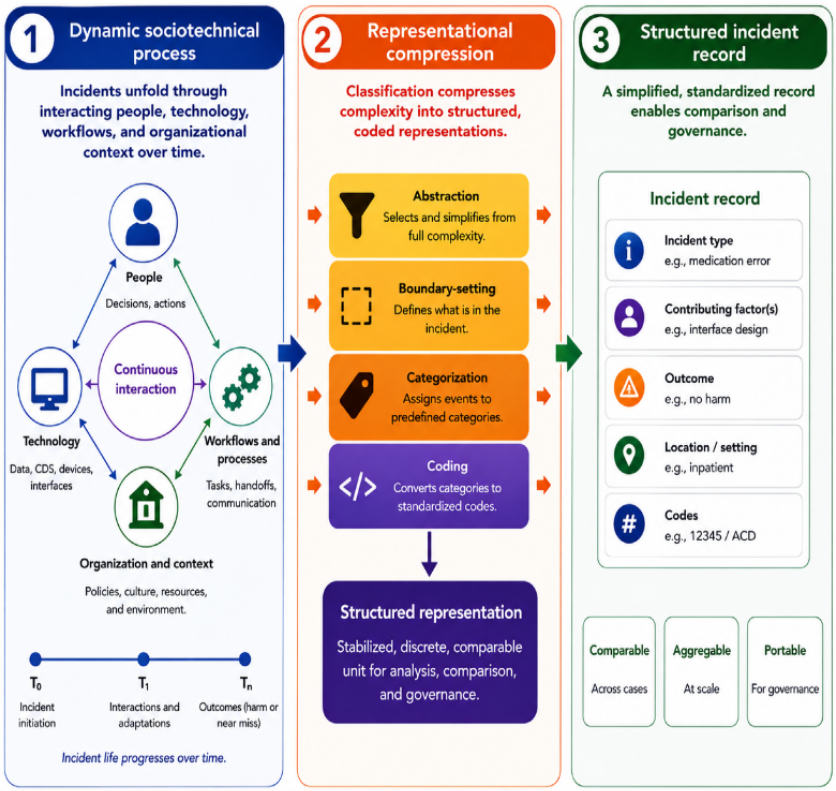
Inherent Limits of Classificatory Work

These characteristics of classification, including abstraction, boundary-setting, and stabilization, are not flaws but constitutive features of classificatory work. As such, they introduce limits that cannot be fully eliminated through refinement or expansion of taxonomies [23,25]. Adding categories, increasing granularity, or tailoring classifications to specific domains may improve representation of particular incident features. However, these refinements do not overcome the underlying logic of classification, which continues to stabilize complex sociotechnical processes into discrete, comparable categories [28]. Instead, they redistribute rather than eliminate representational constraints [27].

In this paper, the term epistemic limits refers to constraints that originate from the fundamental logic of classification itself. These limits differ from design trade-offs, methodological limitations, or pragmatic constraints associated with reporting systems. Design trade-offs involve decisions about how a classification system is constructed or executed, while methodological limitations stem from analytic techniques or data availability. Pragmatic constraints reflect the institutional or operational needs of incident-reporting systems. In contrast, epistemic limits arise from the core features of classification as a knowledge practice, especially abstraction, boundary-setting, and stabilization, which inevitably convert complex, evolving sociotechnical processes into discrete, comparable categories. These limits, therefore, endure across various taxonomies and implementation settings. Figure 1 illustrates the representational trade-offs inherent in patient safety classification. The same structural properties that enable standardized reporting and organizational learning also constrain the representation of complex sociotechnical processes.

Figure 1 illustrates how abstraction, categorization, and standardization simultaneously enable organizational learning while constraining the representation of complex sociotechnical processes.

Figure 1. Representational trade-offs in patient safety classification.



Implications for a Sociotechnical Perspective on Patient Safety

Understanding classification as a representational lens is essential for examining patient safety in complex sociotechnical settings. In such contexts, the tension between the need for standardized representation and the reality of distributed, evolving processes becomes particularly pronounced [18,29,30]. Figure 2 illustrates representational compression in patient safety classification, whereby complex sociotechnical processes are transformed into discrete, standardized incident representations that support recording, categorization, comparison, and analysis.

XSL•FO
RenderX

Taken together, Figure 2 illustrates the core argument of this paper: the difficulties encountered in applying patient safety classification systems to HIT-related incidents arise from fundamental properties of classification itself. By converting evolving sociotechnical processes into discrete, stabilized representations, classification simultaneously enables learning at scale and imposes limits on what can be known, compared, and acted upon.

Figure 2. Representational compression in patient safety classification. CDS: clinical decision support; EHR: electronic health record.

Overview of Patient Safety Classification Approaches Relevant to HIT

Illustrative Classification Traditions and Design Logics

Patient safety classification systems have been developed across diverse institutional, clinical, and analytic contexts. Although they differ in scope, purpose, and intended users, they share common representational commitments, relying on categorization, abstraction, and standardization to render safety incidents legible for analysis, comparison, and organizational learning [20,30,31]. The following examples illustrate how these shared design logics shape the representation of HIT-related safety problems.

Global and General Patient Safety Frameworks

Global patient safety classification efforts aim to establish common conceptual foundations across health care systems. The ICPS was developed to harmonize terminology and incident constructs internationally [23,32,33].

Such frameworks are deliberately generic, prioritizing breadth and interoperability over contextual specificity. Consequently, they typically conceptualize safety incidents as discrete events that can be decomposed into causal elements and outcomes. Although this design supports aggregation and high-level analysis, it also embeds assumptions about temporality, agency, and system boundaries that become consequential when applied to complex sociotechnical phenomena [1,23,32,33].

Reporting-Oriented Classification Systems

Many patient safety classifications are embedded in incident-reporting infrastructures and shaped by practical requirements for data collection, aggregation, and governance. In the United States, the Agency for Healthcare Research and Quality (AHRQ) Common Formats provide standardized categories for reporting adverse events, near misses, and unsafe conditions across care settings [25,34].

Reporting-oriented systems often emphasize clarity, usability, and consistency, favoring predefined categories that frontline reporters can apply. HIT-related issues are typically incorporated as contributing factors or device-related elements rather than as evolving sociotechnical processes [1,25,34].

Domain-Specific and Error-Focused Taxonomies

Some classification systems focus on specific clinical domains or types of harm, such as medication safety. The taxonomy developed by the NCC MERP categorizes medication errors by the stages of the medication-use process and the severity of patient harm [1,5].

Although not specifically designed for HIT, such systems are frequently used for incidents involving electronic prescribing, decision support, and medication administration technologies. In doing so, they often normalize distinctions between “use

XSL•FO
RenderX

error" and system malfunction, reflecting broader classificatory tendencies to localize error within identifiable actions rather than within distributed interactions [3,5].

HIT-Specific and HIT-Adapted Classification Schemes

In response to growing recognition of technology-related risk, HIT-specific classification schemes have been developed to capture incidents involving electronic health records, clinical decision support, and other digital tools. These systems typically expand contributing-factor categories to include software design, interface issues, workflow mismatches, and organizational context. They are often explicitly informed by sociotechnical perspectives [10,35-37].

Despite this specialization, HIT-focused classifications retain core classificatory features shared with broader patient safety taxonomies. Incidents are still represented as bounded events, categorized according to predefined dimensions, and analyzed through stabilized causal structures. Consequently, these systems illuminate how far domain-specific adaptation can go without escaping the underlying logic of classification [10,18,38].

Recently, classification systems have incorporated more detailed categories, mechanisms for linking related events, and structured narrative components to better capture temporal dynamics and sociotechnical interactions [39,40]. Although these developments improve representation, they do not overcome the representational limitations inherent in classification as a mode of organizing patient safety information.

Local and Adapted Classification Approaches

Beyond formal frameworks, many health care organizations and research teams develop local or adapted classification schemes to address perceived gaps in existing systems. These may involve extending categories, reinterpreting definitions, or combining elements from multiple frameworks [6,13,20,41].

The proliferation of adapted schemes underscores both the flexibility and the limits of classification. Efforts to tailor systems to local sociotechnical realities frequently reintroduce familiar representational challenges, suggesting that these challenges are not confined to particular taxonomies but arise from shared classificatory commitments [6,22,35,36].

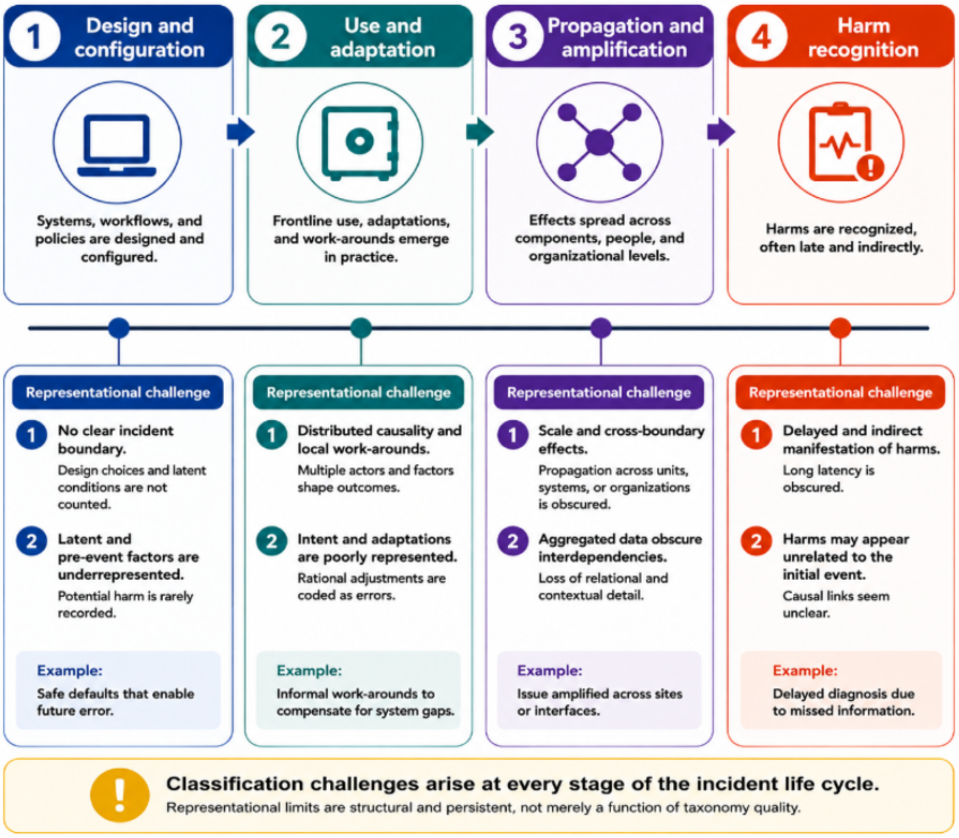
Table 1 summarizes the illustrative classification design logics discussed in this section and highlights the shared representational commitments that shape the rendering of HIT-related safety problems.

Table 1. Illustrative classification design logics and their representational commitments.

Classification design logic	Primary unit of analysis	Assumptions about causality	Treatment of temporality	Typical handling of HIT[a]
Global patient safety frameworks	Discrete incident	Linear or decomposable	Event-based	Contributing factor
Reporting-oriented systems	Reportable event	Action- or device-linked	Snapshot at report time	Embedded category
Domain-specific taxonomies	Process step or error	Localized failure	Stage-based	Use error or malfunction
HIT-specific schemes	Incident with technical context	Sociotechnical (bounded)	Limited process capture	Expanded factors

[a]HIT: health information technology.

Why Classification Struggles to Represent HIT-Related Incidents



Overview

Patient safety classification systems vary in scope, purpose, and design. However, when applied to HIT-related incidents, they often encounter similar representational difficulties. These difficulties do not arise primarily from isolated design choices or implementation failures. Instead, they reflect recurrent representational tensions that emerge from the structural logic of classification itself [1,18].

To illustrate the representational challenges discussed in this section, consider a simplified example involving a duplicate medication order generated through CPOE [14]. A physician enters a medication order, but due to interface design and workflow constraints, the system allows the same order to be entered twice. The duplicate order is later detected and corrected before it can cause harm. Depending on the classification system used, this incident might be coded as a medication error, a user-entry mistake, a workflow issue, or a software design problem [14,42,43]. Figure 3 illustrates where patient safety classification systems encounter recurring representational challenges across the life cycle of HIT-related incidents, from system design and clinical use to propagation and recognition of harm.

XSL•FO
RenderX

Figure 3. Representational challenges across the life cycle of health information technology–related incidents.

Fragmentation of Sociotechnical Interactions

HIT-related safety incidents typically emerge from interactions among multiple system components, including software functionality, clinical workflows, organizational routines, and professional judgment. Classification systems, however, require incidents to be decomposed into discrete elements, such as event types, contributing factors, or actor roles, to render them categorizable [18,44]. In the CPOE duplicate-order example described previously, the incident could be attributed to user error, interface design, or workflow conditions, depending on the classificatory structure, illustrating how sociotechnical interactions become fragmented across multiple categories [14,42,43].

This decomposition breaks sociotechnical interactions into separate components. Consequently, the relational dynamics through which risk emerges may become less visible. Interdependencies between technology and practice are often redistributed across multiple categories, weakening the visibility of interaction effects. Consequently, the classified representation may suggest a set of parallel contributing factors rather than a coupled sociotechnical process [45,46].

This fragmentation is not an error of representation but a consequence of classificatory abstraction. Classification systems are designed to isolate elements that can be consistently named and compared, even when the phenomena of interest are fundamentally relational. For HIT-related incidents, this leads to representations that understate the role of interaction and overstate the independence of contributing components [18,26,46].

Loss of Temporality and Process

Many HIT-related safety problems unfold over extended periods. Design decisions made during system configuration may interact with evolving patterns of use, work-arounds, and adaptation before contributing to harm that becomes apparent only much later. Classification systems, however, typically represent incidents as temporally bounded events, anchored to a moment of recognition or reporting [15,46,47]. In the duplicate-order example, the classification record may capture the moment the error was detected, while the preceding sequence of interface interactions and workflow adaptations that enabled the duplication remains largely invisible [14,42,43].

This event-based representation collapses trajectories into snapshots. Temporal sequencing, latency, and cumulative effects are difficult to encode within categorical structures that privilege discrete occurrences. Even when temporal fields are included, they rarely capture how risks develop, propagate, and transform over time [47].

The loss of temporality limits classification systems' ability to represent HIT-related incidents as processes rather than outcomes. Consequently, downstream analysis may focus on proximal events while obscuring the longer-term dynamics through which sociotechnical risk accumulates [15,47].

Several patient safety classification systems have attempted to address these issues by introducing mechanisms intended to capture temporal and relational dynamics [48,49]. Although these features improve representation, they do not eliminate the underlying constraint that classification ultimately requires incidents to be stabilized into discrete, comparable categories.

XSL•FO
RenderX

Poor Handling of Scale and Propagation

HIT-related incidents frequently propagate beyond the local context in which they originate. A configuration error, interface design issue, or workflow mismatch may affect multiple users, units, or care settings, with effects that scale unevenly and interact with local practices [46,47]. If similar configurations or interface conditions exist across multiple clinical units, duplicate orders may recur, yet classification systems may record them as independent incidents rather than manifestations of a shared systemic issue [12,50].

Classification systems, however, are typically organized around localized incident units. They privilege representations that tie incidents to specific locations, actors, or moments, making it difficult to capture cross-boundary propagation or system-wide effects. When scale is represented, it is often treated as an attribute of individual incidents rather than as a dynamic property of sociotechnical systems [1,51].

This mismatch between localized incident units and distributed effects constrains the conceptual reach of classification-based data. Propagation is rendered as repetition rather than as a feature of system structure, limiting insight into how HIT-related risks amplify across contexts [46,47].

Normalization of "Use Error"

A recurrent feature of patient safety classification systems is the distinction between technical failure and human or "use" error. In HIT contexts, this distinction often becomes a default mode of representation, particularly when classification categories prioritize observable user actions over design-use coupling [11,52,53].

By treating "use error" as a categorical outcome, classification systems may normalize interpretations that assign responsibility to individual behavior, even when user actions are shaped by interface design, workflow constraints, or organizational pressures. Over time, this can reinforce a conceptual framework that treats sociotechnical misalignment as user deviation rather than as a property of system design [10,11,52].

This normalization effect does not require explicit attribution of blame. It emerges from the repeated use of categories that foreground action over interaction and outcome over process. As such, it reflects a deeper classificatory tendency to individualize causality in contexts where agency is distributed [1,38,51].

Representational Limitations Are Structural, Not System-Specific

Taken together, these breakdowns illustrate that the difficulties classification systems encounter with HIT-related incidents are not confined to particular taxonomies or domains. Fragmentation, loss of temporality, scale mismatch, and normalization of use error recur across classification approaches precisely because they arise from shared classificatory commitments [54,55].

Efforts to address these issues through increased granularity or domain-specific adaptation may shift how representational limitations appear, but they do not eliminate the underlying tension between standardized representation and sociotechnical complexity [1,38,51].

The increasing use of large language models (LLMs) and natural language processing (NLP) for analyzing unstructured patient safety reports does not fundamentally eliminate the epistemic limits discussed in this Viewpoint. Although these technologies may improve the extraction, organization, and classification of information from free-text narratives, they ultimately produce structured representations that remain subject to abstraction, boundary-setting, and representational compression [40,54,56]. Consequently, automated text classification may enhance the efficiency and consistency of incident analysis, but it does not overcome the inherent limits of classification as a knowledge practice. Instead, it may automate and scale the same structural constraints that shape how complex sociotechnical incidents are represented and interpreted.

Table 2 summarizes the 4 recurring representational limitations discussed in this Viewpoint and their implications for the classification of HIT-related incidents.

Table 2. Recurring representational limitations in classifying health information technology–related incidents.

Representational limitations	What is lost or distorted?	Why does classification produce this limit?
Sociotechnical fragmentation	Interactions and dependencies	Forced attribution to components
Loss of temporality	Incident trajectories	Event-based representation
Scale and propagation	System-wide effects	Localized incident units
Normalization of use error	Design-use coupling	Person-centered categories

Consequences for Research and Practice

Overview

The representational constraints described in the previous section have important consequences for how patient safety data are interpreted, compared, and acted upon in both research and practice [1,57].

Classification-based incident data rarely function as the sole basis for safety improvement. Instead, they typically serve as starting points for root cause analysis, sociotechnical assessment, and organizational learning. In HIT, these investigations are often informed by sociotechnical frameworks such as the SAFER (Safety Assurance Factors for Electronic Health Record Resilience) Guides and related evaluation methods for electronic health record safety [18,56,58].

Misleading Learning and Partial Explanations

Classification systems support learning by enabling aggregation and comparison across incidents. However, when HIT-related

XSL•FO
RenderX

safety problems are represented as fragmented, temporally bounded events, the resulting learning may be partial or misleading. Aggregated patterns can obscure the sociotechnical interactions and trajectories through which harm emerges, encouraging interpretations that privilege proximal causes over longer-term or distributed dynamics [1,25,57]. When such interactions are flattened into discrete categories, learning may focus on symptoms rather than on the structural conditions that shape risk [1,25,57].

Misaligned Interventions and Corrective Actions

The way incidents are classified influences not only interpretation but also intervention. When classified representations foreground individual actions or isolated failures, they can channel responses toward training, compliance, or local fixes, even when underlying issues are rooted in system design or organizational structure [30,47].

In HIT contexts, interventions derived from classification-based analyses may therefore focus on user behavior while leaving design-use mismatches or workflow constraints unaddressed. Over time, this can lead to repeated corrective efforts that fail to engage with the sources of sociotechnical risk, reinforcing cycles of reporting without commensurate improvement [30,46].

Comparability Problems Across Studies and Settings

One of the primary motivations for classification is to enable comparability across studies, organizations, and jurisdictions. However, when HIT-related incidents are forced into stabilized categories that inadequately capture sociotechnical complexity, apparent comparability may mask substantive differences in how incidents unfold across contexts [22,33].

Differences in local workflows, system configurations, and organizational practices can lead to divergent interpretations of similar classified categories. Consequently, studies drawing on classified incident data may appear comparable at the level of codes while differing substantially in what those codes represent in practice. This complicates synthesis across studies and limits the interpretability of comparative findings in HIT-related patient safety research [22,23,45].

Consequences as Structural, Not Correctable by Refinement

Taken together, these consequences indicate that the challenges associated with classifying HIT-related incidents are structural rather than contingent. Although greater granularity, additional categories, and domain-specific adaptations may improve representation, they do not eliminate the fundamental trade-offs inherent in classification-based representation [18,22].

Recognizing these consequences is not an argument against classification but a call for interpretive caution. Classification systems remain indispensable for surveillance, aggregation, and governance, yet their outputs should be understood as partial representations shaped by underlying design logics. Without this perspective, classification-based knowledge may be overextended beyond its representational limits [18,22].

Implications for Future Research and Interpretation

Overview

Recognizing the structural limits of classification systems has important implications for how future analyses of HIT-related patient safety are conceptualized and interpreted. These implications are particularly relevant for researchers analyzing patient safety datasets, HIT safety specialists interpreting incident reports, and health care organizations using classification-based data to guide quality improvement or governance activities [1]. Rather than seeking a single, more comprehensive classification framework, future research may benefit from approaches that explicitly acknowledge the partial and situated nature of classificatory representations [25,59]. Classification systems are best viewed as one part of a larger safety analysis ecosystem rather than as complete representations of complex sociotechnical events.

Why No Single Framework Is Sufficient

The recurrent representational constraints discussed in this Viewpoint suggest that no single classification framework can fully capture the complexity of HIT-related safety incidents. Sociotechnical phenomena are characterized by interaction, emergence, and temporal evolution, whereas classification systems necessarily stabilize phenomena into bounded, comparable units. This tension cannot be resolved through additional categories or greater granularity alone [1,51,60]. Consequently, classification-based data should be interpreted as partial representations of complex sociotechnical processes. Although such data remain essential for identifying patterns of harm, prioritizing interventions, and comparing safety performance across settings, they should be interpreted alongside complementary approaches that preserve temporal, organizational, and sociotechnical context.

Efforts to design more inclusive or detailed taxonomies may improve the visibility of certain dimensions of risk, but they simultaneously introduce new boundary problems and interpretive constraints. Consequently, attempts to “solve” classificatory limitations by expanding the framework risk reproducing the same representational trade-offs in different forms. These observations suggest the value of a more reflexive interpretation of classification-based safety data, particularly in sociotechnical contexts [1,51,60]. Recognizing the limits of classification can help analysts interpret incident data more cautiously, particularly when drawing conclusions about causality, system-level risk, or the effectiveness of interventions.

The Need for Reflexive Use of Classification Data

Future patient safety analyses that rely on classified incident data should adopt a reflexive stance toward the categories they use. Rather than treating classifications as transparent representations of underlying events, analysts should consider how category definitions, incident boundaries, and causal structures shape what becomes visible and actionable [18,51]. Without this reflexive orientation, there is a risk that classification outputs will be overinterpreted as direct reflections of sociotechnical reality [26,45,60].

XSL•FO
RenderX

Layered and Complementary Analytic Perspectives

Given the limits of any single representational approach, future research on HIT-related patient safety may benefit from layered perspectives that combine classification-based data with complementary approaches. These may include qualitative inquiry, sociotechnical modeling, process tracing, or narrative analysis, each of which foregrounds dimensions of interaction, temporality, context, and emergence that classification tends to suppress [1,51,61].

Classification systems may remain central for surveillance and aggregation, while complementary approaches are used to explore interaction, temporality, and emergence. Together, these perspectives can support a more nuanced understanding of sociotechnical risk without relying on a single conceptual framework [1,51,61].

From Representational Limits to Analytic Awareness

The implications of this Viewpoint are not methodological prescriptions but a call for more reflexive interpretation of classification-based evidence. By making the representational limits of classification explicit, future research can better align its interpretations and inferences with what classification-based data can reasonably support. This awareness can help prevent overgeneralization, misplaced attribution, and premature conclusions about causality or the effectiveness of interventions [1,51,62].

Treating classification as one analytic lens among many, rather than as a definitive account of safety, may enable more responsible and context-sensitive interpretations of HIT-related patient safety data [1,51,62].

Discussion

Patient safety classification systems have become indispensable for surveillance, organizational learning, research, and governance because they provide a standardized means of organizing complex safety information. However, I argue that their value should not obscure an important limitation: classification is not simply a neutral mechanism for recording events but a representational practice that shapes how safety problems are perceived, interpreted, and addressed [13,51]. This distinction is particularly important for HIT-related patient safety incidents, which emerge through dynamic interactions among technologies, clinical workflows, organizational contexts, and human decision-making rather than as discrete, isolated events [35,36].

From this perspective, the recurring representational limitations discussed in this Viewpoint should not be understood as shortcomings of particular classification systems or reporting infrastructures. Rather, they reflect the inherent logic of classification itself. Processes such as abstraction, boundary-setting, and standardization make comparison and aggregation possible, but they also simplify the complexity of sociotechnical systems. Consequently, aspects of HIT-related incidents, including evolving interactions, temporal dynamics, distributed causation, and contextual influences, may be compressed or excluded during classification. These trade-offs are intrinsic to representational systems and cannot be eliminated solely by developing more detailed or domain-specific taxonomies.

Recognizing these representational limits has important implications for patient safety research and practice. Classification-based datasets are often interpreted as comprehensive accounts of safety events and are subsequently used to inform organizational learning, quality improvement, policy development, and regulatory decision-making. However, when classified data are treated as complete representations of underlying events, they may support only a partial understanding of complex safety problems. This can contribute to interventions that address visible categories of harm while overlooking the sociotechnical conditions that produced them, and it may complicate comparisons across organizations and health care settings where contextual factors differ substantially.

My argument is therefore not that patient safety classification systems should be replaced or that more comprehensive classification schemes will fully resolve these challenges. Greater granularity and HIT-specific refinement can undoubtedly improve representation, but they cannot eliminate the fundamental trade-offs inherent in any attempt to translate complex, evolving practices into stable categories. Instead, classification should be understood as one conceptual perspective among several, with its outputs interpreted alongside complementary approaches that preserve temporal, organizational, and sociotechnical context.

Although this Viewpoint focuses on HIT-related patient safety, the underlying argument extends more broadly to contemporary health care. As digital technologies become increasingly embedded within clinical practice and health systems continue to rely on standardized data infrastructures for surveillance, benchmarking, accountability, and learning, similar representational tensions are likely to emerge wherever complex practices are reduced to standardized forms of knowledge. Appreciating these tensions is therefore essential not only for interpreting patient safety data but also for understanding the broader strengths and limitations of data-driven governance in health care.

The contribution of this Viewpoint is not to advocate for another patient safety classification framework. Rather, it is to clarify the epistemic boundaries within which classification-based patient safety data should be interpreted. By making the limits of classification explicit, I encourage a more reflexive use of classification systems that acknowledges both their indispensable role in surveillance, organizational learning, and governance and their inability to fully capture the complexity of HIT-related patient safety. Such an approach supports a more balanced interpretation of classification-based evidence and reinforces the importance of combining standardized classification with complementary sociotechnical perspectives when investigating, learning from, and responding to digital health safety incidents.

Conclusions

This Viewpoint argues that patient safety classification systems are indispensable for organizing, interpreting, and learning from adverse events and near misses. However, when applied to

XSL•FO
RenderX

HIT-related incidents, they encounter recurring representational limitations that cannot be fully overcome through refinement or domain-specific adaptation. These limitations arise from the inherent properties of classification itself (ie, abstraction, boundary-setting, and stabilization), which transform dynamic sociotechnical processes into stable, comparable categories.

Viewing classification as a representational lens, rather than as a neutral container of safety information, helps explain why fragmentation of sociotechnical interactions, loss of temporality, inadequate representation of scale and propagation, and normalization of use error recur across different classificatory traditions. These limitations are not shortcomings of individual classification systems but predictable consequences of representing complex, evolving sociotechnical phenomena through standardized categories.

The contribution of this Viewpoint is not to advocate for another classification framework but to clarify the epistemic boundaries within which classification-based patient safety data should be interpreted. Recognizing both the strengths and the representational limits of classification supports a more reflexive use of classification-based evidence while reinforcing the indispensable role of classification systems in surveillance, organizational learning, research, and governance.

Acknowledgments

The author would like to thank colleagues and health care professionals whose prior discussions and insights into health information technology–related patient safety informed the development of this Viewpoint. During the preparation of this manuscript, the author used ChatGPT (GPT-5.5; OpenAI) to assist with language refinement, editing, and improving the clarity and readability of the manuscript. The author takes full responsibility for the content of the manuscript and has reviewed and verified all outputs generated by the AI tool.

Data Availability

No new data were generated or analyzed in this study. This Viewpoint paper is informed by previously published studies and the author's prior research. As such, data sharing is not applicable.

Funding

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Authors' Contributions

The author was solely responsible for the conception, conceptual development, literature review and synthesis, and writing of the manuscript.

Abstract

Background: Opioids account for 76% of drug overdose deaths in the United States, with nearly 80,000 opioid overdose deaths annually. The risk of overdose is dynamic and influenced by rapidly changing behaviors and contexts that are not well captured by retrospective or infrequent assessments. Ecological momentary assessment (EMA) allows repeated near real-time reporting of behaviors and experiences in natural settings.

Objective: This study evaluated the feasibility and acceptability of smartphone-based EMA among people who use opioids to monitor opioid use, overdose experiences, and naloxone access.

Methods: Participants were recruited through the New Haven Syringe Services Program in New Haven, Connecticut, and completed fixed-time, twice-daily EMA prompts for 30 days using a smartphone app. EMA measures assessed behaviors and experiences occurring within the previous 12 hours, including opioid craving, plans to use drugs, opioid use, overdose experiences, and naloxone access. Feasibility was assessed through recruitment, retention, and EMA completion rates, as well as the reporting of drug use-related behaviors. Acceptability was evaluated using exit surveys assessing ease of use, burden, and privacy, as well as qualitative interviews.

Results: Of the 13 screened individuals, 10 were enrolled and completed the baseline assessment. A total of 9 (90%) participants completed EMA and responded to 411 prompts, with an overall compliance rate of a mean of 85.0% (SD 8.7%). Compliance was similar across morning (84.2%, SD 13.1%) and evening (85.8%, SD 11.2%) prompts. Participants reported opioid cravings (274 reports), plans to use illicit drugs (252 reports), and opioid use (411 reports) during the study period. Two participants reported overdose events (5 reports) and were carrying naloxone during each overdose event. Acceptability ratings were high: all participants reported that EMA prompts were easy to understand and private, and most did not find them burdensome. Qualitative feedback further highlighted the ease of use, integration into daily routines, and increased self-awareness, although some participants reported emotional discomfort when reflecting on their substance use.

Conclusions: Smartphone-based EMA was feasible and acceptable among people who use opioids recruited through a syringe service program. EMA may support the monitoring of opioid use, overdose experiences, and naloxone access, and it may inform future digital health interventions aimed at reducing harm, including overdose risk, among people who use opioids.

KEYWORDS

ecological momentary assessment; opioid overdose; naloxone; harm reduction; syringe service programs; substance use; mobile health

Introduction

Opioid overdose remains a major public health challenge in the United States, with a high overdose mortality rate [1,2]. In 2023, more than 72,000 opioid-involved overdose deaths were reported, largely involving illegally manufactured fentanyl [3], and an estimated 5.6 million individuals aged 12 years or older met the criteria for opioid use disorder [4]. Although evidence-based treatments and harm-reduction strategies, such as expanded access to medications for opioid use disorder and

XSL•FO
RenderX

syringe service programs (SSPs), have expanded [5,6], overdose risk remains high.

People who use opioids often experience fluctuations in drug use, craving, affective states, and contextual exposures, which can influence when and how overdoses occur [7,8]. Prior research has identified factors such as polysubstance use, reduced tolerance, environmental context, and the need for assistance with injections as contributors to overdose risk. Structural and psychosocial vulnerabilities, including homelessness, incarceration, unemployment, psychiatric comorbidity, and suicidal ideation or behavior, have also been linked to increased overdose risk [9,10]. However, most evidence has relied on retrospective self-reports or infrequent clinical assessments [9,11]. These approaches have limited ability to capture the dynamic and context-dependent nature of overdose risk in daily life among people who use opioids, many of whom experience unstable housing [12], unemployment [13], and inconsistent engagement with health care, including early treatment drop-out [14,15]. As a result, clinic-based assessments may not adequately reflect the dynamic conditions and circumstances under which opioid use and overdose events occur.

Ecological momentary assessment (EMA) provides one approach to address this limitation [16,17]. EMA involves collecting repeated self-reports of behaviors and experiences over short time intervals in natural settings as individuals go about their daily lives, thereby reducing recall bias and improving ecological validity [18,19]. Previous research has shown high levels of smartphone access, device ownership, and digital literacy among people who use opioids, including individuals experiencing housing instability, and that EMA has been successfully implemented among these populations [18,20-22]. However, existing EMA studies among this population have primarily focused on momentary predictors of drug use, such as craving, mood, and stress [17,18,23]. Less attention has been given to the use of EMA to monitor overdose-related experiences and naloxone availability and use, and gaps remain regarding the feasibility and acceptability of EMA protocols in populations facing significant social and structural vulnerabilities, such as people who use opioids.

To address these gaps, this pilot study evaluated the feasibility and acceptability of a smartphone-based EMA protocol for people who use opioids for monitoring opioid use, overdose experiences, and naloxone access in daily life. Feasibility was assessed through recruitment, retention, and EMA completion rates, whereas acceptability was assessed through poststudy surveys and qualitative exit interviews. The EMA protocol was designed to capture day-to-day opioid-related experiences and behaviors, including craving, opioid use, overdose experiences, and naloxone access and use through fixed twice-daily EMA prompts. The findings of this study are intended to inform the design and implementation of future EMA-based research and digital interventions targeting opioid use and overdose risk.

Methods

Study Design and Setting

The Smartphone Health Innovation Program was a prospective, observational pilot study that evaluated the feasibility and acceptability of repeated smartphone-based EMA among people who use opioids. The study was conducted in New Haven, Connecticut, at the New Haven Syringe Services Program (NHSSP). The NHSSP is a community harm-reduction program that provides sterile syringe exchange, hygiene supplies, overdose-prevention education, naloxone distribution, and referrals to medical and substance-use treatment services for people who use opioids. Participants were followed for 30 days and completed an in-person baseline visit, a 30-day EMA monitoring period, a structured support check-in approximately 7 days after enrollment, and an end-of-study visit with a qualitative interview.

Recruitment, Eligibility, and Enrollment

Participants were recruited using convenience sampling through flyers posted at the NHSSP and surrounding community locations, word-of-mouth referrals, and referrals from local service organizations in the New Haven area (including treatment and harm-reduction programs, such as the APT Foundation, Inc). Potential participants either approached research staff while visiting the NHSSP for services (eg, syringe exchange visits) or contacted the study team by phone. Eligibility screening was conducted in person at the NHSSP or by telephone. Participants were eligible if they met the following criteria: (1) were aged 18 years or older, (2) reported use of at least one illicit opioid (eg, heroin and fentanyl) within the past 30 days, (3) owned a personal smartphone compatible with the study app (Android or iOS), and (4) resided in the Greater New Haven area.

Eligible participants attended an in-person enrollment visit at the NHSSP. Trained research assistants confirmed eligibility and obtained written informed consent in a private office. Participants then completed baseline questionnaires and onboarding procedures during the same visit. The enrollment and onboarding visit lasted approximately 30 minutes. Baseline questionnaires were administered electronically on a tablet and were primarily self-administered. Research staff read questions aloud and assisted participants when literacy or comprehension barriers were present. Participants were enrolled between November 2024 and February 2025. They completed 30 days of EMA monitoring following enrollment, and end-of-study assessments were conducted between January 2025 and March 2025.

Study Procedures

EMA Protocol Development

EMA prompts were developed based on prior EMA research among people who use substances and were informed by the existing literature on overdose, opioid use, and harm-reduction behaviors [18,23]. The study team and community partners reviewed the prompts to ensure their relevance and appropriateness for the study population and setting.

XSL•FO
RenderX

EMA Monitoring

EMA was conducted using the mEMA app from Ilumivu, a platform designed for smartphone-based EMA studies. Participants received 2 fixed-time-based EMA prompts per day between 9 AM and 10 PM for 30 consecutive days (60 scheduled assessments) on their smartphones. Participants selected their preferred morning and evening times. The prompts were scheduled approximately 12 hours apart to capture nonoverlapping recall periods. This design was selected to support feasibility and engagement by reducing participant burden and allowing integration of EMA into their daily routines [24]. Each EMA remained active for 120 minutes. If unanswered, automated reminders were sent every 30 minutes (a maximum of 4 reminders) for each survey. After 120 minutes, the prompts expired. EMA prompts were brief and required approximately 1 to 2 minutes to complete. Research staff periodically reviewed incoming responses to ensure that prompts were received and completed and to troubleshoot technical problems with participants.

Day-7 Support Contact

Approximately 7 days after enrollment, the research staff conducted structured telephone check-ins. The staff checked on the participants' safety and well-being, asked whether they were receiving notifications, experiencing difficulty charging their phones, or having problems answering EMAs, and reminded them to keep their phones charged and respond to EMAs promptly.

End-of-Study Visit

After 30 days, participants returned to the NHSSP to complete a poststudy questionnaire and a qualitative exit interview describing their experiences using the app to respond to the daily EMA prompts.

Study Measures

EMA Measures

EMA items assessed recent behaviors, risk exposures, and internal states over the prior 12 hours. Participants reported substance use in response to the question, "In the last 12 hours, have you used any drug(s), legal or illegal, that are not prescribed to you?" If the answer was "yes," participants selected the specific drugs used. Additional "yes" or "no" items assessed drug craving ("In the last 12 hours, did you experience any cravings for drug(s)?"), anticipated use ("Do you plan to use any drug(s) in the next 12 hours?"), sexual activity ("In the last 12 hours, have you had vaginal or anal sex with another person?"), overdose exposure ("In the past 12 hours, did you overdose on any drug(s)?" and "In the past 12 hours, did you witness or see another person overdose on drug(s)?"), and naloxone access ("Do you currently have Narcan available to you or someone else, if needed?"). All responses were coded as binary indicators for each EMA item.

Participants also rated affective and physical states using 0-10 numeric rating scales, including happiness ("In the last 12 hours, how happy were you?"), stress ("In the last 12 hours, how stressed were you?"), and physical pain ("In the last 12 hours, how intense was your physical pain?"). Higher scores indicated greater intensity of the respective state.

Baseline Measures

Sociodemographic Characteristics

Participants reported their age, sex, race or ethnicity, education, relationship status, employment status, monthly income, and current housing status.

Substance Use and Overdose History

Participants reported drug use in the past 12 months and the past 30 days, as well as the frequency of opioid use in the past 30 days. The route of administration was categorized as injection, smoking, snorting, oral use, or other. Lifetime overdose was assessed using a structured question that asked whether the participant had ever experienced an opioid overdose. The questionnaire provided symptom examples, including slowed or stopped breathing, blue lips or fingernails, unconsciousness, and inability to talk, to standardize interpretation. Participants also reported past 30-day and lifetime overdoses, as well as whether they had ever witnessed others overdose.

Substance Use Treatment Engagement

Participants were asked whether they were currently enrolled in a treatment program for opioid dependence (methadone, buprenorphine, extended-release naltrexone, or other), whether they had sought treatment in the past 12 months, and whether they had seen a substance use treatment provider in the past 6 months.

Mental Health

Depressive symptoms were measured using the Patient Health Questionnaire-2 [25], a brief, validated screener for depressive symptoms that has been used in drug and alcohol treatment populations [26]. It assesses *how often over the past 2 weeks participants were bothered by little interest or pleasure in doing things* and *feeling down, depressed, or hopeless*. Scores range from 0 to 6, with a cutoff score of ≥3 indicating moderate-to-severe depressive symptoms (Cronbach α=0.83).

Anxiety symptoms were measured using the Generalized Anxiety Disorder 7-item [27], a validated measure of anxiety symptoms that has been used in substance-using populations [28]. The Generalized Anxiety Disorder 7-item assesses how often over the past 2 weeks participants were bothered by 7 symptoms: feeling nervous, anxious, or on edge; not being able to stop or control worrying; worrying too much about different things; trouble relaxing; being so restless that it is hard to sit still; becoming easily annoyed or irritable; and feeling afraid as if something awful might happen. Scores range from 0 to 21, with scores of 10 or more indicating moderate-to-severe anxiety symptoms (Cronbach α=0.94).

Suicidal thoughts and behaviors were assessed using the suicidality module of the World Mental Health Composite International Diagnostic Interview. Participants reported lifetime suicidal ideation, suicide plans, and suicide attempts [29]. Participants also reported whether they had recent contact with a mental health provider (yes or no items). Current pain and

XSL•FO
RenderX

stress levels were assessed using a visual analog scale ranging from 0 to 100, with higher scores indicating greater perceived pain or stress.

Digital Health Literacy

Digital health literacy was assessed using the 3-item Digital Health Care Literacy Scale [30]. Participants rated their agreement with statements indicating that they could independently: (1) use videoconferencing applications, (2) set up a video chat, and (3) solve basic technical problems. Responses were rated on a 5-point Likert agreement scale, ranging from "strongly disagree" to "strongly agree," with a total score ranging from 0 to 12.

Feasibility and Acceptability Outcomes

Feasibility outcomes included recruitment, retention, and EMA compliance. Retention was defined as the completion of the end-of-study visit. EMA compliance was calculated as the proportion of completed prompts out of the total number of expected prompts among participants who initiated EMA monitoring. Morning and evening compliance were calculated separately, and to examine sustained engagement, completion rates were also summarized across 4 weekly intervals (days 1-7, 8-14, 15-21, and 22-30). Consistent with prior EMA literature among people who use substances, compliance rates of approximately 70% to 80% were considered indicative of acceptable feasibility [23,31-33].

Acceptability was assessed using a structured poststudy questionnaire. Participants rated statements such as "The daily EMA questions were easy to understand," "I had privacy and confidentiality while answering the EMA prompts," "The number of daily EMA was burdensome," and their willingness to participate again using multilevel agreement scales. Participants also reported the emotional impact (positive, neutral, or negative), the convenience of EMA timing, the reliability of notifications, the helpfulness of research team reminders, and barriers to responding, including being busy, sleeping, missing notifications, not having a phone, or experiencing technical problems.

Qualitative exit interviews further explored participants' experiences and perceived barriers to daily monitoring. The interview guide was developed by the study team based on the study objectives and prior EMA literature [34]. Participants were asked about their overall experiences and motivations for completing the daily EMA prompts, including perceived benefits and challenges, barriers to responding to prompts, and emotional reactions to questions about drug use (see Multimedia Appendix 1 for the exit interview guide).

Data Analysis

Quantitative data were analyzed using Python version 3.13.4 (Python Software Foundation). Participant characteristics and feasibility outcomes were summarized using descriptive statistics. Continuous variables were summarized using means and SDs, and categorical variables were summarized using counts and percentages. EMA adherence was calculated at the participant level, separately for morning and evening prompts. To assess changes in engagement over time, EMA prompt completion was aggregated into 4 weekly intervals and summarized across participants. EMA behavioral responses (drug use, craving, planned use, overdose events, and naloxone access) were summarized as counts of endorsed events across completed observations. Data management and statistical summaries were conducted using the *pandas* and *NumPy* libraries, and figures were generated using *Matplotlib*.

Qualitative interviews were audio-recorded and transcribed verbatim. Data were analyzed using inductive thematic analysis, following the steps described by Braun and Clarke [35]. Interview transcripts were reviewed multiple times to become familiar with the data. Two coders independently conducted open coding of all transcripts and met regularly to review and refine the coding framework. Any discrepancies were resolved through discussion with the senior coder (KG), and codes were gradually grouped into broader thematic categories. Consistent with recommendations for enhancing rigor in qualitative research, coding decisions and thematic interpretations were reviewed collaboratively throughout the analytic process [36]. Qualitative data were managed and analyzed using Dedoose version 9.0.54 (SocioCultural Research Consultants, LLC).

Ethical Considerations

The study was approved by the institutional review boards (IRB protocol #2000036555) at Yale University and the University of Connecticut. All participants provided written informed consent prior to participation. Participants received US $25 for completing the baseline visit and US $25 for completing the end-of-study visit and interview. EMA completion was incentivized on a per-prompt basis. Participants received US $1 for each completed EMA prompt (maximum of 60 prompts). The maximum total compensation per participant was US $110 over the 30-day study period.

Results

Feasibility

Recruitment and Participation

Thirteen individuals were assessed for eligibility through NHSSP, of whom 10 provided informed consent, were enrolled, and completed the baseline assessment and onboarding for the EMA app. Three eligible individuals did not proceed to enrollment because they did not attend their scheduled baseline interviews and were subsequently unreachable. One enrolled participant withdrew due to a scheduled cataract surgery before completing any EMA prompts. The remaining 9 participants completed the EMA prompts during the 30-day study period. EMA participation remained relatively stable across the study period, with 8 of the 9 participants continuing to respond to EMA prompts through week 4. Seven participants completed the exit survey and qualitative interviews following 30 days of EMA participation.

Participant Characteristics

The mean age of the 10 participants was 43.0 (SD 7.1) years (Table 1). Half identified as male, 4 (40%) as female, and 1 (10%) as transgender. Most participants had a high school education or lower (n=9, 90%), were currently unemployed, and 4 (40%) reported experiencing homelessness. Additionally,

XSL•FO
RenderX

9 (90%) participants reported injection drug use, and 8 (80%) reported daily opioid use in the past 30 days. Furthermore, 7 (70%) participants were receiving medications for opioid use disorder, including methadone maintenance treatment (n=5, 50%) and Vivitrol or other treatment programs (n=2, 20%). A history of opioid overdose was reported by 7 (70%) participants, and most had witnessed an overdose (n=9, 90%) and reported carrying naloxone (n=9, 90%). Digital health literacy was high (mean 10.3, SD 1.94; range 1 - 12).

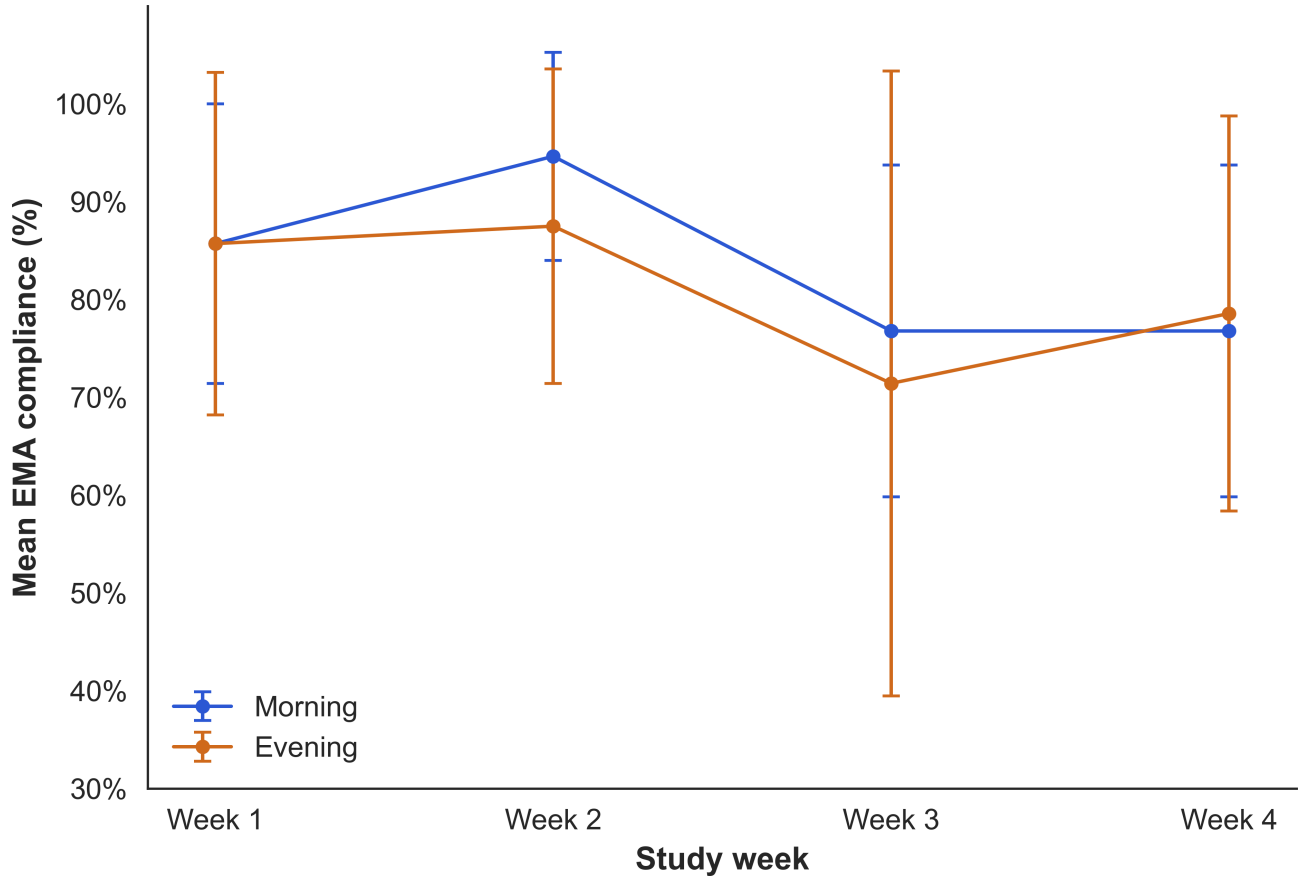
[a]MOUD: medications for opioid use disorder.

EMA Compliance



Among the 9 participants who completed at least 1 EMA, 411 out of 540 expected EMA prompts were completed during the study period. Overall, EMA compliance was high, with an average of 85.0% (SD 8.7%). Compliance was similar between morning (mean 84.2%, SD 13.1%) and evening (mean 85.8%, SD 11.2%) prompts (Table 2), with rates ranging from 17% to 97% among the participants (Figure S1 in Multimedia Appendix 1).

Table . Mean Ecological momentary assessment (EMA) compliance by prompt type during the 30-day study period (N=9).

EMA compliance measure	Values, mean (SD)
Overall compliance	85 (8.7)
Morning prompts	84.2 (13.1)
Evening prompts	85.8 (11.2)

Average EMA compliance varied across participants over the 4 weeks of participation, with similar patterns observed for morning and evening prompts (Figure 1). Morning EMA compliance was highest in week 2 (mean 94.6%, SD 10.6%), followed by week 1 (mean 85.7%, SD 14.3%). Compliance declined in week 3 (mean 76.8%, SD 17.0%) and remained stable in week 4 (mean 76.8%, SD 17.0%). Evening EMA compliance followed a comparable trajectory, peaking in week 2 (mean 87.5%, SD 16.1%) and then in week 1 (mean 85.7%, SD 17.5%). Compliance decreased in week 3 (mean 71.4%, SD 31.9%) and increased in week 4 (mean 78.6%, SD 20.2%).

Figure 1. Ecological momentary assessment (EMA) compliance across the 4 weeks of the participation period.

Drug-Related Behavioral Reporting

Weekly reporting patterns for drug-related behaviors across the 30-day study period are presented in Table 3, with participant-level reporting trajectories shown in Figure S2 in Multimedia Appendix 1. Drug craving was reported in 66.7% (274/411) of completed prompts overall, ranging from 58.4% (66/113) to 76.9% (83/108) across study weeks. Plans to use

XSL•FO
RenderX

drugs were reported in 61.3% (252/411) of completed prompts overall, ranging from 59.3% (67/113) to 62.5% (55/88) across weeks. Opioid use was reported in all completed EMA prompts across all study weeks. Overdose experiences were reported by 2 participants, with a total of 5 reports across the study period 1.2% (5/411). Naloxone possession remained consistently high throughout the study period, reported in 87.1% (358/411) of completed prompts overall and ranging from 80.4% (82/102) to 94.7% (107/113) across study weeks.

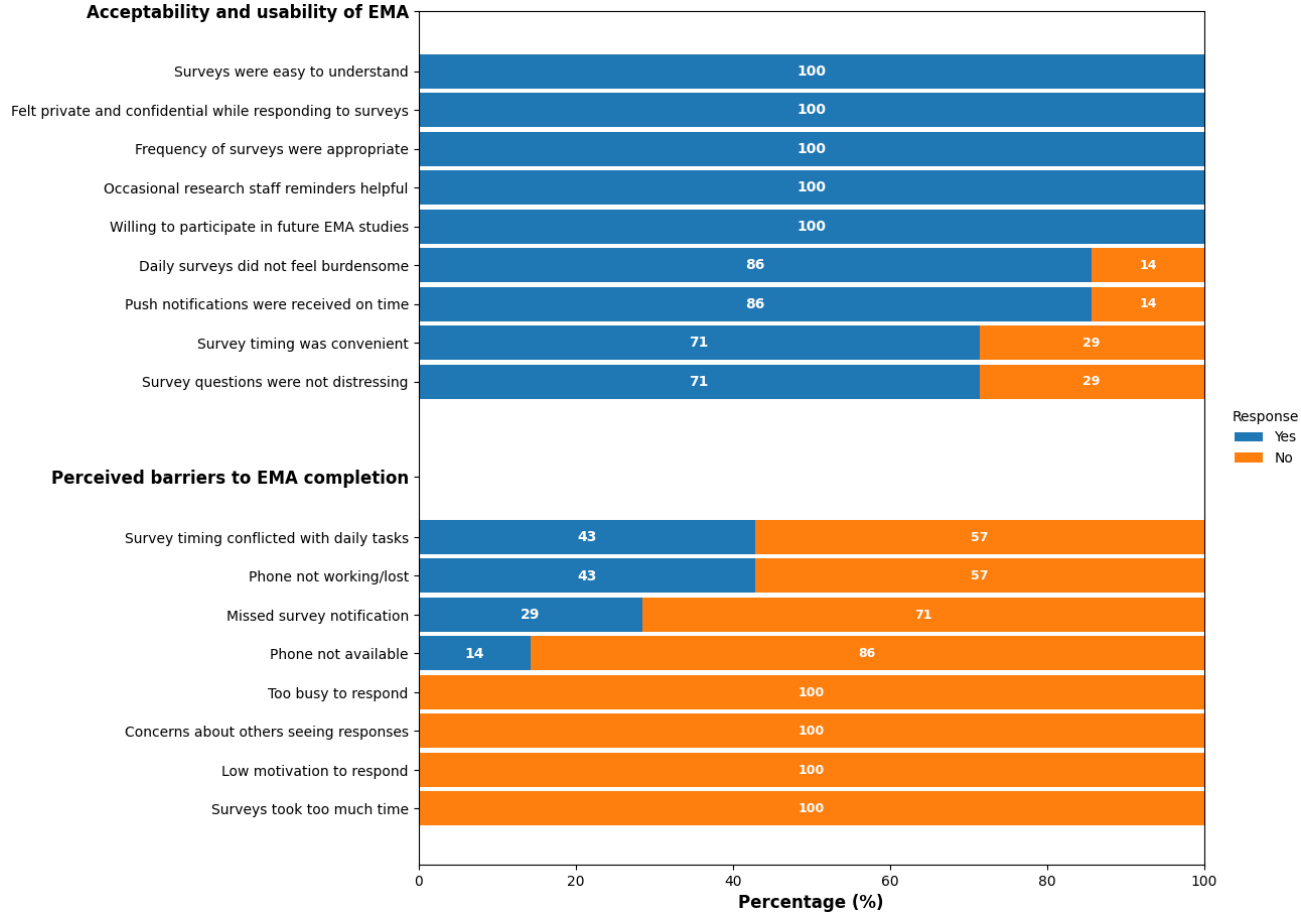


Table . Weekly reporting patterns of drug-related behaviors across ecological momentary assessment (EMA) prompts.

Behavior	Total reports, n (%)	Week 1, n (%)	Week 2, n (%)	Week 3, n (%)	Week 4, n (%)
Drug craving	274 (66.7)	83 (76.9)	66 (64.7)	59 (67.0)	66 (58.4)
Plan to use drugs	252 (61.3)	67 (62.0)	63 (61.8)	55 (62.5)	67 (59.3)
Opioid use	411 (100)	108 (100.0)	102 (100.0)	88 (100.0)	113 (100.0)
Experienced overdose	5 (1.2)	1 (0.9)	0 (0)	2 (2.3)	2 (1.8)
Carry naloxone	358 (87.1)	90 (83.3)	82 (80.4)	79 (89.8)	107 (94.7)

Acceptability

Overall, the acceptability and usability of the EMA protocol were high (Figure 2). All participants reported that the EMA prompts were easy to understand, felt private and confidential, and that the survey frequency was appropriate. All participants also indicated willingness to participate in future EMA studies and found occasional reminders from research staff helpful. Most participants (6/7, 86%) reported receiving push notifications on time and indicated that daily EMA prompts did not feel burdensome. EMA timing was considered convenient by 71% (5/7) of participants, and 71% (5/7) also reported that the survey questions were not distressing.

Figure 2. Participant-reported acceptability, usability, and perceived barriers to ecological momentary assessment (EMA; n=7).

Participants also reported a few barriers to EMA completion. EMA timing conflicts with daily tasks and phone-related issues (eg, phone not working or lost) were each reported by 43% (3/7) of participants. Missed EMA notifications were reported by 29% (2/7) of participants, and lack of phone availability at the time of the EMA was reported by 14% (1/7) of participants. None of the participants reported low motivation, concerns about privacy, or prompt length as barriers to completing the EMA.

XSL•FO
RenderX

Qualitative Findings

Seven participants completed the one-on-one semistructured exit interview. Thematic analysis yielded five themes that reflected the participants' experiences with the EMA study: (1) ease of use and integration into daily routines, (2) self-awareness and reflection related to substance use, (3) perceived accountability through self-monitoring, (4) emotional discomfort related to substance use reflection, and (5) situational and technical barriers to EMA prompt completion.

Ease of Use and Integration Into Daily Routines

Five participants described the EMA prompts as easy to complete and manageable within their daily routines. Participants mentioned that the prompts were brief and delivered at predictable times, which supported routine completion without being perceived as intrusive:

> *It was very convenient, because it was two times a day in the morning and at night, so it wasn't like bugging me or anything.* [P7]
>
> *I already knew what time they were gonna come around, so I kind of prepared to be ready to do it.* [P6]

Self-Awareness and Reflection Related to Substance Use

Four participants reported that repeated reporting increased their awareness of their substance use patterns and daily behaviors. Some participants noted that completing the EMA prompts encouraged them to reflect on their cravings, intentions to use substances, and substance use experiences throughout the day:

> *It showed me that it is true that the first hit makes me crave more… it really showed me that I needed some help.* [P6]
>
> *A lot of the time, I wanted to use drugs, but I didn't plan to, and I didn't actually do it.* [P2]

Perceived Accountability Through Self-Monitoring

Two participants described how regular EMA participation created a sense of accountability, structure, or engagement in their daily routines, even without any intervention or direct interaction with the study staff:

> *It felt good… I looked forward to doing it [EMA prompt] twice a day.* [P1]
>
> *It kept me on my toes… like an assignment or a job, you stay on schedule.* [P6]

Emotional Discomfort Related to Substance Use Reflection

Two participants described experiencing emotional discomfort when reflecting on their substance use through repeated EMA reporting. These experiences included feelings of guilt, sadness, or emotional distress associated with reporting substance use behaviors:

> *It kinda made me feel a little bit guilty when I complete it [EMA prompt] and report drugs use.* [P8]
>
> *It sometimes makes you feel sad and not so good about yourself… it's a hard reality to accept.* [P4]

Situational and Technical Barriers

Two participants described situational or technical barriers that occasionally interfered with EMA prompt completion, including oversleeping, low phone battery, and missed alerts:

> *When I overslept, and I woke up, and I missed the survey, which was challenging.* [P2]
>
> *There were a couple of times that my phone was dead and the notification didn't come through, so I forgot about it.* [P4]

Discussion

Principal Findings

In this study, we explored the feasibility and acceptability of a 30-day smartphone-based EMA protocol among people who use opioids. Recruitment through the SSP was successful and represented an important strength of this study. Overall, 70% of the participants completed the study and follow-up interviews. EMA completion rates were high, with an overall compliance rate of 85%, and similar response rates for morning and evening prompts. Participants regularly reported opioid use, cravings, overdose experiences, and carrying naloxone through EMA, suggesting that twice-daily monitoring of opioid-related behaviors is feasible in community settings.

The EMA compliance rate observed in this study was higher than the pooled compliance rate reported in a meta-analysis of 126 effect sizes from 19,431 participants among EMA studies of people who use substances (75.1%, 95% CI 72.4%-77.7%) [23]. Prior EMA studies among people who use opioids have largely focused on momentary predictors of drug use, such as craving, mood, and stress, rather than on overdose-related experiences or harm-reduction behaviors. Compliance remained generally stable across morning and evening prompts and throughout the 30-day study period, with a modest decline in the third week—a pattern reported in other EMA studies and often attributed to participant fatigue [23-25]. In our study, compliance increased again during the final week, suggesting that participants were able to integrate the EMAs into their daily routines. Predictable EMA prompt timing, brief questionnaires, and regular reminders from the research staff may have contributed to these high response rates. Prior EMA studies often included larger samples and longer study durations, which may partly explain the differences in compliance [17,18,37]. In this context, the high compliance observed in our study may have been influenced by the small sample size, short study duration, and participants' relatively high levels of education and digital literacy [23,38,39].

Importantly, participants reported their drug use behavior and experiences related to overdose and carrying naloxone through daily EMA prompts. Although only a small number of overdose events were reported during the study period, participants reported carrying naloxone on every occasion when an overdose was reported. However, the study did not assess whether naloxone was administered during these overdose events or whether it was used for reversal. These findings suggest that

XSL•FO
RenderX

EMA may be a useful approach for capturing timely information on overdose experiences and harm-reduction responses. Prior EMA-based research among people who use opioids has focused on momentary predictors of drug use, such as craving, mood, pain, and contextual factors, but did not assess overdose experiences or whether participants were carrying naloxone [17,18,40-42]. While preliminary, our findings suggest that EMA may also be useful for capturing overdose-related experiences and harm-reduction behaviors in daily life. Such information may help improve the understanding of the circumstances surrounding overdose events and may inform future real-time prevention and intervention strategies.

Despite disclosing minimal barriers (EMA prompt timing, unavailability of phone, and missed prompt notifications), participants reported that overall participation was acceptable, minimally burdensome, and did not interfere with their daily activities. In similar EMA studies [43,44], privacy and confidentiality were reported as major barriers; however, none of the participants in our study raised these concerns. Participants further reported an overall positive experience, with all indicating that they would participate in a similar study in the future. In real-world settings, it would be helpful to consider the barriers they faced, such as prompt timing, missed push notifications, and the emotional discomfort associated with some questions. Fixed notifications, individualized prompt timing, and participant-friendly question wording may help reduce participant burden and improve engagement when EMA protocols are developed using a user-centered approach. In addition, providing participants with personalized feedback based on EMA data may be more impactful [45], which could motivate them to remain engaged for a longer period. Such EMA data may also support the development of mobile health–based just-in-time adaptive interventions, where timely information on drug craving, planned use, or contextual risk factors could be used to predict periods of elevated overdose risk and deliver timely harm-reduction support, such as reminders to carry and use naloxone [46,47]. However, further research is needed to determine how such approaches can be effectively implemented in real-world settings.

Limitations

Several limitations should be considered when interpreting the findings of this study. First, the sample size was very small, and participants were recruited through a single SSP in New Haven, which limits the stability of the findings and restricts generalizability to the wider opioid-using population. Individuals engaged with harm reduction services may differ from those who are not connected to such programs, including having greater access to harm-reduction resources, higher overdose awareness, and more frequent engagement with health services, potentially limiting the generalizability of the findings to broader populations of people who use opioids. Second, the study sample included individuals with relatively high digital health literacy and smartphone access, which may not reflect the experiences of people who use opioids with lower or more unstable access to digital technologies due to social and structural vulnerabilities, such as housing instability and poverty. Third, EMA items, along with the poststudy acceptability questionnaire, were adapted and were not formally validated, which may limit comparability with other studies. Fourth, all EMA responses and poststudy assessment measures were self-reported and may have been influenced by social desirability or participant fatigue, potentially leading to overreporting of positive experiences and underreporting of barriers. Fifth, although participants reported carrying naloxone, the study did not assess whether naloxone was administered during overdose events. Sixth, the 30-day EMA protocol does not capture long-term adherence or engagement beyond the short monitoring period. Finally, participants received compensation for completing EMA prompts, which may have influenced response rates and engagement observed in this pilot study and may not reflect participation in real-world settings, where similar incentives may not be available.

Conclusions

Our findings suggest that a smartphone-based EMA protocol is feasible and acceptable among people who use opioids. Participants demonstrated high compliance with twice-daily EMA prompts and reported opioid use, overdose experiences, and naloxone possession. These findings highlight the potential of EMA to capture day-to-day patterns of substance use and overdose-related behavior. Future research should examine how EMA data can be leveraged to inform adaptive interventions, such as just-in-time adaptive interventions, to reduce the risk of overdose. Larger and longer-term studies are needed to further evaluate EMA for monitoring opioid use, supporting harm-reduction strategies, and understanding broader aspects of daily functioning and well-being among people who use opioids.

Abstract

Background: In the early stage of human-centered design (HCD), qualitative and generative methods are commonly used to explore patients' contexts and needs, emphasizing active patient involvement to ensure that design insights accurately reflect real experiences and enhance both design effectiveness and patient empowerment. However, certain challenges arise in the early stage of the HCD process, including (1) high vulnerability of patient participants, (2) less diverse and representative patient groups due to recruitment challenges, and (3) insufficient problem framing across diverse patient experiences.

Objective: To address these challenges while embracing the system-level HCD perspective, we propose a data-enabled mixed method combining large-scale patient digital research (module A) and in-depth patient engagement research (module B). This paper explores the feasibility and potential value of this mixed method in addressing the identified challenges through a case study.

Methods: In module A, we analyzed a large-scale dataset of online forum posts and validated the extracted topics with medical experts to create a patient community journey map through cocreation sessions. Guided by these findings, module B involved a diary study using a sensitizing paper prototype and semistructured follow-up interviews with 4 patients.

Results: In module A, 37 topics and 10 upper clusters were summarized from 212,107 online posts, revealing that topics associated with the home context exhibited a higher density of emotional content than those related to the hospital context. Patients placed more emphasis on social and mental health during the follow-up stage than in the diagnosis and treatment phases. This shift reveals a gap in current remote monitoring systems, which focus mainly on physical health. Addressing this identified gap, we developed a prototype for use in the module B diary study involving 4 patients. Patients responded positively to the prototype, noting that remote monitoring incorporating social and mental well-being could help them better understand themselves, enhance self-awareness, and improve communication with their physicians. Overall, this study explores the preliminary value of this mixed method in effectively reframing design problems and deeply contextualizing patient needs.

Conclusions: This study provides preliminary evidence supporting the potential of integrating large-scale digital patient research (module A) with in-depth patient engagement (module B) during the early stages of human-centered health care design. The core strength of this mixed method approach lies in its ability to facilitate problem reframing and cultivate a deeper sense of empathy and understanding of patient vulnerability prior to direct engagement. Simultaneously, it captures both the breadth and depth of patient perspectives, offering evidence-based insights that enhance the overall efficacy of user research. Further research across diverse medical contexts is essential to establish the generalizability of these findings.

Introduction

Background

Human-centered design (HCD) plays an important role in designing for patients in health care in order to understand patient needs [1], improve patient experience [2], and enhance patient safety [3]. The focus is on empowering designers to understand human needs at a systemic level through empathetic communication and interaction with the individuals within the system [4].

The health care design process typically starts with exploring patients' needs using the HCD approach before formulating design solutions [5], specifically in the initial stage, such as the discover and define phases of the Double Diamond Model [6] and the fuzzy front end of the design development process [7]. To understand patient context, qualitative research methods are frequently used in the initial stage of the design process to perceive the context [5]. The specific methods proposed in such an explorative stage include both conventional methods, such as interviews and observations, and other innovative methods, such as generative techniques [8], which enable health care designers to deeply explore patients' needs [9] while also facilitating the examination of the complex interactions among various system components [10].

Central to these methods is involving patients as the end users, serving as a foundational principle for ensuring that insights derived from qualitative research accurately reflect patients' needs and experiences. For instance, Van Smoorenburg et al [11] asked 10 patients with type 2 diabetes mellitus to fill in sensitizing booklets before conducting interviews to prompt them to reflect on their experiences with self-management of diabetes. Researchers illustrate that the involvement of patients can not only increase the effectiveness and success of the design process [12] but also facilitate patients' knowledge-building and relationships [13].

Challenges in Human-Centered Health Care Design

However, implementing HCD and engaging patients in health care settings is more complex than in other domains, primarily due to the intricate nature of health care systems and patients' compromised health states [14,15]. In this paper, we explore the challenges of designing for patients in the initial stage of the design process, including high vulnerability of patient participants, less diverse and representative patient groups due to recruitment challenges, and insufficient problem framing across diverse patient experiences.

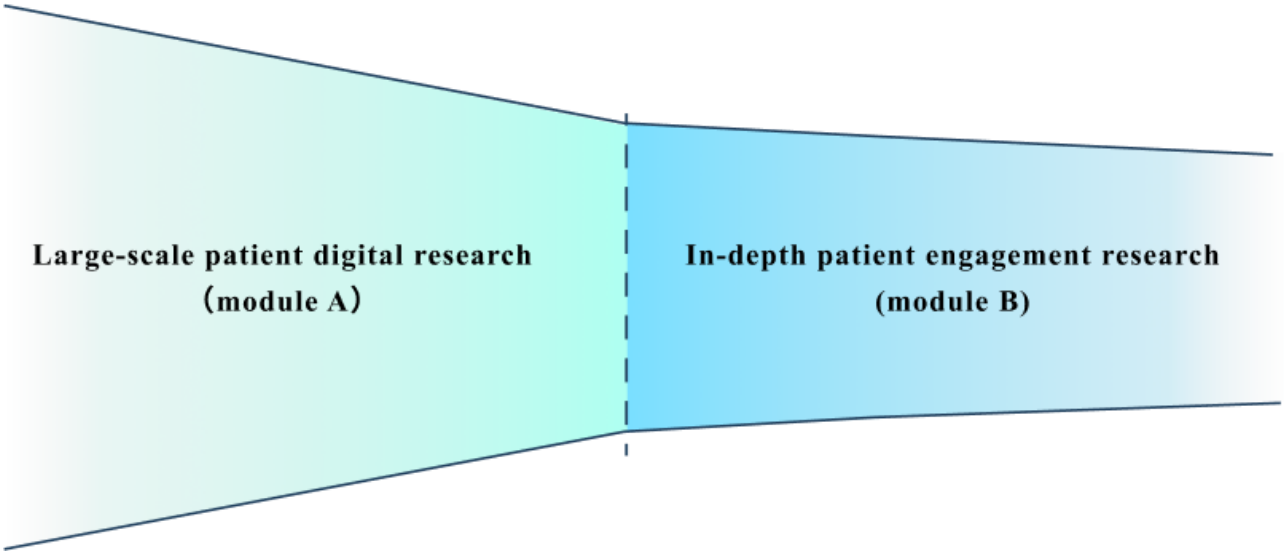
High Vulnerability of Patient Participants

Patients are often regarded as a vulnerable demographic, which necessitates careful ethical consideration when involving them in research. For instance, Das and Svanæs [1] noted that discussions about obesity may evoke stigma and shame, requiring designers to plan workshops and participant groupings sensitively to avoid offending others. Furthermore, obtaining medical study approval typically demands a lengthy preparation process, which can be partially attributed to the risk of patients recalling distressing experiences during participation [16]. However, despite the ethical need to protect patients from potential harm, designers are also expected to gain a deep and systematic understanding of their lived experiences to develop meaningful interventions. This requirement poses a notable challenge, as patient participation, despite its recognized value, can introduce burdens that hinder meaningful collaboration [17,18]. Furthermore, designers may not yet be familiar with the patient group in the early design stages, making it challenging to anticipate negative experiences or address such vulnerabilities effectively in advance.

Less Diverse and Representative Patient Groups Due to Recruitment Challenges

In the early exploratory phases of HCD, qualitative research methods such as user observations, interviews, and generative techniques are used to emphasize the necessity of continuous patient involvement throughout the entire design lifecycle, rather than limiting participation to a single stage [8,19]. However, these methods face certain dilemmas related to diversity and representativeness of patient groups, which have been criticized as a manifestation of sampling bias in HCD [17]. Specifically, researchers have attributed this challenge to limited sample sizes, difficulties in engaging representative end users, and insufficient participant diversity during patient recruitment, all of which raise concerns about the generalizability, validity, and reliability of the results [15,16,20]. For example, a study developing an intervention with a participatory design approach has reported difficulties in identifying appropriate patient groups and achieving adequate diversity among participants in terms of age, sex, and disease duration [21].

Insufficient Problem Framing Across Diverse Patient Experiences



Problem framing is a foundational step in HCD, aiming to ensure that interventions address the right problem [22]. It requires understanding not only users' needs but also their experiences, values, behaviors, and environmental contexts from a system's perspective [8]. Nevertheless, the awareness of problem definition in current HCD practices within health care remains limited, with few studies attempting to reframe the initial problem based on diverse user perspectives [23]. More studies adopt a solution-driven rather than a problem-driven approach, generating numerous ideas while leaving the initial design problem insufficiently defined [5]. Moreover, many studies focus on the general principles of HCD rather than detailing specific processes, tools, or methods [24], thereby marginalizing the attention given to defining problems based on patient experiences. For example, some studies fail to clearly distinguish between the discover and define phases in the Double Diamond model [25]. Problem-driven design is essential for prioritizing interventions based on a deep understanding of the underlying problem [5,26]. When patient experiences are explored only within a preestablished problem scope and narrow aspects, rather than through iterative problem reframing, opportunities for creative and efficient solutions are limited [23].

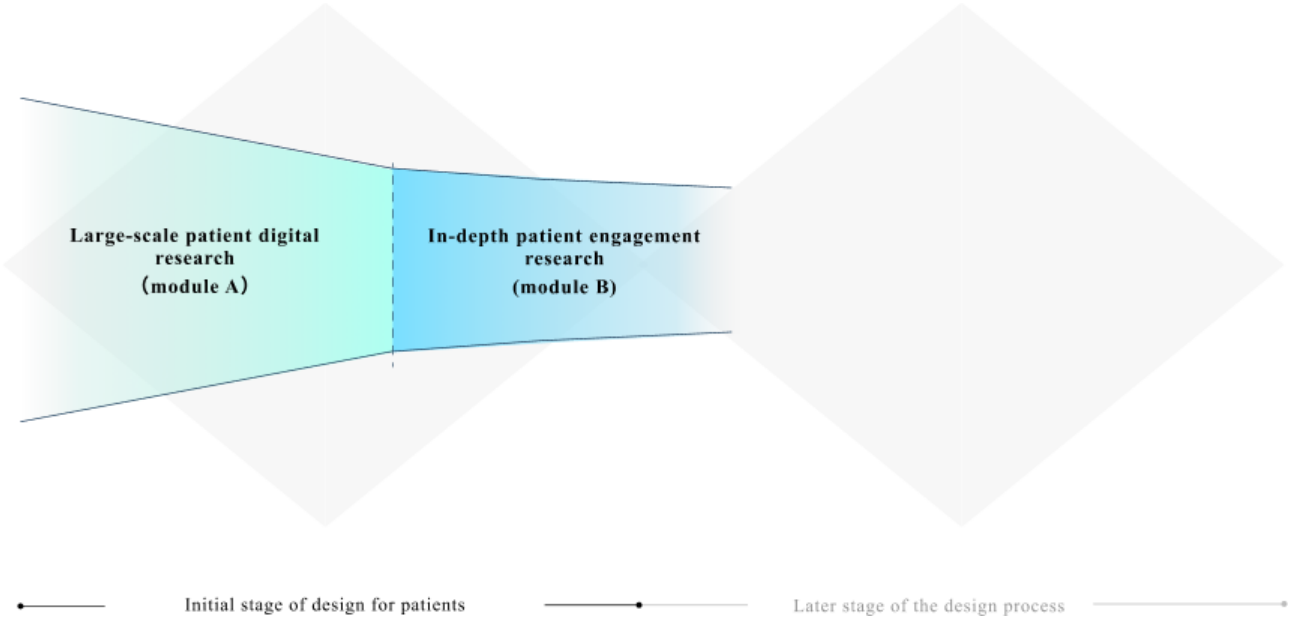
Advancing the Exploration of Patient Experience With an HCD Perspective: Development of a Data-Enabled Mixed Method



To deal with the challenges of designing for patients and achieve the goal of HCD in the early stage, we propose a data-enabled mixed method as illustrated in Figure 1, which prioritizes large-scale patient digital research (module A), subsequently followed by in-depth patient engagement research (module B). It is important to note that we currently consider this mixed method to be most valuable when adopted during the initial stages of the design process, such as the first diamond of the Double Diamond model [6] and the fuzzy front end of the design development process [7]. Figure 2 illustrates the stage in which this mixed method is applied using the Double Diamond model as an example.

Figure 1. The data-enabled mixed method for designing for patients in the initial stage of the design process.

In large-scale patient digital research, extensive datasets derived from digital patient data are used to generate meaningful insights. The potential data source can be digital patient platforms such as Facebook groups or patient online forums, which are emerging in patient research [27,28]. In this way, designers can indirectly conduct an in-depth analysis of the data with patients' perspectives and empathy for patients' experiences, which further facilitates resonance and the handling of sensitive issues when engaging with patients in the next stage. Patient engagement research in module B refers to conducting conventional qualitative or design research that requires the involvement of patients, such as interviews, diary studies, and focus groups. In other words, we suggest adding large-scale patient digital research to have a generalized understanding before patient engagement in the design process.

Figure 2. The Double Diamond model as an example illustrates the stage in which the data-enabled mixed method is applied.

About This Case

An explorative case study illustrates how this data-enabled mixed method was adopted to explore patient experience during the initial stage. The case provides preliminary indications of this method's potential benefits, including enabling health care designers to acquire rich knowledge that features patients' perspectives, cultivating an empathetic perspective toward the difficult medical context, facilitating designers to define research and design direction, and designing engaging research activities.

The initial goal of the case was to develop remote patient monitoring for patients with colorectal cancer (CRC) in the Netherlands, considering their quality of life during the follow-up phase. Within this context, this case investigates the care path of patients with CRC with a particular focus on understanding their experiences, especially in the follow-up phase, to lay the groundwork for the development of the remote patient-monitoring system. This study brings together a Netherlands-based interdisciplinary team with expertise in design, computer science, and CRC research.

CRC Background and the Theoretical Framework

CRC is the third most common cancer worldwide. It accounts for 10% of the global cancer incidence [29] and is expected to exceed 3 million by 2040 [30]. In the Netherlands, where the case study was conducted, patients who have undergone treatment and surgery for CRC typically enter a 5-year follow-up phase. This phase involves regular meetings between patients and health care professionals to monitor their recovery progress and provide necessary information and support.

During the follow-up phase, patients often experience long-term health issues including physical, social, and mental health. The World Health Organization has highlighted the importance of these 3 aspects in relation to health-related quality of life. These 3 aspects are related to each other and form the basis of a framework called "Three-dimensional Theoretical Framework of Health" (Figure 3) [31]. This framework illustrates that the intersection of the 3 aspects has an equally high impact on the quality of life of patients' health but is often overlooked. It is important to pay attention to all aspects of health of a patient with CRC in the follow-up phase to enhance the patient's quality of life.

Methods

Study Design

Figure 4 outlines an overview of the methods used in this case. Module A adopts the patient community journey mapping method developed by Jung et al [32] through the collaboration between the designer and a computer scientist. This method applies natural language processing techniques to online patient posts, analyzing the text and visualizing the results as a journey map [32]. The goal of this method is to perceive the experiences of patients with CRC, reframe the research question, and gain an overview of the patient context. Based on the findings and perceptions from module A, we reframed the research question and then conducted a diary study and interviews involving patient participants to dive deep into the context in module B.

Figure 4. The data-enabled mixed method in the colorectal cancer case.

Module A: Patient Community Journey Map

Introduction of Patient Community Journey Map

The conventional development of the patient journey map mainly relies on the data collected from qualitative methods, such as interviews and ethnographic data [33]. Although the qualitative patient journey map reflects a person's entire journey through the health systems, it requires patient involvement for developing the map and restricts the sample size to at most a few dozen patients [32], bringing the 3 challenges previously mentioned to light. In this case, we adopt the data-enabled "patient community journey mapping" method as one of the examples that can address the 3 challenges and the limitations of the qualitative patient journey map. It takes advantage of natural language processing techniques, such as topic modeling, to process online patients' stories and further create a journey map with the results [32].

Data Collection and Analysis

This study uses the same dataset as our earlier work [34], which introduced the data collection and topic modeling that form an earlier version of module A. Building upon that early-stage exploration, we further investigate the combining of these large-scale digital insights (module A) with in-depth qualitative patient engagement (module B). Additionally, we extend the previous analysis of the patient community journey map by introducing the three-dimensional framework of health to contextualize the findings in module A.

To ensure privacy protection, all data were preprocessed by removing personal identifiers prior to analysis. A total of 212,107 forum posts related to CRC were collected from the publicly accessible Cancer Survivors Network and further preprocessed by applying lemmatization and Term Frequency–Inverse Document Frequency by a computer scientist. The computer scientist then used nonnegative matrix factorization for topic modeling. Because quantitative metrics, such as topic coherence and model stability, consistently declined and lacked clear insights, determining the optimal number of topics relied on rigorous human evaluation. Four researchers, including 2 designers, iteratively reviewed models with 40, 45, and 50 topics, ultimately selecting 50 initial topics as they provided the most diverse and distinctive clusters based on keyword and postexamination. Thirteen topics, such as platform use and expressions of gratitude, were then excluded as they were unrelated to patient experiences, leaving 37 topics for the final analysis.

XSL•FO
RenderX

To analyze the 37 topics, 1 designer reviewed the top 50 posts and top 20 keywords per topic. These were selected by the nonnegative matrix factorization algorithm for possessing the highest dominant topic scores and term weights, respectively, calculated using Term Frequency–Inverse Document Frequency metrics. The review of 50 posts was guided by data saturation: recurring narratives typically emerged after analyzing approximately 30 posts, and the additional 20 were reviewed to rigorously confirm and solidify the extracted themes. The 37 topics were then classified into 10 upper clusters.

After the initial interpretation, a 2-step validation process was implemented to ensure the rigor of the interpretation of the themes. First, the initial interpretation of the 37 topics conducted by the designer was reviewed and validated by a senior design researcher. Second, we subsequently organized cocreation sessions with a panel of local domain experts from the Netherlands. During the 90-minute session, the experts used printed 37 topic cards featuring the top 20 keywords and patient quotes to formulate independent interpretations. These interpretations were then compared with the designer's initial descriptions for validation. By actively absorbing the experts' insights and feedback, the team refined the topic descriptions and collaboratively positioned them onto a blank journey map to reflect the 37 topics within the Dutch health care context. This process also ensured that the findings derived from the US-based forum were relevant and contextualized to the Dutch health care system. The expert panel comprised 5 medical professionals: 2 oncological surgeons with 20 and 12 years of experience, respectively; an epidemiologist specializing in patient experience and quality of life with 15 years of expertise; and 2 MD-PhD candidates in surgical oncology with a research focus on CRC. Through these sessions, the expert panel reviewed and validated the identified topics and clusters, ultimately informing the patient community journey map.

After defining the themes, the designer introduced 2 dimensions to classify the topics. The first dimension was to judge whether the topics belonged to a hospital or home context. The second dimension was to decide whether the topics were related to physical, social, or mental health, according to the three-dimensional theoretical framework of health (Figure 3). Additionally, 2 interviews with CRC specialists were carried out to create the journey part of a patient community journey map, visually illustrating patients' experiences and key concerns.

Module B: Diary Study and Follow-Up Interview

Module Overview

In module A, the research question was reframed: rather than exploring how to develop remote monitoring of patients with CRC during the follow-up stage with a broad consideration of quality of life, the focus was narrowed to specifically supporting patients' social and mental health. Carrying this new research question forward, module B dives deep into the context of patients with CRC' by conducting a diary study and interviews on their social and mental health in the follow-up stage when they are at home. The purpose of the study is to understand patients' social and daily activities and explore patients' attitudes toward monitoring their activities and emotions.

Data Collection and Analysis

In module B, we conducted the diary study and interviewed 4 participants in their follow-up stage. In the diary study, the designer created a paper prototype to simulate remote data collection, aiming to capture patients' daily activities and emotional states. The content of the prototype was developed based on the 5W1H (What, Why, Who, When, Where, How) structure. By recording the details (what, where, when, who) and their reflections (why, how), patients capture a complete context of their daily lives. The process concludes with patients drawing an emotional curve for the day to visualize their mood trends.

In addition, to ensure that the diary study was closely grounded in actual patient experiences, the designer synthesized the 37 topics to create a patient-facing Contextual Prompt Card (Figure 5); for example, the eating activities from topic 17 were in the "What" section in the prompt card. Accompanying the 5W1H paper prototype, this card inspired patients and prevented cognitive overload. It functioned purely as a sensitizing tool, featuring open-ended "Other" options to encourage recording individualized experiences.

Four patients with CRC (Table 1) participated in the study through both online and offline recruitment. Participants were recruited via posters, online forums, and Facebook groups. The patients were invited to finish a 3- to 4-day diary study, followed by a 30-minute semistructured interview to share their findings and attitude.

Although serving as a sensitizing paper prototype rather than independent qualitative data for systematic coding, the diary cards revealed intuitive insights that provided core background for the interviews and acted as observational corroboration in the findings. The formal analytical procedure was exclusively applied to the data collected from the 30-minute semistructured follow-up interviews. We used the thematic analysis consisting of 4 iterative phases. First, descriptive coding was applied to segment the interview text and assign unique codes capturing patients' direct feedback and daily reflections. Next, through subcategorization, these codes were grouped into specific categories aligned with the interview questions. During the clustering phase, similar codes within each category were aggregated into narrative topics. Finally, theme determination was conducted to categorize related topics and label the final overarching themes.

XSL•FO
RenderX

Table . Demographic and characteristics of the 4 patient participants with colorectal cancer involved in the diary study and follow-up interviews (module B).

Participant	Age (years)	Year of diagnosis	Number of finished days for diary study	Online or offline interview
Participant A	61	2014	2	Online
Participant B	53	2021	4	Online
Participant C	45	2019	3	Online
Participant D	50	2021	3	Offline (designer visited patient's home)

Ethical Considerations

The study was approved by the Human Research Ethics Committee of Delft University of Technology (reference number 2596). Participation was entirely voluntary, with participants retaining the right to withdraw their consent at any time. To guarantee confidentiality and privacy, all collected data were fully anonymized. Participants were assigned unique identification codes, and these deidentified records were stored on secure university servers, accessible exclusively to authorized research members.

Results

Module A Results

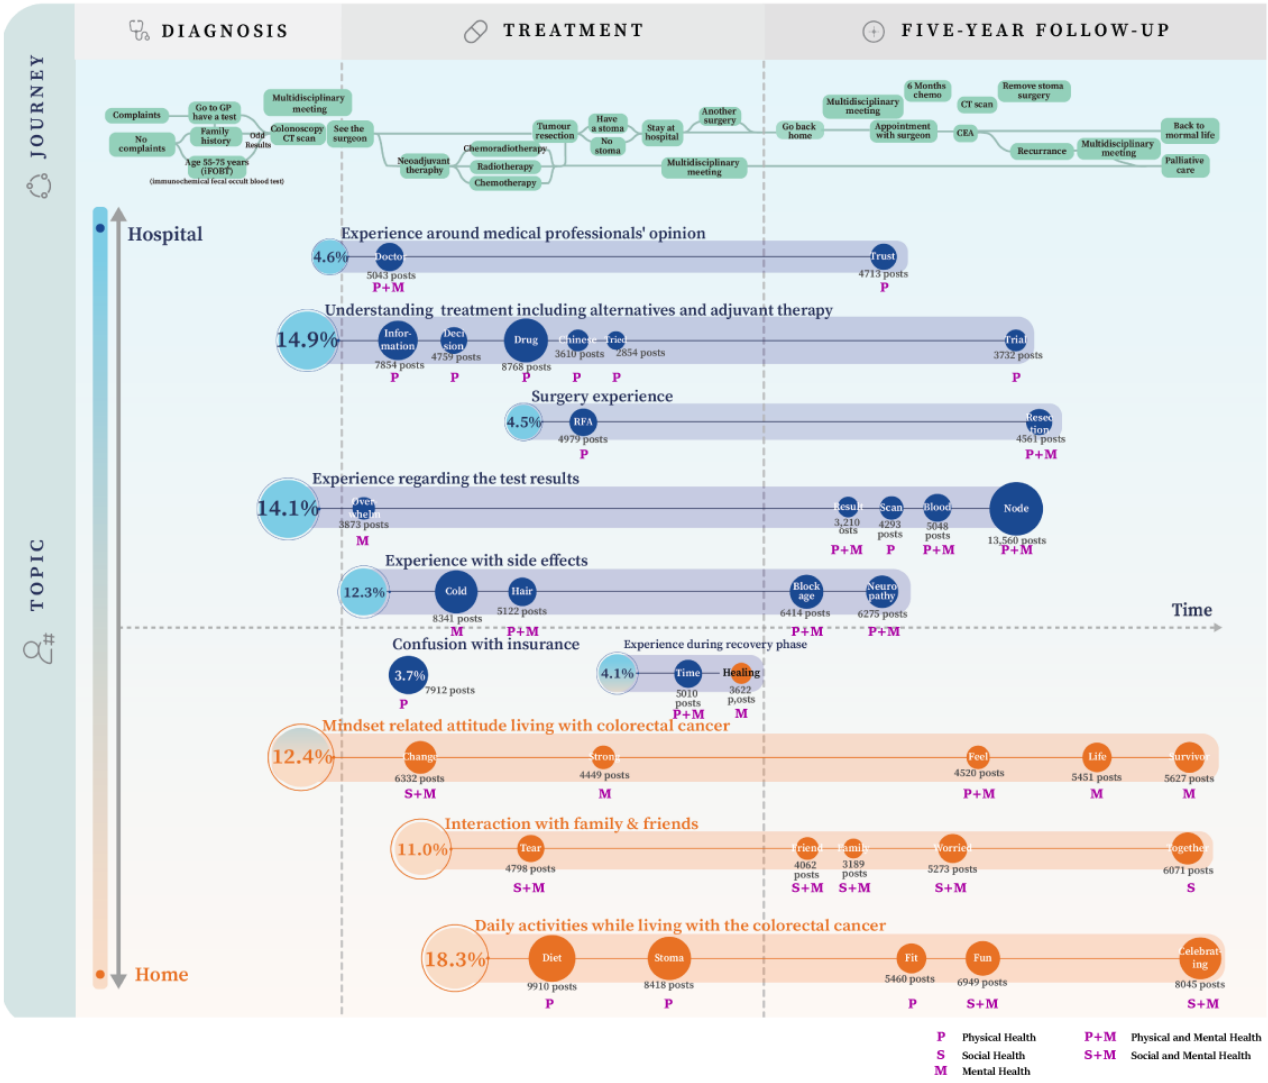
Overview of Module A Results

Table 2 shows the themes of the 37 topics and 10 upper clusters, and Figure 6 shows the patient community journey map. These topics reflect the broad range of discussions among patients, covering themes from medications and treatments to family life.

XSL•FO
RenderX

Table . Overview of the 10 upper clusters and 37 topics identified from the large-scale online forum posts (module A) of patient with colorectal cancer (adapted from Voigt et al [34], which is published under Creative Commons Attribution 4.0 International License [35]), with topic numbers added for this analysis.

Cluster number, cluster theme, and topic number	Number of posts under the topic	Topic theme
Cluster 1: Experience around medical professionals' opinion		
39	5043	Doubts about treatment opinions from medical professionals
45	4713	Suggestion to look for a second medical opinion
Cluster 2: Understanding treatment including alternatives and adjunctive therapy		
30	7854	Patients share their research about alternative therapy options from websites and articles
10	4759	Making treatment decisions for the future with regard to the best outcome and path
33	8768	Listing type, side effect, regimen, and effectiveness of drugs
14	3610	Sharing experience on using Traditional Chinese Medicine to manage health
21	2854	Sharing experiences and recommendations for supplements and medication
48	3732	Sharing information and experiences regarding clinical trials
Cluster 3: Surgery experience		
25	4979	Sharing experience around radio frequency ablation for the liver
23	4561	Sharing negative experience about resection in liver and lung
Cluster 4: Experience regarding the test results (including being worried and confused)		
15	3873	Sharing negative emotions and experiences to live with CRC[a]: overwhelmed, confused, and scared, especially for the tests and screenings
9	3210	Being worried about upcoming scans and results
18	4293	Sharing their outcomes (clear or not) from scanning and caring about how frequently they scan
49	5048	Describing a stressful experience in a blood test; worry about the numbers in the result
8	13,560	Being worried and confused about odd scan results in liver, lung, and lymph
Cluster 5: Experience with side effects		
42	8341	Sharing their experience on managing the side effects of treatment
37	5122	Negative feelings of hair loss due to cancer treatments
34	6414	Feeling uncomfortable due to the obstipation
32	6275	Experiencing pain and numbness due to neuropathy
Cluster 6: Confusion with insurance		
38	7912	Confusion about insurance coverage
Cluster 7: Experience during recovery phase		
27	5010	Describing negative experience of repeated visits to the hospital



XSL•FO
RenderX

Cluster number, cluster theme, and topic number	Number of posts under the topic	Topic theme
20	3622	Staying positive and making life adjustments to their cancer circumstances during the recovery phase
Cluster 8: Mindset-related attitude living with CRC		
0	6332	Difficulties to adjust and adapt to their lives with CRC
41	4449	Sharing how patients can be resilient and positive
24	4520	Sharing their feelings: sick, tired, weak, and bad
46	5451	Sharing their positive philosophical thoughts about living with cancer
11	5627	Survivors sharing their attitudes toward living with cancer along with survival rate
Cluster 9: Interaction with family and friends		
40	4798	Family members' emotional struggle about having a patient with cancer in their family
47	4062	Experience regarding relationships with friends while having cancer
28	3189	Sharing changes in their family relationship due to cancer journey
43	5273	Being worried about their family members and seeking information on family history (eg, genetic testing)
13	6071	Arguing the importance to spend moments with family members during the cancer journey
Cluster 10: Daily activities while living with the CRC		
17	9910	Sharing suggestions on diets focused on balanced meals and healthy alternatives
22	8418	Suggesting how to take good care of a stoma
35	5460	Sharing experience on being fit again, caring about weight control
31	6949	Sharing ways to stay in a positive mood through planning for distractions
3	8045	Celebrating anniversaries and birthdays for patients as a big milestone of their lives

[a]CRC: colorectal cancer.

XSL•FO
RenderX

Figure 6. Community journey map of patient with colorectal cancer, with 37 topics classified into 2 dimensions: home and hospital dimension, and three-dimensional framework of health (adapted from Voigt et al [34], which is published under Creative Commons Attribution 4.0 International License [35]) by adding the three-dimensional framework of health [31]. CEA: carcinoembryonic antigen; CT: computed tomography; GP: general practitioner; iFOBT: immunochemical fecal occult blood test; RFA: radio frequency ablation.

Some topics highlight common concerns among patients with cancer. For example, cluster 1 revolves around sharing apprehensions about doctors' recommendations and whether seeking a second opinion is necessary. Additionally, under cluster 5, topic 37 indicates the negative feelings of hair loss due to the treatment. Still, some topics go beyond the designer's initial expectations. To give an example, topic 43 reveals patients' concerns about the genetic inheritability of cancer and whether their children should undergo genetic testing.

The designer uncovered new insights through reading the posts. Among others, topic 14 indicates that a significant number of patients use Traditional Chinese Medicine to manage their health, and topic 38 reflects patients' uncertainty about the scope of insurance reimbursement. Additionally, this sensitizing process fostered moments of empathy for the designer. For instance, summarizing topic 40 involved reading numerous posts from family members of patients with cancer, sharing their emotional struggles in coping with a loved one's illness. Similarly, topic 0 revealed the challenges patients face in adapting to life after being diagnosed.

Through the process of immersing in the posts, the designer gradually perceived the diverse contexts in which these topics occur. Some topics are situated in the hospital context, while others unfold entirely at home. Moreover, these topics span across various health-related categories, including physical, mental, and social health related to the three-dimensional theoretical framework of health [31]. Therefore, we introduced 2 dimensions to the 37 topics, classifying them based on whether they belong to the hospital or home context, as well as by the three-dimensional theoretical framework of health. These topics were visualized into the patient community journey map (Figure 6).

Almost all aspects of health are represented on the map when the topics are examined through the lens of the three-dimensional theoretical framework of health. This indicates that patients with CRC face a wide range of health issues, encompassing most of the categories outlined in Figure 3. The only category not represented is "role limitations due to health," corresponding to number 7 in the framework shown in Figure 3, which includes aspects such as sexual functioning.

XSL•FO
RenderX

We assume that this is because topics related to sexual health are highly private, and consequently, patients may be reluctant to discuss them on public social forums. Nevertheless, this does not imply that these issues are nonexistent but still need attention, as several studies highlight significant challenges in the sexual lives of patients with CRC, such as sexual dysfunction [36-39].

Topics under the hospital context are mostly related to physical health, pathological knowledge, medical procedures, and medical systems. Conversely, topics within the home context primarily revolve around daily life, social interactions, and personal reflections. Patients tend to approach discussions within the hospital context in an objective, rational, and focused manner, while discussions within the home context tend to be more emotionally charged and subjective in their descriptions, aligning with our previous research [34].

In addition, a closer reading of the topics reveals a notable trend: patients' mental health is frequently influenced by their physical condition. For example, cluster 5 expresses that side effects often cause a lot of physical pain and daily inconveniences, which can be quite stressful for the patient and further affect mental health. This trend is also observed between social and mental health, usually occurring in the home context. For instance, as illustrated in topic 28, patients may experience strong emotional responses to shifts in their social relationships, largely depending on whether these changes are beneficial to them.

Turning to the right side of Figure 6, namely, in the follow-up stage, there is a significant increase in the number of topics in the home context compared with the number of topics associated with the hospital context. Topics such as sharing experience on being fit again (topic 35) appear in this area, demonstrating that patients pay more attention to life in the follow-up stage. As patients become more accustomed to living with their diagnosis, their acute clinical anxiety typically decreases, allowing them to redirect their energy toward social interactions and daily activities. Therefore, social- and mental-related topics are also emerging actively at this stage. Patients gradually become aware of changes occurring in their surroundings. For example, they notice changes in their relationships with friends (topic 47) and illustrate the importance of spending moments with family members (topic 13). These changes are frequently attributed to the impact of cancer and can also lead to emotional fluctuations in the patient. The patients even began to deeply reflect on life, such as being more resilient in the face of fear and death, and share their thoughts with their peers, as observed in topic 46.

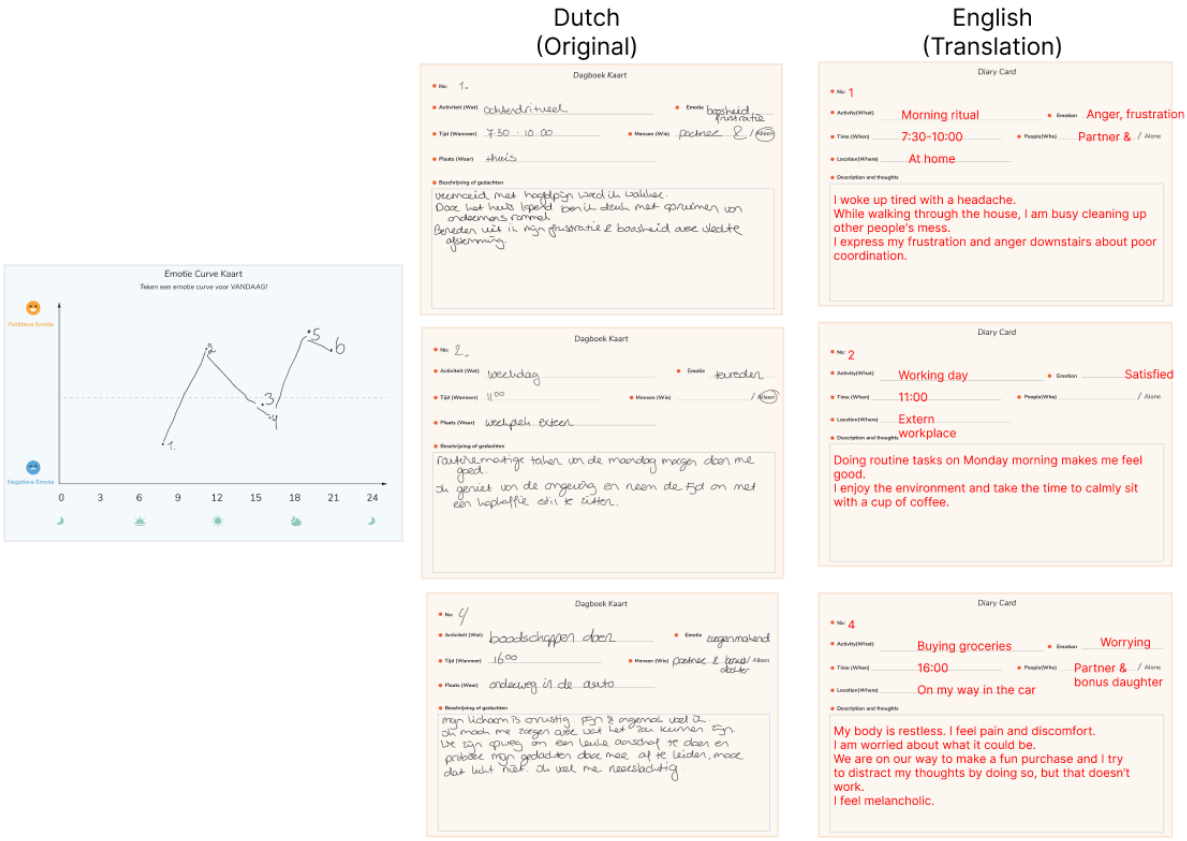
By contrast, during the diagnosis and treatment phase, patients frequently prioritize attending to their physical well-being, such as being worried about upcoming scans and results (topic 9) and numbers in the result of a blood test (topic 49).

Module A Summary

In this case, patient community journey mapping acts as an example to illustrate how large-scale patient research of module A can be conducted. We applied natural language processing techniques to analyze 212,107 posts from patient forums and categorized them into 37 topics. These topics were further classified into 2 dimensions and mapped onto the patient care path.

Since the designer previously lacked knowledge about CRC, this method provides an empathetic and effective starting point, allowing the designer to perceive the context by reading numerous patients' stories and posts. This indirect dialogue not only contributes empathetic and generalized context to the designer but also allows the designer to have adequate preparation for the patient engagement research in module B.

In module A, the designer not only gained insights into patient experiences throughout the entire care journey but also reframed the research question as follows: How can remote patient monitoring be developed for the follow-up stage with a focus on patients' social and mental health? This insight emerges from the patient community journey map, echoing that current remote patient monitoring primarily focuses on physical health aspects, such as tracking vital signs while paying relatively little attention to social and mental health. A gap therefore exists, potentially linked to the limited awareness of patients' social and mental health outside the clinical setting. As a result, it is important to build a remote patient-monitoring system related to social and mental health.



Module B Results

Overview of Module B Results

The designer observed significant fluctuations in most patients' emotions throughout the day (Figure 7). These emotional variations are closely linked to specific events or activities. Specifically, emotions are highly correlated with the 5W1H. When patients describe their emotional fluctuations, they often mention the involvement of individuals or the locations where these emotions were experienced. Being alone can also trigger emotional changes in patients, usually associated with past events or experiences, where memories induce emotional responses.

XSL•FO
RenderX

Figure 7. An example of a completed diary card from a patient with colorectal cancer.

During the study, the designer observed that patients frequently discussed challenges related to their energy levels. Many participants reported experiencing a significant decline in energy following their cancer diagnosis, which restricted their ability to engage in daily activities. For example, participant C expressed that the persistent lack of energy caused considerable frustration:

> *I often feel like I want to do something...but it's very difficult. My body, brain, and mind are not as active anymore...If something takes too much energy, it makes me feel very frustrated.* [Participant C]

Social engagements are also significantly connected to energy levels. Participants reported that their social circles include more patients, providing mutual support. Patients consider this peer support crucial. However, it also brings certain challenges. Due to their reduced energy levels compared with before their cancer diagnosis, maintaining relationships with old friends, especially those living far away, has become increasingly difficult. As participant D mentioned:

> *I'm glad to have friends who are in similar situations as me...and we support each other. However, I also find it difficult to maintain some relationships...I have a good friend who lives a two-hour drive away. In the past, meeting her was easy because driving was not a problem for me, but after the surgery, it has become a bit difficult.* [Participant D]

Regarding their attitudes toward the prototype and tracking progress, the 4 participants have a very positive attitude. Although 1 patient (participant A) did not complete the study as required, she said that she enjoyed the process very much. The difficulty she found was simply due to the timing, as many years had passed since her CRC diagnosis. "If I had been invited to do this study five years ago, I am sure there would have been very much to record," explaining her incomplete entries. This also highlights the necessity of early monitoring, given that patients experience much more severe social and emotional fluctuations initially than they do years after diagnosis. Most participants expressed that the process of recording their activities and emotions had heightened their self-awareness and facilitated a deeper understanding of themselves, as the following quotation illustrates:

> *It (the prototype) can make you think more about the activities and how you feel about it. For me I am shocked to see how I feel.* [Participant B]

This self-awareness enables patients to be aware of what activities can have an impact on their mental health:

> *It was for me a bad week. I wasn't feeling well and then because of it (prototype) I was very aware that my best friends were my biggest triggers. So I understand more on what happened between them and me.* [Participant C]

Some patients have reported that the prototype can influence their way of seeing a day and even subsequent behaviors in a positive way:

XSL•FO
RenderX

> *When I think I had a bad day, I look back at the diary and I think, oh, it wasn't so bad. There were just two bad moments...And what this awareness brings as extra is some influence on me...On the third day of the diary study, I realized I didn't have my mindful moment like before which made me realize that it is so important to me, so I'll pick up again.* [Participant C]

Patients also expressed that they like the prototype more than the questionnaire because it is more personalized and attractive:

> *I prefer this one (prototype) because it's about me.* [Participant A]

> *I really like this...The process is like a story that I can look back on from time to time. I am also tracking myself on diet and weight...* [Participant D]

When it comes to sharing their data with stakeholders, patients expressed both cautious and positive attitudes. They felt that sharing information about their daily activities and emotions with doctors could help foster a better understanding of their overall well-being. Patients also perceived that health care providers often paid limited attention to their everyday life conditions and emotional states. As a result, these aspects were frequently managed independently by patients, although they had a substantial impact on their health:

> *I am willing to share with my doctor, especially when I think I need help. Because I also understand that doctors are very busy...it's really nice to share your story with other patients that...I woke up and then I got a leakage again. And there is a lot of information I would share with them.* [Participant D]

Module B Summary

Module B used the diary study and follow-up interviews to study 4 patients, mainly to explore the possibility of remote monitoring of activities and emotional well-being in the follow-up phase. Overall, the patients' attitudes toward the prototype were positive, although there are still several limitations that require further design iterations and refinement. However, the diary study helped us to conduct a preliminary trial of remote patient monitoring and gain a deeper understanding of the patient's daily life after surgery. The interviews helped us understand the patients' attitudes and expectations about remote patient monitoring. It also pointed out the possible impacts of remote patient monitoring on patients and key considerations for future implementations. The results of module B are very inspiring for the design of the monitoring system.

Discussion

Mixed Methods and the Evolving HCD Context

Emerging research shows the benefits of using mixed methods in patient research, including support for investigating complex health care processes and systems and identifying improvement opportunities [40-42], and the patient data from both qualitative and quantitative research are significant for patient-centered improvement [43]. Despite these benefits, the use of mixed methods in the early HCD process remains underdeveloped, lacking clearly defined best practices and implementation approaches.

Meanwhile, a more system-level perspective in the HCD is required in contemporary practice. Recently, HCD has evolved into 5 principles of humanity-centered design that integrate ecosystems and community perspectives more comprehensively than the 4 principles of HCD, which are solving the core issues, focusing on people, taking a systems point of view, and rapid iterations on interventions [44]. Continually testing and refining proposals is therefore necessary to ensure that they truly meet the needs of the people for whom they are intended. A closer look at this brand-new principle reveals: "Design with the community and as much as possible support designs by the community. Professional designers should serve as enablers, facilitators, and resources, aiding community members to meet their concerns [44]." It requires the designers to take actions not only individually but also from a community or even system level, which corresponds with other research from the view of human-computer interaction [45]. Thus, designers need to understand not only the patients themselves but also the environment and systems around them. It implies that research methods should evolve by combining emerging technologies.

Our experience shows that the mixed method of large-scale research and in-depth research can play an essential role in the beginning of the HCD process. The possible implementation of this method is explored by a case study about the development of the remote patient-monitoring system for patients with CRC. It is important to emphasize that this data-enabled mixed method is not intended to replace traditional qualitative approaches (such as standard interview-only or ethnographic methods), nor do we claim it is universally superior. Rather, it serves as a complementary approach that leverages emerging digital technologies to uncover new possibilities within user research. Compared with other mixed methods, the difference is involving large-scale digital research such as big data analysis in module A, followed by patient engagement research.

Connection Between Module A and Module B

The connection between module A and module B relies on combining broad and deep analysis, reframing the problem, and translating data into designer empathy.

First, the 2 modules, where module A's big data results and module B's in-depth insight, worked as a unified process to ensure both breadth and depth. The large-scale analysis in module A established a macro-level understanding of the persistent social and mental health struggles facing patients with CRC, which acted as a research scope for the entire process. This scope was then brought into sharp focus by module B, where the in-depth engagement with the 4 patients provided the concrete lived experiences that humanized the patterns identified in the big data. During the interviews, the participants' words did not simply validate the previous findings but extended them by illustrating how these social and mental challenges manifest in daily life. This connection shows that module A provided the necessary generalizability to scope the research, while module B provided the contextual precision to interpret the findings.

XSL•FO
RenderX

Second, module A facilitated the process of problem reframing. Through the analysis of 212,107 posts, our patient community journey map revealed that patients with CRC in the follow-up stage shifted their focus from clinical recovery to social and mental well-being. By contrasting these large-scale digital insights with existing literature, we identified a critical gap: current remote patient monitoring systems overlook the psychosocial dimensions of home-based recovery. This finding directly dictated the scope of the prototype design, shifting it from simple physiological tracking to a system designed to capture daily activities and emotional nuances.

Finally, module A provided a foundational understanding that informed the design of the engagement prototype in module B. An immersion into the patient experience allowed the designer to develop a rich understanding of the participants' lived realities. By navigating 37 topics and 10 clusters, the designer internalized the emotional landscape of patients with CRC. For instance, when analyzing topic 28, the designer was exposed to the intimate struggles surrounding family relationships and the resulting emotional volatility. This process of deep engagement with patient narratives enabled the designer to move beyond clinical observations and truly resonate with the patients' underlying anxieties and needs. Consequently, this developed empathy acted as the primary design driver: the designer was moved to incorporate an emotion curve tracking task and specific emotional reflection prompts into the diary study. By transforming these internalized emotional insights into practical research materials, the designer ensured that the engagement activities in module B were designed not just to collect data but to resonate with the patients' most pressing social and mental health challenges.

Potential Values of the Data-Enabled Mixed Method

The preliminary findings suggest this data-enabled mixed method has the potential to help health care designers acquire representative insights that reflect patients' perspectives, develop an empathetic understanding to navigate the complexities of medical contexts, guide the definition of research and design directions, and support the creation of engaging research activities. Together, these capabilities provide critical, informed insights that enhance the effectiveness of patient engagement research. In the following sections, we will illustrate these values in detail by addressing the 3 challenges outlined in the introduction.

Addressing the Current HCD Health Care Design Challenges

This case study also provides preliminary evidence that using the data-enabled mixed method has the potential to address the challenges of the current human-centered health care design process involving patients, which are (1) high vulnerability of patient participants, (2) less diverse and representative patient groups due to recruitment challenges, and (3) insufficient problem framing across diverse patient experiences.

The first challenge describes the vulnerability of patient participants. Our data-enabled mixed method tackles this challenge by cultivating designers' contextual sensitivity prior to patient engagement in the study. In our CRC case, the designer identified sensitive topics, necessary caution in words and behavior, and moments that require alertness before involving them. Meanwhile, the diary study and interviews in module B were more considerate of patients' vulnerability. For instance, based on insights from module A that patients with CRC often experience fatigue as topic 24 describes, we provided both online and offline interview study options. As shown in Table 1, 3 out of 4 participants chose the online option. For the participant who opted for an offline interview, the designer visited her home for a face-to-face discussion with her consent. Furthermore, as expected, patients also mentioned the impact of declining energy levels on changes in their daily activities and social circles during the interviews. The designer also gained insights into whether patients express positive or negative emotions when discussing these topics. Particularly when patients presented certain topics with highly negative emotions, the topics were given special attention during the interview process. This enables the designer to avoid language and actions that may cause discomfort or be sensitive to patients, or at the very least, have expectations and preparations for the upcoming situation. The respect for patients aligns with the proposal by Das and Svanæs, referring to "Particular considerations and facilitation is required when including vulnerable user groups in human-centered design activities [1]."

The second challenge, related to less diverse and representative patient groups due to recruitment challenges, can be effectively addressed by the combination of modules A and B. The large dataset of 212,107 posts given in module A contributed to mitigating the lack of representativeness caused by small samples [46]. The 37 topics related to patient experiences during their care path have been identified from these posts, with thousands of posts associated with each topic. Furthermore, we realized that many of these topics align with the ones discussed during the patient engagement studies in module B. For example, participant D illustrates the mutual support shared among patient peers, which also reflects in patient posts of sharing strategies for coping and improving quality of life during the follow-up stage. However, some of the topics found in module A were more detailed and did not show up in module B. For example, topic 43 revealed patients' concerns about the potential hereditary nature of CRC and topic 3 highlighted the significance of anniversaries and birthdays to patients. These findings, which were not evident in the diary study, yet represent intriguing new insights. These representative outcomes provide shared insights from different demographic patient groups and can be applicable to a wider system.

The third challenge concerns the reframing of problems from the patient perspective during the early stages of HCD. The potential of our method in addressing this challenge has been discussed in the previous section (Connection Between Module A and Module B), where we highlighted that conducting large-scale patient research can help reframe research and design problems. If module A had not been conducted and a more solution-driven approach had been adopted instead, the focus might have been on features such as information registration, symptom monitoring, patient education, and personalized advice. Consequently, the social and mental health needs of patients might remain overlooked or fail to emerge as explicit areas of

XSL•FO
RenderX

concern. Our method encourages designers to define research and design questions based on the diverse and in-depth perspectives of patient voices. For instance, designers can easily learn that patients with CRC need to undergo blood tests to monitor treatment effectiveness. However, it was only through topic 49 in module A that the designer realized that the numerical results of these tests can cause emotional instability for a large number of patients. The rich context obtained from the large-scale data can not only identify problems within complex health systems [47] but also contribute to designing desirable experiences [48].

Limitations

Naturally, this data-enabled mixed method has certain limitations. From the perspective of organizations, designers may lack proficiency in handling large-scale data. The data processing process would require the involvement of computer scientists. Although interdisciplinary collaboration is beneficial to the design process, in practice user research in HCD itself has been proven to be time-consuming and costly [49], and collaboration with computer scientists may exacerbate this phenomenon. It is therefore necessary to explore further how to effectively work together with data scientists. While the vastness of the data helps obscure individual identities, ethical and privacy concerns still demand rigorous attention. When collecting raw data, researchers must selectively gather information to ensure complete anonymization.

In addition, a notable limitation of this case study is the selection bias inherent in using English-language online forums, which excludes those with limited digital literacy or non-English proficiency. To mitigate this, we engaged local domain experts from Rotterdam, an area with a high concentration of underserved and diverse patient populations, and further enriched our data through interviews with Dutch-speaking patients in module B. However, due to the small sample size in these engagement phases, our findings may still underrepresent marginalized or offline populations. Future research should incorporate multilingual, multiplatform datasets and larger, more diverse cohorts to enhance generalizability.

Another potential limitation of this case study is that relying on a single designer restricts the capacity for independent cross-validation. While the expert cocreation sessions in module A helped mitigate this risk, future applications should ideally involve a larger interdisciplinary team to independently cross-analyze the modules, thereby further minimizing subjective bias and enhancing overall reliability.

Although the proposed approach was empirically applied to the specific context of CRC, the results indicate preliminary feasibility rather than definitive proof of the method's applicability across diverse health care domains, care paths, or varying team structures. Additionally, the small sample size in module B (n=4) restricts the generalizability of the qualitative findings in this case, precluding a comprehensive evaluation of the prototype's efficacy or definitive design requirements. However, the primary objective of this study was to explore the feasibility and values of the methodological pipeline. Within this scope, the small-scale engagement shed light on preliminary insights into how qualitative interactions can contextualize, ground, and humanize the broad insights derived from the massive data in module A, ultimately addressing the challenges encountered by health care designers in the initial design stage.

Future Research

Building upon the limitations identified in this exploratory case study, future work should prioritize rigorously validating the method's generalizability and establishing best practices. Since our current findings represent preliminary indications based on a CRC case, future comparative studies and multiple case studies across diverse health care domains and different disease care paths are required to establish robust evidence.

Furthermore, to mitigate the selection bias inherent in online datasets, subsequent applications of this data-enabled mixed method should incorporate multilingual datasets from diverse geographical platforms. During the engagement research phase (module B), researchers should also explore the specific contexts of the participants, particularly investigating whether their situations reflect the experiences of marginalized populations, such as non-English speakers or individuals with limited digital access.

In addition to diversifying the data platforms, as longitudinal datasets are increasingly integrated into this process, future studies using this data-enabled mixed method should consider and validate the temporal insights to ensure that they reflect current state-of-the-art practices. To explain this within the context of our case, researchers using longitudinal online datasets must be mindful of the temporal dimension. This caution is necessary because while certain patient experiences, such as psychosocial challenges, often remain consistent over time, specific medical contexts, such as treatment modalities, surgical advancements, or evolving care protocols, can undergo rapid technological shifts.

While this method has initially centered on patients, future research should expand to include other stakeholders, such as caregivers and health care professionals, thereby fostering a more holistic design approach. In parallel with expanding the participant scope, future practices could also explore methodological flexibility. For instance, although we currently recommend conducting module A before module B, researchers might alternate this sequence by using large-scale digital research to validate prior in-depth qualitative findings. Ultimately, to support these methodological advancements, integrate emerging technologies, and mitigate the risk of confirmation bias, continuous interdisciplinary collaboration among health care designers, data scientists, and health care professionals is essential. Such team-based approaches will enable cross-validation of the results in both modules and establish standardized, objective best practices.

Conclusions

This paper highlights the trend of HCD adopting a more system-level perspective, which introduces challenges for health care designers at the early stages of patient-focused design, including (1) high vulnerability of patient participants, (2) less diverse and representative patient groups due to recruitment challenges, and (3) insufficient problem framing across diverse patient experiences. To address these challenges, we propose a

XSL•FO
RenderX

data-enabled mixed method combining large-scale digital patient research (module A) and in-depth engagement research (module B).

We explore this approach through a case study of CRC follow-up care, using patient community journey mapping (module A) and diary studies and interviews (module B) to inform the development of a remote patient-monitoring system.

Based on this specific case study, there are preliminary indications that this method has the potential to support problem reframing and cultivate empathy toward patient vulnerability before conducting engagement research. By capturing the diversity and depth of patient voices within this context, it generated evidence-based insights that appeared to enhance the design of subsequent patient engagement activities. While these initial findings are promising, future research across broader health care contexts is needed to generate generalizable evidence.

Acknowledgments

The authors thank all the patient participants and the computer scientist for their valuable contribution. Google Gemini 3.1 Pro was used for correcting grammatical errors and enhancing readability.

Funding

The authors declared no financial support was received for this work.

Data Availability

The datasets generated and analyzed during module A are available from the corresponding author on reasonable request. The data gathered during module B are not publicly available and cannot be shared due to confidentiality and original ethics approval restrictions.

Abstract

Background: Participatory co-design is a design approach that involves end users in intervention design and its use in health care applications has become widespread. Traditionally, co-design has been conducted in person in a laboratory-based setting; however, it has recently shifted to being performed remotely. Remote co-design has the potential to overcome some of the limitations of traditional in-person approaches, including expanding a study's geographic reach, recruiting participants from underrepresented groups, reducing power imbalances between researchers and participants, and enhancing engagement through online tools. Given these benefits, further reporting and refinement of remote co-design methods are needed.

Objective: This paper's objective is to present our Remote and Accessible Participatory Intervention Design (RAPID) method and discuss the choices and challenges we encountered adapting participatory co-design for remote use.

Methods: We adapted our previously developed 5-step in-person participatory co-design method for health intervention design. To apply the adapted co-design method, we recruited 2 groups of 5 participants (one of older adult pharmacy patients and the other of pharmacy staff) to design a digital kiosk for use by older adults to promote safe over-the-counter medication purchases in retail pharmacies.

Results: Adaptations made to the co-design process were classified under the following categories: facilitation; collaboration, communication, and sensemaking; accessibility and universality; tangible tools and games; and research compliance. Anecdotally, the remote co-design process took longer when compared to in person due to shorter sessions and between-session refinement, but it allowed for flexible scheduling and makeup sessions when required.

Conclusions: Our RAPID method offers an approach to remote co-design that other teams can implement or adapt to their needs. Our experiences with RAPID identify certain drawbacks to remote co-design; however, these are balanced by advantages in convenience and flexibility.

Introduction

Centering patients in health intervention research has become a priority to ensure that interventions align with the patients' needs, values, and priorities [1-6]. Patient-centered interventions are more likely to be adopted and implemented, maximizing their impact [6,7], and there is evidence that they result in improved health outcomes [8]. Participatory co-design methods are a formal way to involve intervention end users in product or service design to directly center user needs (eg, usability, acceptability, and usefulness) [9] including those of patients to design patient-centered interventions [1]. With the rise of the "digital health citizen" [10-12]— empowered patients who are active consumers and generators of their own health data—the demand for patient-centered tools and services will only increase. Co-design with patients and informal caregivers has been increasingly adopted in healthcare systems design to address these demands [13].

Traditional participatory co-design is performed face-to-face, requiring end users to physically travel to a secondary location

XSL•FO
RenderX

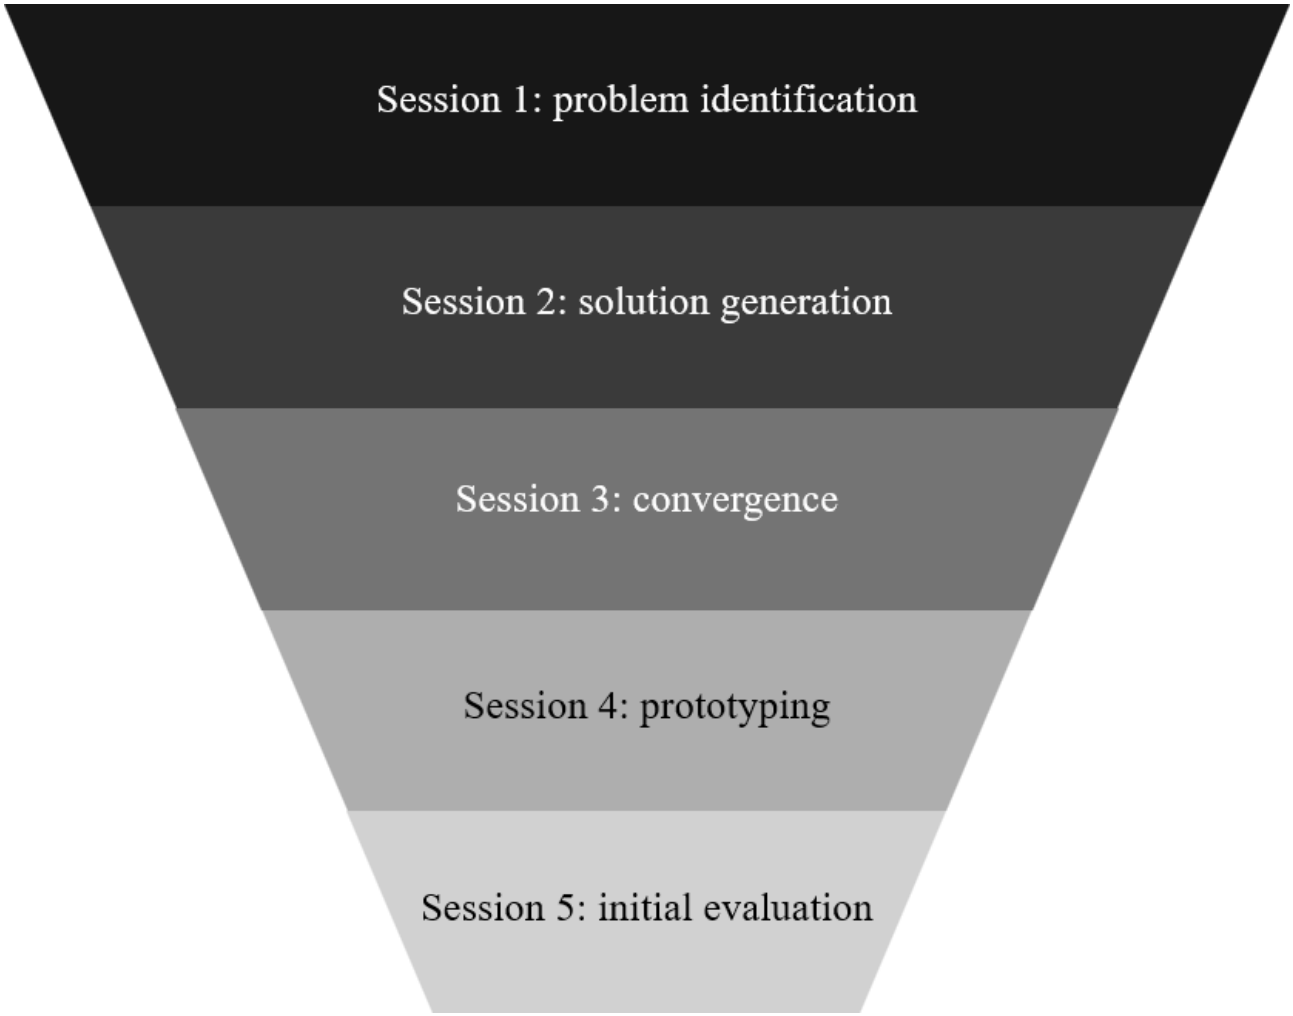
to attend activities such as design workshops. Remote approaches to co-design had been considered before but became necessary during the COVID-19 pandemic [14]. Since then, remote co-design has been performed with various populations of interest including children [14-16], racially underrepresented young adults [17], and caregivers of patients with dementia [18,19]. The applications have been similarly heterogeneous from supporting antibullying [16] to helping family caregivers with legal and financial planning [18,19].

While there are challenges to implementing participatory co-design (eg, differences in familiarity with technology and difficulty aligning goals and language of various stakeholders) [20], remote co-design may have advantages over traditional face-to-face approaches. Pioneers of remote co-design methods report recruiting participants from wider geographic areas [15,21] and extending their study's reach to populations sometimes excluded from research [15,17]. The remote format can also facilitate certain user interactions. Bertran et al [21] described how study facilitators and designers were able to disappear "behind the scenes" to attain a more naturalistic perspective of participants interacting with their prototype. Similarly, Fails et al [14] reported that the lack of researchers' physical presence balanced some of the child-adult or facilitator-participant power dynamics. Additionally, some online features such as chats during video calls enabled more participants to engage, respond, and discuss [17]. Some remote co-design methods (eg, surveys and asynchronous feedback) also enable the collection of large amounts of data when compared to small studies conducted in person [22]; this is especially important when considering the big data implications of widespread digital health use and data generation. With the benefits becoming increasingly apparent, it is imperative to report on and improve upon the use of remote participatory co-design methods.

This paper's objective is to present our Remote and Accessible Participatory Intervention Design (RAPID) method. There is a clear need to develop RAPID because, while there have been some methods-focused or instructional papers on remote co-design [14,23,24], we have not found any that specifically focus on engaging older adults in remote co-design. RAPID addresses this gap as it was adapted specifically for older adults and has been used successfully with older adults in other studies [18,19]. There are challenges in engaging older adults in digital research: the digital divide persists with fewer older adults using the internet [25], having access to broadband internet at home [26], and owning a smartphone [27] when compared to other demographics; and older adults are stereotyped as having less technological ability than younger adults [28]. However, older adult technology adoption is growing [27,29]. Nearly 1 in 5 Americans is over the age of 65 years (18%) [30], and this age group experiences more chronic diseases. It is important that digital health interventions are designed centering older adults as they are likely to be widespread users in the future.

In this paper, we discuss the choices and challenges we encountered in adapting participatory co-design for remote use. Building on existing work, we organize our results using the framework outlined in Mallakin et al [23]. We hope this method will be useful for others designing patient-centered interventions for older adults and potentially other populations who may experience challenges with co-design, and that it will encourage further involvement of older adults in digital health intervention design.

Methods



Overview

The RAPID method was originally developed for and applied in a specific study [31]. However, it was also envisioned as a formative method that could be adopted for future studies, further observed in practice, refined, and adapted over time. The initial study, called Senior Station, had the goals of co-designing and testing a technological intervention (a kiosk) to support older adults in making safer over-the-counter (OTC) medication decisions by providing them with information on which medications had ingredients that may not be safe for their brain health. More detail on the intervention designed can be found in a separate publication [31].

To develop RAPID, we adapted our previously developed 5-step in-person participatory co-design method (Figure 1) for remote delivery. This funnel framework was developed for health intervention design in an older adult OTC medication decision-making study [32] and subsequently applied in a broad array of projects and settings [18,19,31,33]. Details on each RAPID session and how we adapted them for remote settings are described in the results section.

XSL•FO
RenderX

Figure 1. Remote and Accessible Participatory Intervention Design (RAPID) co-design stages.

To apply RAPID, we recruited 2 groups of 5 participants each (N=10): one of older adult pharmacy patients and the other of pharmacy staff. All participants were recruited from a large pharmacy chain retailer in the United States.

Older adults, aged 60 years or older, were those who had previously purchased or planned to purchase OTC medication, could communicate in English, and were able to join a video call from a computer, tablet, or smartphone. Potential participants were approached in person by a member of the research team at the pharmacy retailer and were screened for eligibility if they expressed interest in participating. The research team member reviewed a paper study information sheet and obtained verbal consent. Participants provided their contact information for future coordination to attend the remote design sessions.

Pharmacy staff were pharmacists and technicians who had previous experience counseling older adults on the purchase of OTC medications, could communicate in English, and were willing and able to join a video call. They were recruited via the research team's professional contacts at the same retailer from which older adults were recruited and filled out an online survey with their contact information if they were interested in participating. A member of the research team then contacted pharmacy staff, reviewed the consent form, obtained verbal consent for participation, and captured demographic information via a Qualtrics survey.

Each session was facilitated by 3 to 4 members of the research team. An expert in participatory co-design facilitation acted as "master of ceremonies." The "master of ceremonies" was responsible for leading the agenda, guiding the participants through co-design activities, and prompting participants to assess each other's design ideas. In later sessions, the same individual guided participants to review solution prototypes. The second role in each session was an administrator or "problem solver." They ensured participants had the information and resources they needed to participate in the study. This role was critical to help some participants troubleshoot technical issues during the session. The third role was a human-computer interaction expert who observed participants' design ideas through the lens of implementation and usability. Their role during the discussion was mainly asking clarifying questions. Finally, a scribe participated in the sessions to capture participant ideas in real time. In our study, this person was a design student who was also able to sketch prototypes in real time.

The 5 steps of the RAPID method were adapted for remote delivery as shown in Table 1.

The observations in the following sections are based on team self-reflections and a review of notes, correspondence, and other

XSL•FO
RenderX

documents over the course of the project. There was no systematic method in place for the analysis of the results of the RAPID sessions.

Table . Remote and Accessible Participatory Intervention Design (RAPID) procedure for remote co-design.

Step	Procedure	Remote approach
Problem identification	• Introduce the research team and have participants introduce themselves. • Have participants describe their experiences with the challenge or situation of interest (eg, tell a story) • Visually represent these stories using journey maps to identify pain points and targets for intervention • Explicitly introduce the concept or challenge the design seeks to address • Present different choices or scenarios to participants to determine what factors are most important (eg, do cost savings outweigh warnings of risks) and which design features are more desirable	• Videoconferencing (Zoom; Zoom Communications Inc) • Microsoft PowerPoint presentation on shared screen • Turn-taking • Heavy facilitation and experienced facilitator
Solution generation	• Present a problem scenario to participants with an undescribed solution to help them • Guide participants through brainstorming the design of different aspects of the solution, such as size, information communicated, advertisements, features, and symbols. • Have participants roughly sketch their designs on whiteboards and present them to the group. This enables participants to express themselves creatively, provide diverse perspectives, and turn abstract ideas into something tangible. • Take photos or some other record of the drawings	• Videoconferencing (Zoom) • PowerPoint presentation on shared screen • Turn-taking • Heavy facilitation and experienced facilitator • Whiteboards mailed to participants before the session • Photos of drawn designs taken over Zoom or by participants and emailed to the research team
Convergence	• Present low-fidelity, hand-drawn designs to participants based on ideas in previous session. Low-fidelity prototypes make it clearer to participants that design ideas are preliminary and not “set in stone.” • Walk through the sequence of use of design, seeking feedback on each design and making it clear that designs were flexible. • Ask participants to provide more details (eg, specific information and what is prioritized) on designs. • The goal is to converge the multiple designs into one with which to proceed.	• Videoconferencing (Zoom) • PowerPoint presentation on shared screen • Turn-taking • Heavy facilitation and experienced facilitator • Hand-drawn designs on a tablet or computer and shared on screen during session
Prototyping	• Present a higher-fidelity prototype (eg, a clickable wireframe) that is the result of feedback from the previous session. The higher-fidelity prototype made the design feel more real and indicative of the final intervention. • Solicit feedback from participants	• Videoconferencing (Zoom) • PowerPoint presentation on shared screen • Turn taking • Heavy facilitation and experienced facilitator • Prototype in Figma (Figma, Inc.) and presented on screen during session
Initial evaluation	• Present the final design based on the design sessions from both participant groups • Solicit feedback from participants	• Videoconferencing (Zoom) • PowerPoint presentation on shared screen • Turn taking • Heavy facilitation and experienced facilitator • Prototype in Figma and presented on screen during session

RenderX

Ethical Considerations

This study was approved by the Indiana University Human Research Protection Program (institutional review board number 13200) and co-design sessions occurred from January 2022 to November 2022. Participants were compensated US $50 in gift cards for each session they attended in addition to bonus payments as incentives to avoid participant attrition: US $100 bonus for attending all of the first 3 sessions or US $250 bonus to attend all 5 sessions (for a potential total of US $500 in compensation). A research team member reviewed a paper study information sheet with participants and obtained verbal consent. All participants were able to opt out of the study and terminate their participation at any time. Any transcripts and meeting notes generated during sessions were de-identified to protect confidentiality and privacy. Session photos of participant designs or sketches did not contain any identifiable information.

Results

Here we describe our adaptations, organized retrospectively using Mallakin et al's [23] framework for considerations for remote co-design.

Facilitation

Definition

Facilitation is the process by which designers and researchers "set the scene," then guide participants through the design process to stimulate creativity and generate collaborative design solutions.

Remote Considerations

Remote facilitators may not be aware of the physical space or equipment limitations or assets of the remote co-designers. They cannot directly set up, demonstrate, or manipulate the co-designers' physical design space or equipment and are more constrained in their strategies to establish trust, open dialogue, or rapport such as one-on-one time, informal side conversations, or physical gestures. Remote sessions are typically shorter than in person, which are often day-long or half-day events.

Successful co-design activities rely on open conversation where participants generate prototypes, pitch ideas, provide feedback, and then build on one another's concepts. When online, this process is impeded because the ability to present ideas is limited and the nature of discussions is restricted. For example, it is hard to manage crosstalk during online discussions, which results in participants being more hesitant to contribute out of fear of interrupting another person.

While in-person sessions feel more like a collaborative group conversation, the online session requires significantly more facilitation. For example, in an in-person setting, it would be easy to look at 2 participant prototypes at the same time to compare them. That is much harder online and would require the facilitator to collect images of the prototypes before talking about them.

Our Approach

The co-design facilitator had extensive experience with in-person facilitation and anticipated what interactions could be replicated remotely versus required accommodation. The entire research team, including the facilitator, met extensively before the start of co-design activities to fully conceptualize the design problem and develop cases, scenarios, and prompts to guide participants through the design process. More time was allotted in the first session for rapport building with the research team and among the participants, using turn-taking to ensure everyone had a chance to speak. The facilitator was intentional to lead discussion and call on participants, as a countermeasure to the awkwardness of interrupting a speaker in an online format (due to audio delays, the abruptness of teleconference interruptions, and uncertainty about the source of interruption). Prototyping tools conducive to remote co-design were selected (eg, Adobe XD, Figma, and individual whiteboards). To facilitate co-designers' critiquing of each other, the facilitator guided participants to offer initial feedback then build on each other's initial ideas rather than directly grading designs.

Lessons Learned

The facilitator is important in remote settings because they must be skilled in co-design methods and adjust those methods to suit the setting. Facilitators cannot assume methods that work in person will be as effective online. They should also have strong technology skills for more seamless remote co-design meetings.

Remote settings can feel socially distant, impersonal, or more businesslike compared to in person. A facilitator needs to be intentional about creating a creative and open environment where participants feel comfortable working together. This could include focusing on friendliness by adding a joke to the session or asking pointed questions to get participants to talk about something they mentioned in passing.

Online meeting conventions and limitations (eg, one person speaking at a time, no cross-talk, and limited body language cues) can hamper study interactions. It often falls on the facilitator to smooth the conversation and facilitate group communication.

Facilitator expectations regarding how many design activities can be accomplished in each session need to be adjusted when performing co-design online. There are 2 factors of online co-design that impact a facilitator's time management. First, it is harder to hold participants' attention, thus favoring shorter sessions. Second, technical issues will arise in online sessions. Our team lost time during most sessions waiting for participants to join, troubleshooting technology issues, or clarifying instructions.

Collaboration, Communication, and Sensemaking

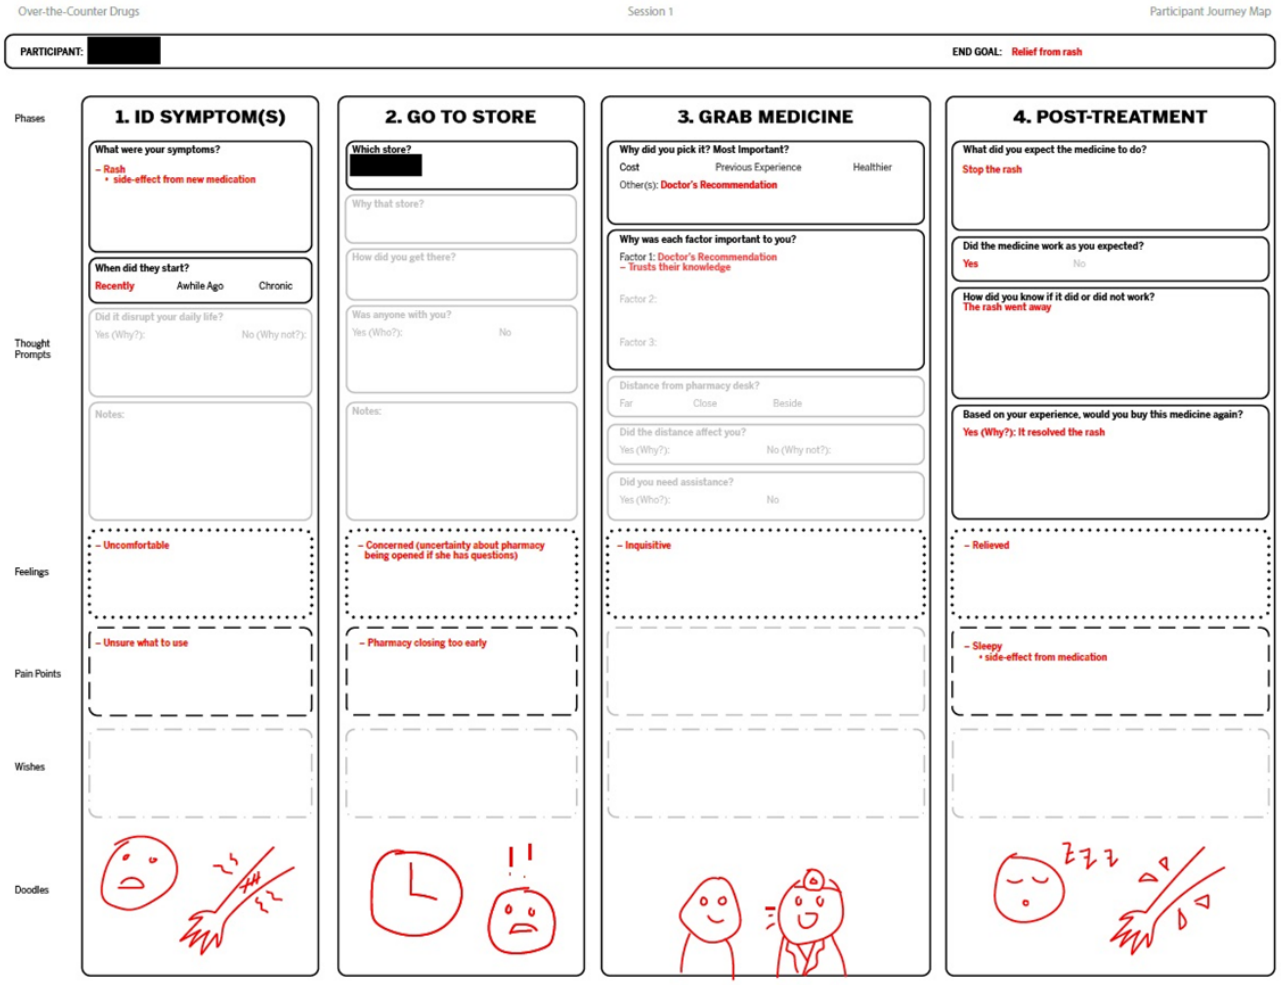
Definition

Collaboration, communication, and sensemaking are the processes by which participants work together with the research team to produce co-design.

Remote Considerations

Participants are not co-located in the same physical space (eg, a design studio) and must meet and interact virtually. There is no shared physical whiteboard, flip chart, or other materials to

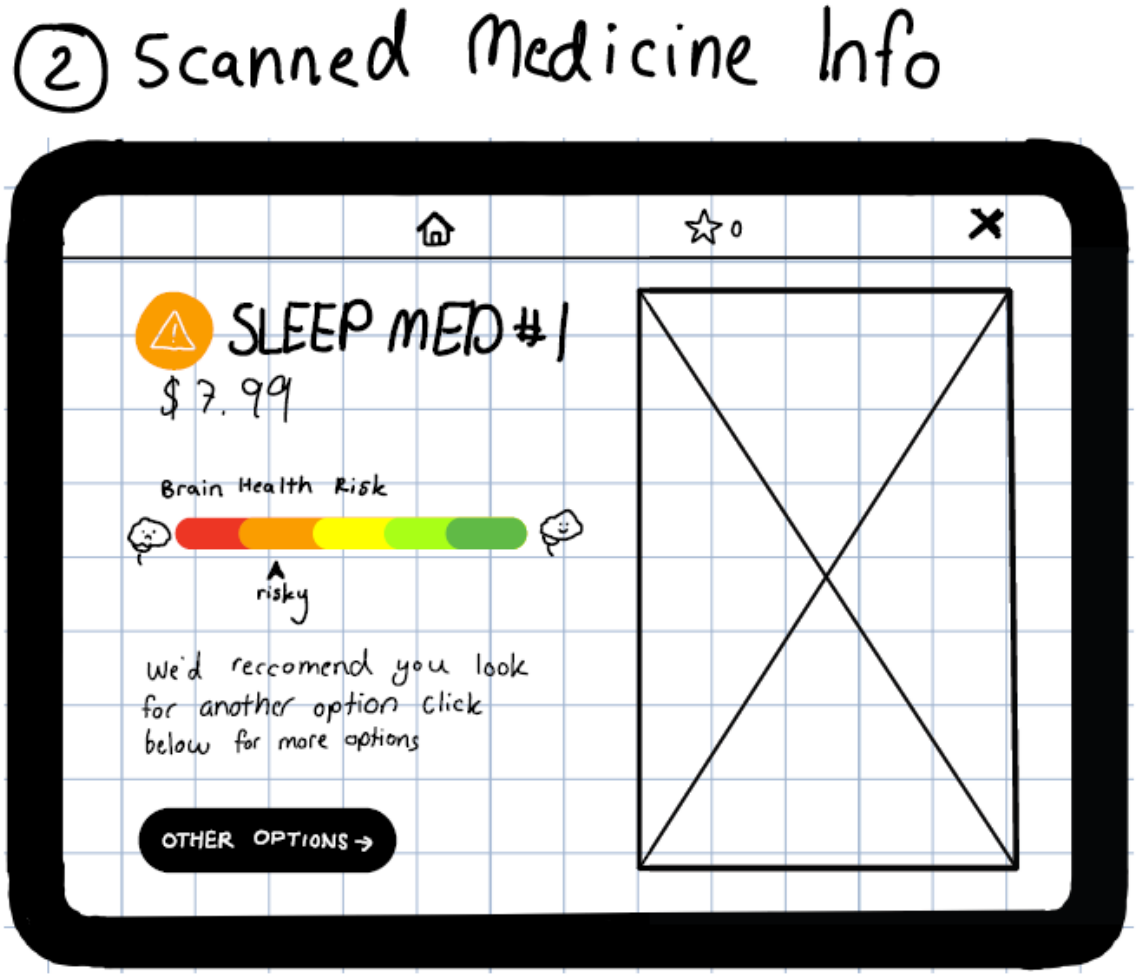
XSL•FO
RenderX



which every participant has real-time access to externalize their thoughts in a manner directly visible to others. Some designs, for example, those that are drawn or constructed on nondigital artifacts (eg, scrap paper) or have 3D elements (eg, gestures), may not be easily shared on a screen or will need to be digitized. Differences in familiarity and comfort with remote technologies may affect how individuals engage in collaboration, communication, and sensemaking.

Our Approach

To host online sessions, we selected Zoom videoconferencing software (Zoom Communications Inc) as it was freely accessible on a range of devices and operating systems, widely used during the pandemic, supported through the research team's institutions, and supported recording for later review and analysis. A design student attended our virtual sessions to take notes so that the facilitator could focus on supporting interaction.



A journey map template was created to help the designer capture notes in a manner that could be easily shared with others (Figure 2). Our designer created simple, low-fidelity wireframes summarizing the designs that could be easily shared online, but despite being digital, looked rudimentary enough to facilitate critiques (Figure 3).

Figure 2. Deidentified journey map notes.

XSL•FO
RenderX

Figure 3. Low-fidelity wireframe.

Lessons Learned

Conversation does not flow as naturally or collectively online as in person, so participants are disinclined to build on each other's ideas, implying they may perceive their roles as developing individual designs rather than a single co-owned design. Participants were frequently distracted in the online environment (phone calls, family members in the home, and so on) and felt more comfortable attending to distractions and multitasking.

The primary physical medium for online co-design, a 2D computer screen, is not as inherently a creative space as a 3D design studio. An atmosphere of creativity is therefore often created through the activities, words, and interactions of co-design rather than the setting. Physical tools and virtual environments could be used to increase creativity.

Participants did nevertheless develop a sense of community and comfort over the course of 5 sessions, despite being in a relatively sterile remote setting.

Accessibility and Universality

Definition

Accessibility and universality refer to the degree to which a wide and inclusive range of individuals can and do participate in co-design.

Remote Considerations

Comfort with technology and access to a stable internet connection are important considerations for remote co-design, especially with certain groups such as older adults. Unexpected problems (eg, technical difficulties) are more likely to occur in remote settings, and not every participant is equally adept at using online interaction features such as typing private or public messages, digital gestures (eg, raised hand) and reactions, electronic whiteboard, screen sharing, audio sharing, muting or unmuting, and hyperlinking. Communication can be hampered or interrupted by having to concurrently deal with technology issues such as typing, audio, video, switching windows, computer slowness, and internet connectivity. Not all participants joined from a desktop or laptop computer. Those who joined using cellphones were hampered by having smaller screens.

XSL•FO
RenderX

Our Approach

One member of the research team spent significant time outside of design sessions working with the participants, including the older adults, to ensure they could join a videoconference and practicing with them to increase comfort. In one case, this required live phone assistance prior to every session. We designated a "problem solver" to provide support for emergent accessibility needs such as troubleshooting technical difficulties and phoning participants who did not join the session on time. To compensate for participants joining from smaller screens (eg, cellphone), the facilitator spent time during the session explaining what was being shown on screen.

Lessons Learned

Including participants who were less comfortable with technology was a benefit, not a downside, of the remote co-design approach, as they provided a novel perspective that was especially important in our attempts to design universally usable technology for older adults. The problem solver was invaluable to the smooth operation of design sessions as they handled unexpected problems without disrupting the session for the facilitator, designer, and participants. The provision of technical support during and outside of sessions requires additional personnel and associated expenses.

Tangible Tools and Games

Definition

Tangible tools and games refer to the tools and games used to encourage participants' creativity and facilitate co-design work.

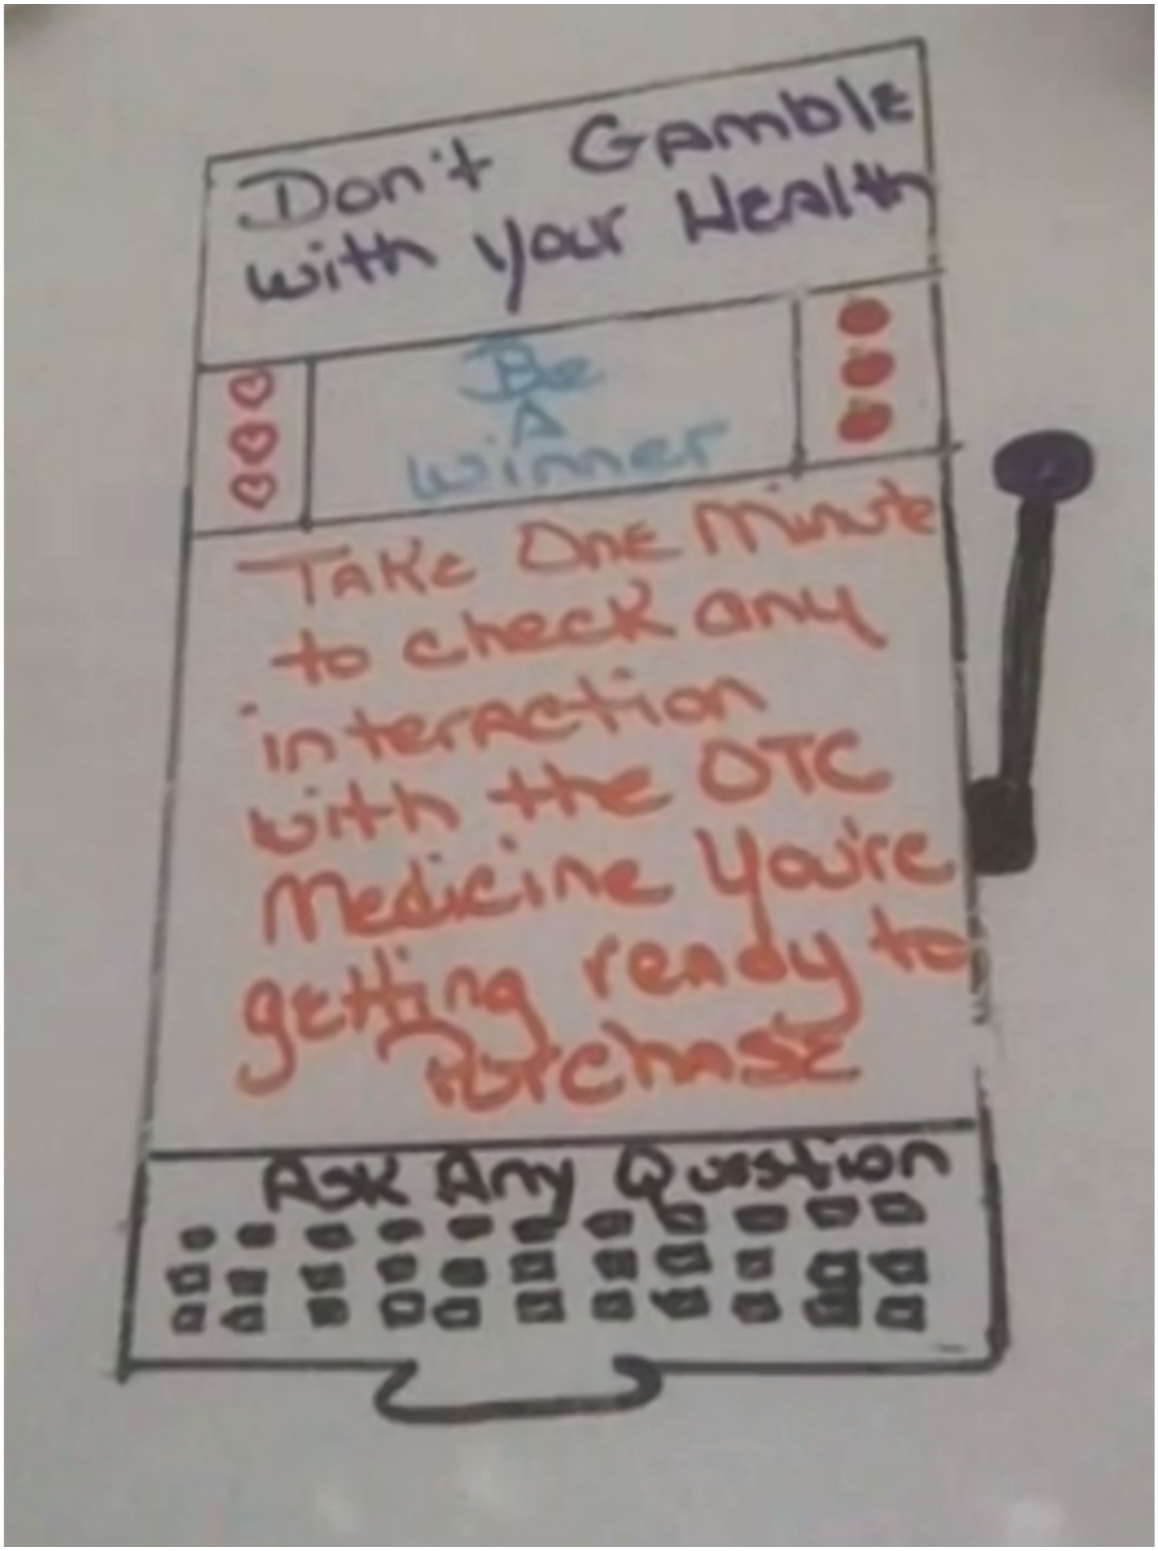
Remote Considerations

Traditionally, co-design tools and games are hands-on and require physical items. Games are often experienced in a playful, informal, low-risk context, whereas online meetings may be associated with formal, serious, and more sterile functions (eg, work).

Our Approach

Before each session, participants were mailed relevant materials for that session. This included prototyping tools or prototype concepts for their review. We provided personal whiteboards and markers to participants, mailed directly to their homes by an online retailer. Some participants spontaneously did "homework" to create preliminary designs before the session, thus extending creativity beyond the time and space confines of the formal design sessions.

Lessons Learned



Not all traditional co-design tools and games could be translated to the online setting, and some could not be used. New or adapted tools need to be intentionally and innovatively planned to enable activities such as online sharing of participant-created prototypes. It is more difficult to adjust or introduce new tools or ideas in real-time online, and modifications to set schedules are often not well received or understood in online spaces. As such, remote sessions require additional planning and forethought. The spirit of fun and creativity of in-person games and activities felt constrained in online encounters. Our tools were limited to the software and hardware we chose to use, making it difficult or impossible to introduce ad hoc tools and activities often available in a traditional design studio.

Mailing whiteboards was a low-cost, low-tech option that provided participants the ability to do some design activities without a steep learning curve. Participants were easily able to photograph their whiteboard designs and send them to the research team. Other options were dismissed as too costly, complex to learn, or disruptive to the project timeline.

Participants doing extra work between sessions produced creative designs (Figure 4) and may have increased reflection. It is possible in our project and in others that working between sessions would allow participants to engage others in their household, social network, or community to enrich their designs. In other cases, working independently could allow co-designers the ability to use novel tools such as generative artificial intelligence that could stimulate their creativity and self-efficacy.

XSL•FO
RenderX

Figure 4. Participant design on whiteboard.

Research Compliance

Definition

Research compliance is the degree to which co-design adheres to the applicable ethical principles and requirements

Remote Considerations

When participants are in a public online gathering place, especially one that is being recorded, additional steps are needed to ensure privacy for participants and provide opportunities for participants to privately interact with researchers. While some physical affordances such as private rooms may have online analogs (eg, private breakout rooms), their use may not be as easy.

The physical setting for remote interactions may be less controllable for researchers and co-design participants who may be joining from a shared space such as their home, workplace,

XSL•FO
RenderX

or coffee shop. This impacts both privacy and confidentiality considerations, particularly when using video or audio recording.

Our Approach

We conducted recruitment and informed consenting in person in community pharmacies, rather than during the online sessions, and provided older adult participants with printed study information sheets. Sessions were hosted using institutional videoconferencing accounts (Zoom) for added security. Standard web-based data security approaches applicable to all forms of internet-based research (eg, deidentification of data, and storage of data on secure, approved servers) were used.

Lessons Learned

Participants do join remote co-design sessions from locations such as workplaces, homes, and cars, and those joining from work often turned off their cameras, which made conversations more difficult.

General Lessons

In addition to considerations inspired by the Mallakin et al [23] framework, implementing RAPID produced the following general takeaways.

Drawing on our prior experience with in-person co-design, we observed that the remote co-design process took considerably longer in the remote format. This is likely because RAPID sessions were in shorter 90-minute bursts, and in between sessions, designers spent considerable time refining the designs and preparing materials for the next round. This was advantageous for advancing the designed product but increased the total project duration.

A second general lesson is the need for flexibility and willingness to implement contingencies for the unexpected. For example, we recommend over-recruiting for each group to ensure an adequate number of participants. In both the older adult and pharmacy staff groups, we had fewer than 5 participants participate in all but 1 session. However, a benefit of RAPID was the ease of adding makeup sessions when multiple participants could not attend a prior session.

Third, we performed our remote co-design sequentially with the 2 groups due to recruitment and timing considerations. We believe that it would be beneficial to complete the sessions concurrently to ensure that each group's designs are not incompatible with the other's. For example, the older adult participants wanted a scale to demonstrate a medication's effectiveness versus safety. Upon further investigation and discussion with pharmacy staff, such a scale was infeasible and would not apply to all users. Our research team made some decisions that were not purely end user driven to reconcile differences between the 2 groups' designs.

Participant Feedback

We did not explicitly or systematically collect feedback on the co-design sessions from participants. However, during the last session, participants provided unprompted opinions on their experiences. The feedback was positive and older adult participants expressed their enjoyment in participating:

> *"This was fun! I enjoyed it."* [Female older adult participant, age 79]
>
> *"Thanks for the opportunity to participate."* [Male older adult participant, age 74]
>
> *"Oh my gosh, it was really really fun. I felt so important!"* [Female older adult participant, age 66]

Discussion

Principal Findings

We produced RAPID by adapting our co-design method to be performed remotely and gained valuable learning to guide future remote co-design projects.

The primary lesson learned was that the online setting is intrinsically less creative and more socially distant than traditional, in-person environments. Our experiences of constraints on participant rapport and trust [14,15], engagement [14], and fewer generative side conversations [19] have been reported in other studies. Practically, this emphasizes the importance of having skilled and experienced facilitators (ie, facilitators with strong technology and communication skills, and an in-depth understanding of transforming user needs into design choices), using activities that promote social interaction among participants (eg, ice breakers, jokes, pointed questions, and turn-taking), and anticipating delays and distractions throughout sessions.

In line with other literature, we found that the remote co-design, compared to our past experiences with traditional in-person co-design, had higher participant attrition than expected [16,17,19], required more researcher flexibility [14,15,17], and was slower [14,16]. We attribute our slower process to shorter design sessions, additional between-session activities, and scheduling serial rather than concurrent independent co-design groups (older adult vs pharmacy staff). The restriction on session duration, chosen to manage participant fatigue, may require the most creativity to overcome.

Our experience with participant differences in technology comfort and experience validates recommendations by Jolliff et al [19] and Fails et al [14] to provide technical support outside sessions, during sessions, or both, as we did.

Despite certain disadvantages of remote co-design, there were also benefits that promoted the continued use and refinement of RAPID. The convenience for participants to participate in research from anywhere with a suitable internet connection is the greatest advantage of any remote research methodology and applies to remote co-design. We engaged participants who otherwise may not have participated due to geographical separation, weather, or work or family obligations. This benefit is noted by others [14,15]. We identified an additional financial benefit by avoiding transportation and facility costs.

We found that, without prompting, participants completed extra work between sessions ("homework"). This enhanced design creativity during sessions and comports with the general benefits of presession activities and time for reflection in co-design [15,17,19]. We recommend prospectively incorporating

XSL•FO
RenderX

"homework" into future RAPID applications to help reflect and create without researcher influence or time pressure.

Limitations

Our experiences, lessons learned, and recommendations were limited in several ways, including the fact that the study sample was small, and this was an early-stage, exploratory study. First, we took a pragmatic but unsystematic approach to creating and reflecting on RAPID, disproportionately leveraging our team's expertise and adapting "on the fly." This is to be expected with a method that arose rapidly out of necessity (ie, COVID-19 pandemic restrictions). Indeed, the ability to fail safely and learn quickly is a hallmark of strategies such as Agile [34,35]. However, with time and experience, new approaches such as RAPID and frameworks such as Mallakin et al [23] can be more systematically evaluated and refined. Second, we did not independently measure success of RAPID or compare it to traditional in-person co-design, a necessary future research direction. Explicitly soliciting participant feedback would also be an important future step in assessing the method. Third, despite efforts to include a sufficiently large and heterogeneous set of co-design participants, the first users of RAPID needed to own a computer, tablet, or smartphone with stable internet and sufficient technology comfort to participate in the study. Even if devices with internet access were provided, something we have done in other studies, this may exclude individuals who do not feel comfortable enough with technology.

Conclusions

Remote co-design is increasingly used. Our RAPID method offers an approach to remote co-design that other teams can implement or adapt to their needs. Our experiences with RAPID identify certain drawbacks to remote co-design; however, these are balanced by advantages in convenience and flexibility. Our use of RAPID also offers various strategies to address challenges to remote co-design.

Acknowledgments

The authors would like to thank Rachel Knierman and Nishad Kumbhare for their design support during co-design sessions.

Funding

This project was funded with support from the Indiana Clinical and Translational Sciences Institute, which is funded in part by award UM1TR004402 from the National Institutes of Health, National Center for Advancing Translational Sciences, Clinical and Translational Sciences Award. MAC was also supported by grants from AHRQ (R18 HS024490 and R18HS027737) and from the National Center for Advancing Translational Sciences (UL1TR002373). EA received support through a grant from the National Institute on Minority Health and Health Disparities of the National Institutes of Health (K01MD016167). Sponsor had no role in study design; in the collection, analysis and interpretation of data; in the writing of the report; or in the decision to submit the article for publication. Abstract

Background: Mammograms are the most readily used procedures for early breast cancer detection but are notorious for the discomfort they induce in patients. This physiological strain has been validated by many questionnaire-based investigations, some of which indicate that it may discourage and deter women from potentially lifesaving health care. While informative, these subjective measures are highly variable and do not provide an objective perspective regarding the coordinated physiological and ergonomic response required for the procedure.

Objective: A multimuscle surface electromyography (sEMG) methodology is proposed to better understand the machine-patient dynamics and potentially develop objective measures of mammogram-related pain and stress.

Methods: Seven different muscle pairs on the neck, shoulders, and torso were identified as being critical in postural positioning during the industry-standard mammogram procedure. sEMG was recorded during 8 compressions across 2 mammogram simulations for 25 women wearing wireless devices. An illustrative map of muscle activity was created based on a comprehensive 10-metric sEMG analysis that compared baseline recordings with activated states during each compression.

Results: The deltoid demonstrated the highest muscular activation across trials with an increase in the mean of the root mean square activity of up to 436%, while the trapezius upper fibers, infraspinatus, and teres major also showed significant increases in muscle activation, averaging 89% to 155% when compared with rest states. Across metrics, muscle activations were ipsilaterally correlated, with significant differences observed only when the breast was compressed on the same side as the muscle being measured. The serratus anterior and external oblique muscles showed minimal activation for any compression or positioning. No significant differences were found between curved and flat paddle designs. After the breast, patient-reported discomfort localized primarily to the shoulder and neck regions, corroborating the physiological measurements.

Conclusions: The juxtaposition of muscle-specific activity against inactive muscles, along with reported discomfort values, demonstrates that the sEMG methodology accurately captures the patient-machine interaction dynamics with objective, quantifiable precision that complements subjective feedback. By providing real-time physiological data on muscular patterns and biomechanical responses throughout the procedure, this sEMG-based approach offers measurable metrics for evaluating proposed improvements to mammogram equipment design and protocols.

Introduction

Background

Charles Gross developed the first dedicated unit for obtaining radiographic images of breasts in 1965. Since then, mammogram machines and procedures have undergone continuous improvements in imaging quality, versatility, and accuracy [1]. However, many concerns have arisen, including high rates of false positives, radiation injury, overdiagnosis, and, most notably, procedure-induced pain [2,3]. This pain is commonly accepted by women who endure the taxing requirements of mammograms in hopes of better health [4]. Nonetheless, it is important to try to understand and address mammogram discomfort and related stress both out of compassion for patients and to encourage regular screening.

XSL•FO
RenderX

Understanding the manifestation of pain, both the physical toll it takes and the cognitive stress it induces, is inherently complex. While many researchers have used questionnaires and interviews to better understand mammogram-induced pain in women, a more complete methodology is required to fully examine all the variables that contribute to the discomfort of the procedure. A quantitative measure, such as that provided by surface electromyography (sEMG), can provide an objective perspective on the prevalence and intensity of mammogram-induced discomfort. sEMG is a noninvasive method using sensors on the skin to measure the change in voltage potential that occurs when a muscle is stimulated by the nervous system [5]. The primary waveform acquired is informative, as it reflects muscle activation resulting from the overall recruitment of fibers during contraction. sEMG also enables calculation of a wide range of secondary metrics, each of which can uniquely characterize different signal features as well as the physiological pathway that oversees their activity.

The depth of analysis that sEMG provides allows for a complex, multifaceted mapping of muscle activity, especially when multiple muscles are monitored simultaneously. Analysis of the signal and its related metrics has been used in a wide range of applications including, but not limited to, studies of comfort and ergonomics [6], emotion detection and regulation [7], and diagnostic techniques for muscular diseases [8]. Similarly, sEMG has been used in various approaches to identify and quantify pain and stress [9-11].

As a noninvasive method that can characterize a wide range of human states (eg, muscular demand and discomfort), sEMG is ideal for a comprehensive, quantitative biometric analysis of positioning and the resulting discomfort during mammograms. Such discomfort is realized when the technologist positions the patient into a forced and unnatural posture to ensure proper imaging. The patient stands with feet pointed at the machine and torso parallel to the imaging table while simultaneously rotating the head and grasping the side of the machine with a single arm. While holding this demanding position, patients must hold their breath and remain completely still. A detailed understanding of the muscular response of a patient during this machine-human positioning can provide greater context to fully understand the effect it has on the body. The breast-positioning procedure is extremely demanding on the patients' muscles, ultimately inducing high physiological strain on the patient, a state that is further exacerbated by the intrinsic psychological stress associated with the screening itself.

Building upon our preliminary investigations presented in the studies by Gielo-Perczak et al [12,13], this study presents a comprehensive multimetric analysis of sEMG signals collected from 14 different muscles across 25 women during a traditional mammogram procedure. While previous work provided initial insights into a select range of muscles, the current investigation significantly expands both the scope and the depth of the analysis to evaluate the practicality and efficacy of using sEMG as a tool to understand the patient-machine dynamics and to quantify patient discomfort. The methodology seeks to understand the effects of different breast compressions, the required body positioning, and the overall physiological demand of the procedure. We analyzed the performance of 10 different sEMG metrics across each muscle throughout the baseline phases and stimulated (breast compression) phases. We then compared the difference in each metric response between the 2 phases to identify any significant trends resulting from the force of the paddles and the positioning required for the imaging.

Previous Work

The application of sEMG to understand muscular distress or discomfort and the ergonomics of specific tasks or procedures has been widely explored. This work generally involves naturalistic observation whereby a muscle and an electromyography (EMG) metric are analyzed throughout a given task. Some groups expand upon this approach by including additional muscles or metrics but rarely both. By monitoring the signal during either real or simulated activities, sEMG has been used for diagnostic purposes as well as for targeting specific, localized task characteristics. This technique has helped to identify the physiological impact and strain of specific, observed tasks on participants, such as workers, patients, surgeons, or even musicians.

For example, Steinmetz et al [14] recorded sEMG from the sternocleidomastoid muscle of 2 groups of violinists—those with and those without neck pain. By analyzing the root mean square (RMS) of the signal, the research simultaneously observed the effect of violin playing on the muscle and examined how the presence or absence of pain could be captured with the signal. A similar, single-muscle approach was conducted by de Oliveira and Nadal [15], who analyzed the erector spinae of helicopter pilots to evaluate the effect of required in-flight posture and environmental vibrations on their back muscles. In addition to analyzing the RMS of the signal, they derived the median frequency to quantify muscle fatigue more specifically over time, allowing for a wider analysis. Harnessing a similar multimetric approach, Wijsman et al[16] and collaborators targeted the trapezius upper fibers during a cognitive task representative of work-related stress. They analyzed 9 different sEMG metrics including RMS, mean value of the RMS, median value of the RMS, peak value of the RMS, mean frequency of the signals-derived power spectra, median frequency of the signals-derived power spectra, and trends. Almost all the metrics indicated a significant difference when comparing the response between a given stressed and relaxed state, and some simultaneously exhibited differences between *types* of stressed states. The resulting multimetric visual gave a more profound interpretation as the frequency-based features were analyzed for muscle fatigue over the task period. RMS-based metrics were used to quantify the overall activation, while trends allowed for a synthesized report of RMS activity over time.

In each of these studies, the tasks required not only the targeted muscles but also many other muscles that were not a primary focus. While a multimetric approach like Wijsman's [16] provides a more profound analysis of sEMG from a given muscle, a broader perspective is gained from evaluating entire task-relevant sections of the body. Bhardwaj et al [17] implemented such an approach in a study of truck driver fatigue. Bhardwaj's team collected bilateral sEMG from 3 different posterior muscle groups (trapezius medial, latissimus dorsi

XSL•FO
RenderX

medial, and erector spinae) as drivers operated both semitrucks and simulators. Although they implemented only 1 metric, the additional muscle data provided a more comprehensive view than if only a single muscle was selected. Both Luttmann et al [18] and Niu et al [19] analyzed multiple sEMG metrics to understand the ergonomics or effects of performing surgeries. Luttmann's team used electrical activity (a metric indicative of smoothed and rectified sEMG) and median frequency to characterize sEMG from 3 different posterior muscles over a series of repeated surgeries. With this approach, they were ultimately able to quantify the muscular strain and fatigue. Niu and colleagues [19] observed surgeons' arm muscles during laparoscopic and robotic surgeries to assess biomechanical stress. The analysis focused on integrated electromyography and mean frequency derived from 4 muscles located in the lower and upper arms. These 2 research teams, among others, demonstrate the value of a multimetric, multimuscle approach when implementing sEMG as a quantitative tool.

Often, a single muscle observation is sufficient to satisfy study objectives. However, when the study seeks a more complete illustration of muscular-related physiology (including factors such as posture, pain, fatigue, or stress), additional muscle observations augment the context for interpreting the results. Similarly, using multiple sEMG features in the analysis allows for more profound conclusions. The studies previously mentioned are summarized in Table 1.

Methods

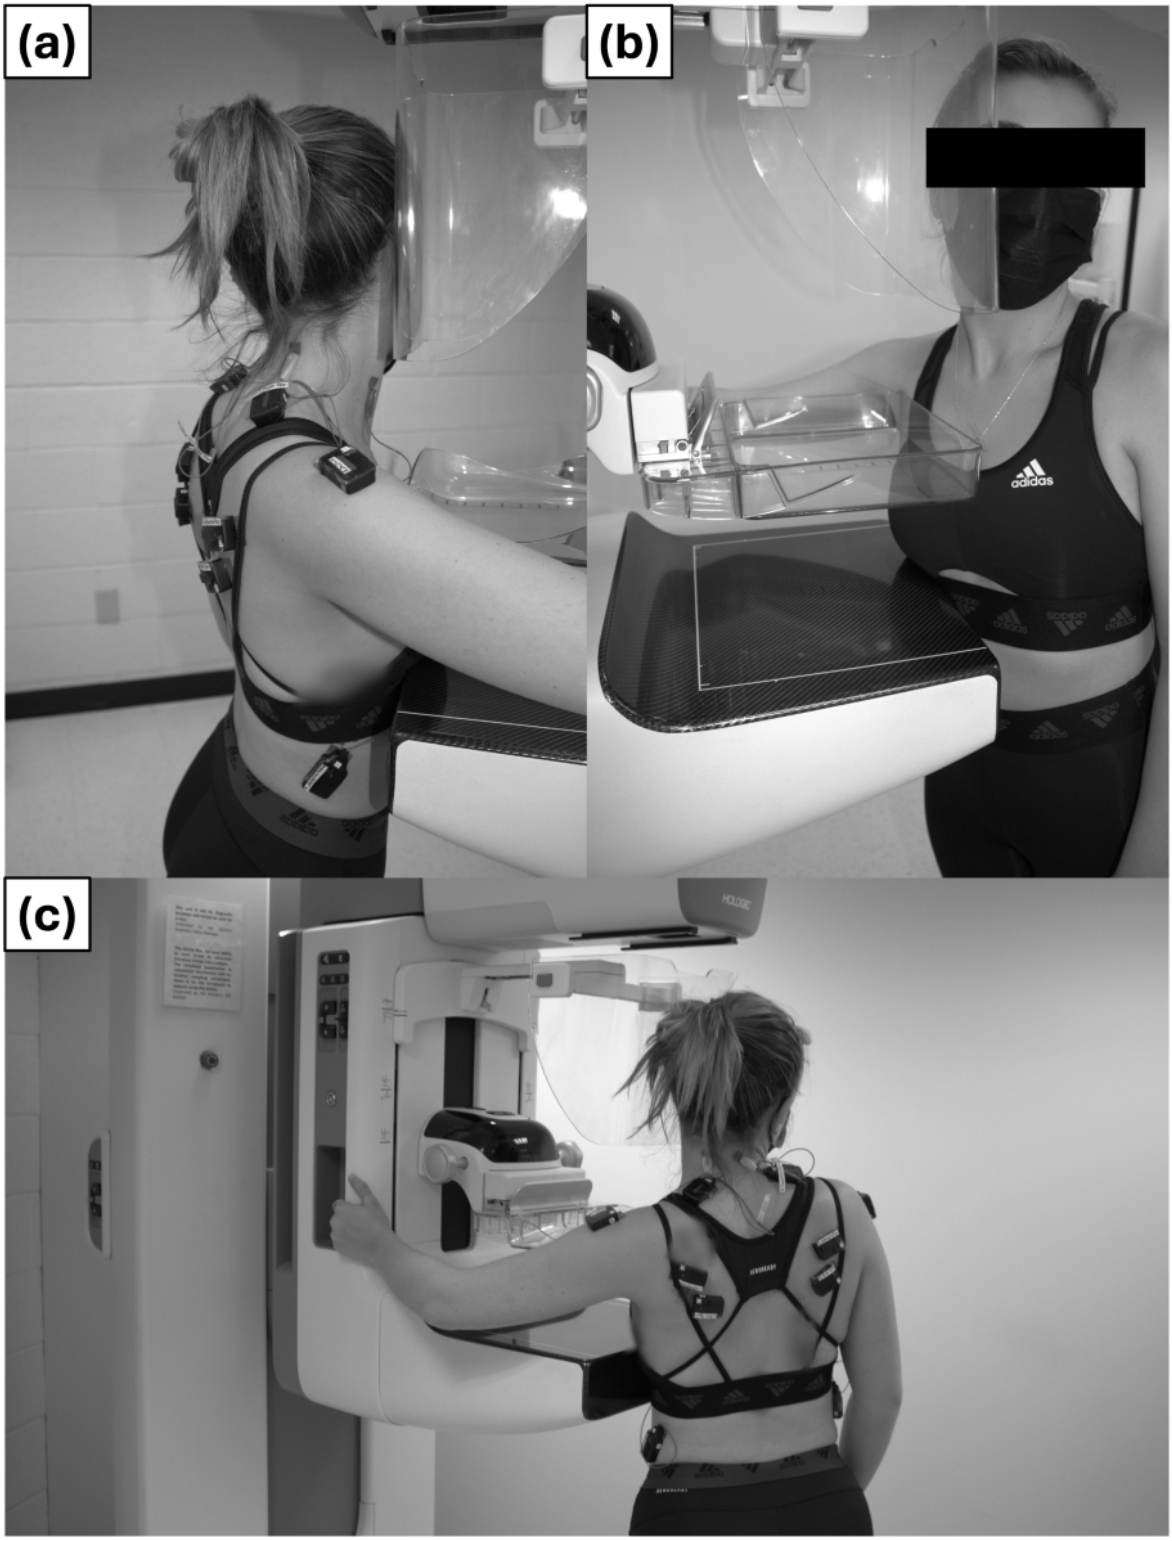
Study Design

The proposed sEMG methodology to evaluate patient stress and discomfort during mammograms consists of a multimuscle, multimetric analysis. Researchers applied wearable sensors to 25 participants to simultaneously collect sEMG from 14 different relevant muscles during a simulated mammogram. The recordings collected during the imaging phase provide a comprehensive snapshot of muscular states during compressions. An in-depth analysis of 10 unique sEMG metrics provides important contextual information for the muscular mapping.

Mammogram Positioning and Muscle Selection

The vertical, standing system is one of the most widely used imaging methods for mammograms. While slight variations can be seen between systems depending on the manufacturer, the overall patient-machine interaction remains consistent throughout the field. During the procedure, the patient stands with both feet facing toward the machine and torso pressed against the edge of an imaging table that protrudes from the device. The patient's head is rotated significantly to the left or the right (depending on the breast being imaged), with the side of the face pressed against a rigid shield. The arm opposite to the breast being imaged simultaneously extends toward the machine.

Considering the rigid structures of the machine as well as the stationary placement of the feet, there are several muscles that can be evaluated to capture the restricted trunk torsion in conjunction with the head rotation and arm extension. The serratus anterior and external oblique can be observed to characterize relevant activity in the torso region. The deltoids along with the infraspinatus and teres major groups provide insight into the shoulder and upper arm during arm extension. The sternocleidomastoid and trapezius upper fibers together illustrate neck movements during rotation and extended flexion.



The left and right pairs of these 7 muscles (14 muscles total) were selected for observation in the proposed methodology. These muscles consisted of previously studied muscles [20] as well as a selection of new muscles that targeted areas not yet evaluated. It is important to note that none of the muscles identified are on or in direct contact with the breasts. The breasts themselves have no muscles and consist of lobules and ducts encapsulated by fatty adipose tissue. The proposed sEMG methodology focuses on muscle strain as a result of patient-machine positioning rather than the force applied to the breast itself.

Instrumentation

Surface EMG recordings were taken using wearable Trigno and Avanti sensors from Delsys, Inc. Four different sensor types were used including the Avanti, Avanti Duo, Trigno, and Trigno Mini. The type of sensor used was determined by the characteristics of the corresponding muscle and the restrictions presented by the procedure. The Avanti and Trigno sensors include embedded electrodes and are ideal for direct placement on muscles that exhibit limited movement during the imaging (placed parallel to the muscle fiber pattern on the center medial deltoid, lowest rib on the external abdominal oblique, center infraspinatus, and center teres major). The Mini and Duo systems use external reference electrodes connected by a wire to the measured electrodes, making them more suitable for smaller, isolated muscle areas that show more movement during the procedure (placed parallel to the muscle fiber pattern on the center trapezius upper fibers, center sternocleidomastoid, and the center band of the serratus anterior). Despite differences in electrode configuration, all 4 Delsys sensor models share identical sampling rate, bandwidth, and input range specifications, providing consistent EMG signal characteristics. To account for any minor variability intrinsic to sensor design or placement, all EMG signals were normalized prior to analysis to ensure valid comparisons across sensors and participants. Both the Avanti and Trigno sensor systems use default sampling defined by Delsys (1925.925 Hz). Figure 1A-C shows the localization of some of these sensors.

Figure 1. Example of human-machine positioning for compression and imaging (note: research staff member shown in images; participants were in a hospital gown for the duration of the study). (A) Lateral view of right craniocaudal compression position, (B) front view of right craniocaudal compression, and (C) rear view of left craniocaudal compression.

Simulation

The mammogram procedure was simulated using the 3Dimensions Genius Mammography System from Hologic, Inc. This system (Figure 1) is commonly found in medical offices across the country and is similar to many other brands. Two different paddle designs—a flat, industry standard paddle and a newer Hologic SmartCurve Breast Stabilization Paddle—were used throughout the protocol to observe whether these design modifications produced any response differences [21]. A certified mammography technologist adjusted the height of the machine and positioned the breast for the simulated compressions to ensure proper handling of the patient and to provide a realistic simulation experience.

Ethical Considerations

The University of Connecticut Institutional Review Board for human participant research approved all the study procedures (protocol H20-0146). Participants gave consent after reviewing the subject protocol.

All identifiable information collected from the participants was numerically coded and anonymized.

Compensation of US $100 was given to participants after completing the visit for the study.

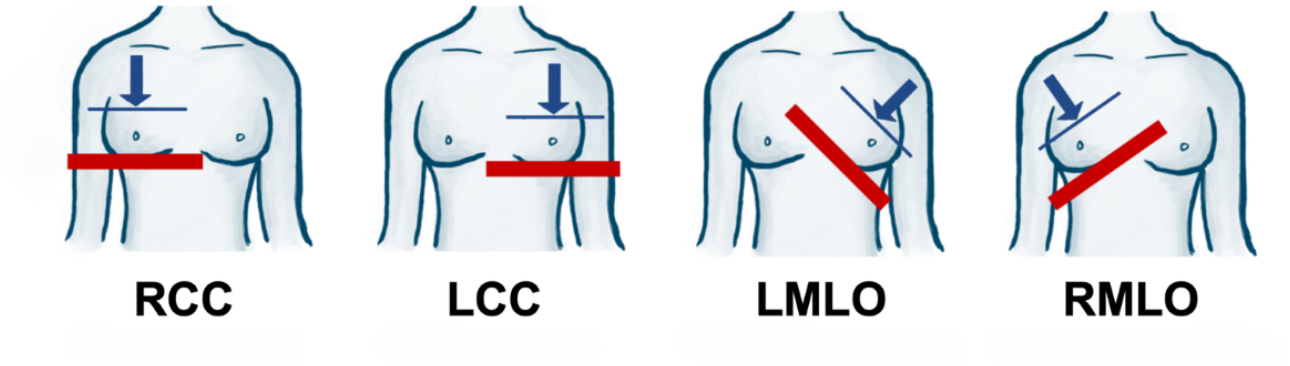
Protocol

The study enrolled 25 healthy female volunteers (aged 40 - 67, median 50.8, SD 8 years; mean height 163.7, SD 7 cm; mean weight 78.0, SD 21 kg; and mean BMI 28.9, SD 6 kg/m^2). The sample size was determined based on practical considerations such as recruitment feasibility and clinical workflow constraints, and it aligns with typical cohort sizes in similar procedural studies, which often include 10 to 20 participants [20]. While both men and women are susceptible to breast cancer, only biological female volunteers were selected for this study as breast cancer, which requires repetitive mammography screenings, is significantly more common in this population.

Participants were screened using a preliminary questionnaire that flagged allergies related to any of the study equipment and identified previous injuries or scars that could impact the procedure. Participants were required to have previously completed at least 1 standard mammogram procedure to provide accurate feedback. Additional self-reported information was collected, including previous mammogram visual analog scale (VAS) pain or stress scores from 1 to 10 and a reference level for physical activity derived from grip strength recordings [22].

Once screened, the participant changed into a hospital gown in a private room. The participant's left and right deltoid, infraspinatus, teres major, external oblique, serratus anterior, trapezius upper fibers, and sternocleidomastoid were equipped with an array of wearable, wireless EMG sensors. Prior to the placement of any device, the skin at each electrode location was cleaned with 70% isopropyl alcohol. The placement and orientation of each sensor were kept constant for all participants to aid in signal analysis.

An initial EMG control recording (C1) was taken in a bright, large room (1341 square feet) during which the participant stood still in a relaxed position facing forward. This recording, as well as all subsequent EMG control recordings, lasted 2 minutes. The participant was then guided to the Hologic Mammography system, which was housed in a smaller, quiet, moderately lit room (171 square feet) with an ambient temperature ranging from 26 °C to 27 °C. Another control recording (C2) was taken in this smaller room before starting the simulated mammogram (Table 2).



The team then initiated the mammogram simulation. The certified mammography technologist walked the participant through the procedure, which followed the same order of compressions currently used in the health care field. The compressions took the following order: (1) right craniocaudal (RCC) view (the right breast is compressed vertically), (2) left craniocaudal (LCC) view (the left breast is compressed vertically), (3) left mediolateral oblique (LMLO) view (the left breast is compressed laterally), and (4) right mediolateral oblique (RMLO) view (the right breast is compressed laterally). Figure 2 illustrates the 4 compressions. Both CC and MLO views require the participant to grasp the imaging unit for stability. In MLO views, the imaging table extends beneath the axilla, creating a larger body-machine contact surface and placing greater positional demands on the upper arm and shoulder girdle relative to the more vertically oriented CC positioning. Each of the 4 compressions (15 seconds each) was conducted twice, once using the flat traditional paddle (F_) and again with the curved SmartCurve Hologic Paddle (C_). The EMG recording was collected during the simulated imaging portion of the procedure when the breast was fully compressed, and the participant was in the restricted body position holding their breath. The compression force used was less than that which is typically applied in clinical settings. This was done to limit unnecessary participant pain since this work focuses on strain from patient-machine positioning rather than breast compression pain. No X-ray was emitted in this procedure. All other steps followed standard clinical practice. A third control recording (C3) was taken between the first and second sets of 4 compressions when the paddle was being changed. The entire protocol is summarized in Table 2.

Table . . Study protocol.

Compression event	Abbreviations	Duration
Control 1 in large room	C1	2 minutes
Control 2 in examination room	C2	2 minutes
Flat paddle compressions		
Right craniocaudal compression	F_RCC	15 seconds
Left craniocaudal compression	F_LCC	15 seconds
Left mediolateral oblique compression	F_LMLO	15 seconds
Right mediolateral oblique compression	F_RMLO	15 seconds
Control 3 in examination room	C3	2 minutes
Curved paddle compressions		
Right craniocaudal compression	C_RCC	15 seconds
Left craniocaudal compression	C_LCC	15 seconds
Left mediolateral oblique compression	C_LMLO	15 seconds
Right mediolateral oblique compression	C_RMLO	15 seconds

Figure 2. The 4 different positions of the breast for the simulated mammogram—typical for screening procedures. Blue line and arrow indicate paddle and direction of compressive force, respectively. Red line indicates imaging table on which the breast rests while being compressed. LCC: left craniocaudal; LMLO: left mediolateral oblique; RCC: right craniocaudal; RMLO: right mediolateral oblique. Adapted from Gielo-Perczak et al [12,13].

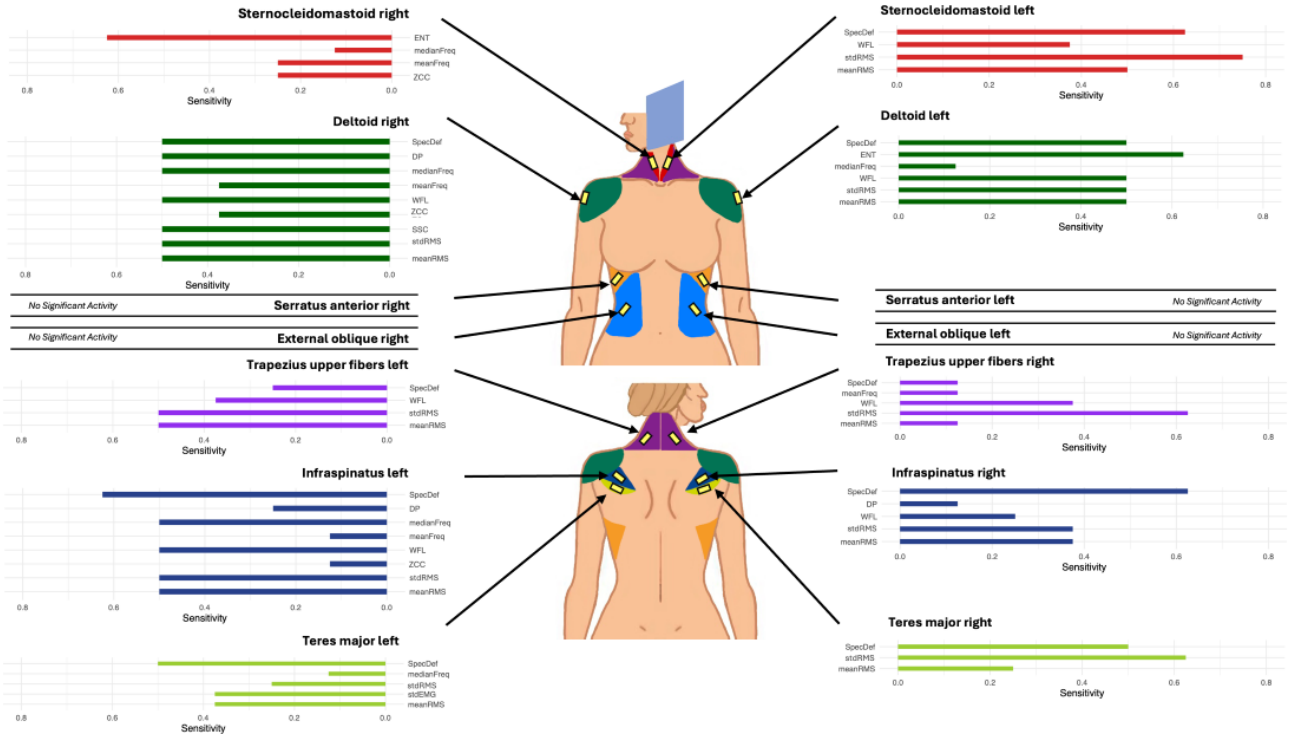
EMG Signal Processing and Data Analysis

The sEMG processing and analysis was completed using MATLAB. The first and last 1.5 seconds were removed from the beginning and the end of each recording to remove fringe artifacts resulting from the misalignment with the start of the recording and the start of the imaging phase. The trimmed segment was then filtered with a fourth-order bandpass filter (20-500 Hz), which accounted for the variability in unique frequencies across the targeted muscles. Each segment for the flat paddle was normalized to the first control of the small room (C2), and the second set of recordings corresponding to the curved paddle was normalized to the second control of the small room (C3).

Ten different metrics were then derived from the cleaned signals to characterize each of the segments. The selection of these metrics was informed by prior literature in which similar measures have proven effective for assessing muscular pain, stress, fatigue, and strain in physically demanding contexts (Table 1). Five time-domain metrics were selected. These include the mean of the root mean square (meanRMS) waveform, standard deviation of the RMS (stdRMS) feature, slope sign change count, zero crossing count, and the waveform length (WFL). Five frequency domain metrics were selected to further analyze the EMG activity during each state of the protocol. These included the mean frequency (meanFreq), median frequency (medianFreq), signal spectral entropy, drop in power (DP), and spectral deformation (SpecDef). To determine these features, the power spectrum of each EMG signal was calculated using Welch's periodogram method with 50% overlap and a 128-sample Blackman window on the filtered data. The average of each metric for a measurement window was used for analysis. Given the static nature of the participants during each measurement period and observed uniformity in sEMG data, limited variation in metrics was expected across each window.

Data Analysis

Three interactions between stages of the protocol were identified as potentially illustrative comparisons. The first interaction illustrates the sEMG activity between the compressive state and its respective control. This finding highlights the sensitivity of the measure to illustrate the change from a relaxed to aroused state while also indicating overall muscle activity (eg, C_RCC



XSL•FO
RenderX

vs C3). The second interaction revealed the sEMG activity between the same compressive state between the 2 different paddle types. This interaction would indicate any difference in muscle activity resulting from a change in the paddle form (eg, F_RCC vs C_RCC). The third interaction revealed the sEMG activity that occurred when the compression angle was changed for a given breast to identify any effect of angle on the signal (eg, F_RCC vs F_RMLO). Normality for each metric was assessed using the Kolmogorov-Smirnov test. Metrics were analyzed using paired *t* tests. Because each metric involved multiple comparisons across compressions, *P* values were adjusted using Bonferroni correction. Bonferroni was selected due to its conservative nature and its suitability for protecting against type 1 errors in settings with many planned comparisons.

Results

The first interaction comparing activity during a compression to a control state was identified as the most informative with respect to the main goals of the proposed methodology. For this comparison, the metrics for a given muscle were evaluated across all 8 compression segments and the 2 small room controls C2 and C3. Statistical difference was noted according to the corrected Bonferroni values. This resulted in a total of 8 comparisons for a given metric and muscle combination. Figure 3 summarizes the percentage of compressions where this comparison was significant. The metrics listed for each muscle are those that detected a significant difference in sEMG activity at least once between relaxed and stimulated states for a given muscle.

Figure 3. Percentage of compressions that showed a statistical difference between control and baseline for each muscle across all metrics. Displayed as a ratio out of the total number of compressions (n=8). Only metrics that showed significance for a given muscle are displayed. DP: drop in power; ENT: spectral entropy; meanFreq: mean frequency; meanRMS: mean of the root mean square; medianFreq: median frequency; SpecDef: spectral deformation; SSC: slope sign change count; stdRMS: standard deviation of the root mean square; WFL: waveform length; ZCC: zero crossing count.

The deltoid and infraspinatus muscles (left and right) demonstrated high relative sensitivity according to the frequency matrix when observing meanRMS, stdRMS, WFL, meanFreq, medianFreq, and SpecDef. The deltoid consistently showed differences in about 50% of cases. Similarly, the trapezius upper fibers and the teres major were also relatively sensitive to compressions when observing meanRMS, stdRMS, WFL, and SpecDef. The serratus anterior and the external oblique did not show any sensitivity to the compressions for any of the metrics explored. Regardless of the other muscles, meanRMS, stdRMS, WFL, mean and medianFreq, and SpecDef all indicated a change in sEMG between the 2 states. It is noted that meanRMS, stdRMS, and WFL are all somewhat correlated in addition to meanFreq and medianFreq. While each is slightly different (as they underscore various characteristics of the signal), the methodology of their derivation lends to shared trends, providing flexibility to researchers in metric selection when pursuing similar methods.

Those muscles that showed both frequent and significant responses across various metrics (all but the serratus and external oblique groups) are included in Table 3. The top 3 most frequently activated metrics in each muscle group are present for both paddle types. Any compression resulting in a significant change in comparison to the controls is noted with an asterisk and red font. Note that only C2 and C3 recordings are included in the table as they were the reference for the flat and curved paddle compression sets, respectively. No significant difference was found between the large room control C1 and C2 or between C1 and C3 in the examination room.

[a]meanRMS: mean of root mean square.

[b]Bolding indicates significant difference between compressive state and respective control (C2 for flat paddle compressions, C3 for curved paddle compressions) with $P<.05$.

[c]stdRMS: standard deviation of the root mean square.

[d]ENT: spectral entropy.

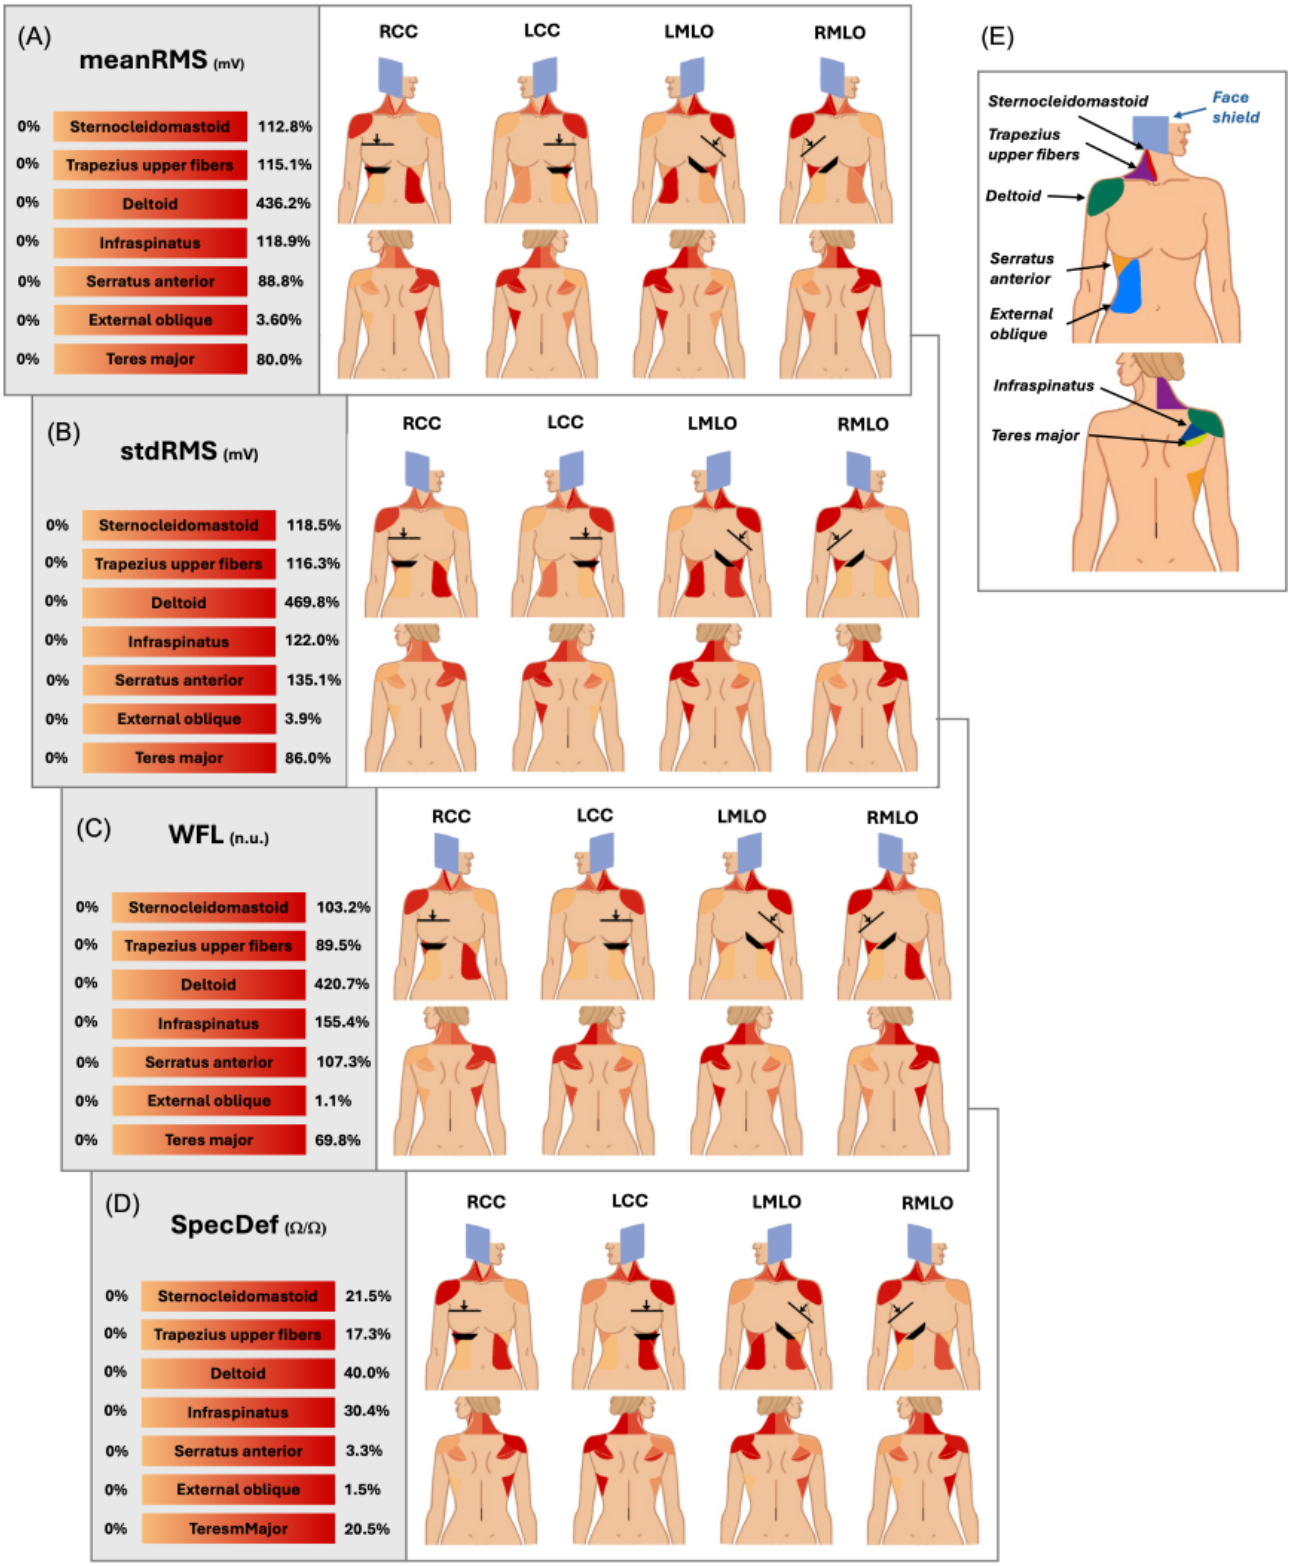
[e]WFL: waveform length.

[f]SpecDef: spectral deformation.

[g]Ω/Ω: Ohm ratio—unitless.

For the sternocleidomastoid, deltoid, infraspinatus, and teres major muscle groups, significant differences were observed only during compression of the ipsilateral breast (the breast on the same side as the muscle being measured). This pattern is demonstrated by the sensitivity clustering in the LCC and LMLO columns for left-sided muscles and in the RCC and RMLO columns for right-sided muscles.

Curved and flat paddle compressions resulted in similar changes in the metric performance. There was no significant difference found between compressions of the 2 paddle designs. This can



XSL•FO
RenderX

be similarly extrapolated from Table 3 where pairs of rows generally follow the same trend. Parentheses indicate the larger of the 2 mean values for a given metric and compression. It is important to note that in the case of metrics meanFreq, medianFreq, and DP, a decrease in mean was found in response to the provided stimuli as is commonly expected in physiological response to stressors [23].

Figure 4 clarifies the differences by presenting the absolute percentage change relative to the control for the 4 most responsive metrics of the study. Figure 4E provides a summary key of the muscles of interest. Combining the curved and flat compressions into 1 population (RCC, LCC, LMLO, and RMLO), the physiological heatmaps illustrate the change for all the muscles studied. The deltoid had a maximum percentage change of 436.2% when considering meanRMS (Figure 4A and C). The increase is corroborated by the results in Table 3. Similar percentages are seen across stdRMS, WFL, and SpecDef, noting 469.8% - 420.7% and 40.0%, respectively (Figure 4B-D). The teres major showed a maximum increase of 80.0%, 86.0%, 69.8%, and 20.5% for each of the metrics, which are also significant increases. On average, the sternocleidomastoid increased 112.8%, 118.5%, 103.2%, and 155.4%; the trapezius upper fibers 115.1%, 116.3%, 89.5%, and 17.3%; and infraspinatus 118.9%, 122%, 155.4%, and 30.4% for meanRMS, stdRMS, WFL, and SpecDef, respectively. For the external oblique, averages were 3.6%, 3.9%, 1.1%, and 1.5% for meanRMS, stdRMS, WFL, and SpecDef, respectively.

RenderX

Figure 4. Anatomical heatmap marking absolute percentage change of metrics of interest (A, stdRMS; B, stdRMS; C, WFL; and D, SpecDef) for muscle groups (E) between control and a given compression as participants are positioned against the machine. Curved and flat compression types combined to wholistically represent the 4 mammogram positions. Max% of color bar indicated maximum percentage change considering both left and right components of muscle group. LCC: left craniocaudal; LMLO: left mediolateral; meanRMS: mean of the root mean square; RCC: right craniocaudal; RMLO: right mediolateral; stdRMS: standard deviation of the root mean square; SpecDef: spectral deformation; WFL: waveform length.

Before starting the study, participants were asked to report VAS pain ratings for their previous mammogram experiences. The results were between 1 and 9 and had a mean of 5.6 and an SD of 2.1. They again reported a VAS pain rating after finishing the study with respect to the simulated procedure. The results were between 1 and 5 and had a mean of 2.2 and an SD of 1.2. In the second report, participants were also requested to indicate which locations were the most uncomfortable during the study, if any. As indicated in Table 4, the breast was the most often

XSL•FO
RenderX

reported location for discomfort, followed by the shoulder and the neck. These reports are summarized in Table 4.

Table . Reported VAS[a] pain ratings[b].

Location	Number of reports
Breast	10
Shoulder	7
Neck	2
Leg	3
Feet	2
None	1
Overall VAS pain reported, mean (SD)	2.2 (1.2)

[a]VAS: visual analog scale.

[b]Study sample size (N=25).

Using the same standards but varying the segments, we used statistical comparisons to explore the effects of compression angle as previously discussed. These comparisons demonstrated no notable trends in significance. Similarly, no significance was observed for any metric between the large and small room controls.

Discussion

This study proposed a multimetric analysis of sEMG activity across 14 different muscles as a methodology to analyze women's muscular response during a simulated mammogram. The results allowed for a more complete understanding of the machine-patient dynamics and have the potential to further clarify the manifestation of pain or stress relevant to the procedure. To date, this is one of the most complete and thorough studies of EMG activity during mammogram screening.

To arrive at a nuanced understanding of the muscle's response, 10 EMG-based metrics were used to characterize the signal activity. When compared with related studies, the additional metrics allowed for greater resolution in classifying muscle responses. Out of the 10 metrics, the following 6 frequently indicated differences between the relaxed and stimulated states: meanRMS, stdRMS, medianFreq, meanFreq, WFL, and SpecDef. Out of those 6, meanRMS, stdRMS, medianFreq, and SpecDef showed large differences from one another, with each capturing a distinct characteristic of the signal behavior. In showing greater activation among muscles, these metrics can be reliably used to quantify muscle response throughout the procedure. This reliability is similarly represented in related studies in which greater activation of these metrics was related to greater pain and stress [16,23,24]. Uchiyama et al [20] implemented integrated electromyography, which is a metric that is closely related to meanRMS, and demonstrated similar muscle reactivity when quantifying trapezius, bicep, sternocleidomastoid, and gastrocnemius activation. No prior studies have examined changes in muscle activity trends during mammograms using sEMG recordings and displayed the trends of these 10 metrics. It is important to note that the overall magnitude of percentage change is relative to each muscle so that some muscles may have smaller variations but still represent significant activation.

Analysis of these metrics provides detailed insights into the demanding and stressful positioning required by mammograms. Specifically, the high sensitivity among many of the metrics in the deltoid, teres major, and infraspinatus can be attributed to the strained torsion of the upper torso. Although there is activation relative to the control, the absence of true significance in the external obliques further illustrates this point. The lower torso, including the obliques and abdomen, would normally twist with the upper body to relieve such strain, but mammogram positioning restricts waist and trunk torsion, inducing an uncomfortable, constricted hold. Similarly, in keeping the chest parallel with the imaging table, the patient extends the arm corresponding to the breast being imaged. This position further engages the shoulder or the upper body region and increases the overall demand on the static muscles during imaging. When compared with their baseline, the dominant activation of the deltoid muscles indicates its role as a positioning muscle and a likely source of pain, stress, or fatigue in women during breast compressions. The combined activation of the trapezius upper fibers and the deltoid provides insights into the patient's lower neck rotation and arm positioning due to the interaction with the face shield. The meanRMS and stdRMS of the associated neck muscles corresponding to the breast being compressed indicated differences for most of the respective compressions. This can be attributed to the engagement of the patient's arm with the side of the machine as well as the twisting of the head to accommodate the obtrusive face shield.

While visual observation of the body can begin to qualify the described positioning, the complete sEMG analysis illustrates the intensity of the strain that the procedure induces. There is a significant contrast between the involved muscles of the upper extremity and the limited activity of torso muscles. The torso muscles showed no interactions supposed by the imaging table pressing on the breastbone and rib. The data also corroborate the pain locations reported by participants who noted that, after the breast, the shoulders (deltoid, infraspinatus, and teres major) were the most uncomfortable body region during compressions.

XSL•FO
RenderX

A multimetric approach may lead to a more sensitive model that can quantify complex responses involving multiple muscle contributors of varied sizes and locations. This can be seen when comparing the responses of the trapezius upper fiber, deltoid, infraspinatus, and teres major muscle groups. The meanRMS and stdRMS show high activation among all 4 groups (8 muscles). However, out of these, only the deltoid and the infraspinatus muscle groups (4 muscles) show moderate activation for other metrics including slope sign change count, zero crossing count, meanFreq, medianFreq, and DP. This finding could be indicative of a more intense response on behalf of these muscles in comparison with the others. Similarly, it is possible that the additional metrics capture characteristics unique to each muscle that would otherwise be lost if only meanRMS was observed (one of the most common sEMG metrics applied in practice). The study results illustrated this likelihood in a few cases. One such case considers the mean and median frequency response, metrics that are frequently implemented as measures of fatigue [23]. In the results presented, we see cases in which a significant change of these metrics occurs in the deltoid and the infraspinatus but not in the other muscles. This may indicate that the right and left deltoid and the right and left infraspinatus are exposed to more fatigue-inducing strain arising from the type of positioning, repetitive muscle involvement, or some other factor intrinsic to the procedure.

The robustness and sensitivity of the proposed measurement methodology are further strengthened by evidence that they can distinguish lateral variance in compressions. Figure 3 reveals that the metrics that frequently show sensitivity only do so in roughly half of the total compressions. This lateral bias originates from the idea that the activation of a muscle depends on which breast is being imaged. The breast being imaged in turn dictates the location of the muscular tension in the upper torso and neck muscles, isolating the strain to one side in this group of muscles. For example, in the case of the LMLO, the 5 muscle pairs detected a difference more frequently for left breast compressions (flat paddle 8/8 instances, curved paddle 5/8 instances), whereas the RMLO noted a difference mostly for right breast compressions (flat paddle 6/8 instances, curved paddle 5/8 instances) as seen in Table 3. Similar lateral patterns were observed by Uchiyama et al [20]. While these patterns support the sensitivity of the measurement approach, the ability to detect more subtle differences such as those between paddle types may be limited. A larger sample size would likely be required to resolve smaller effect sizes that distinguish paddle-related influences.

While the study relied on a single overall VAS score, which provided meaningful context by identifying common regions of discomfort consistent with our sEMG findings, this format limited direct statistical correlation. Future studies incorporating VAS ratings after each compression would allow a more precise linkage between subjective and objective indicators for complete biomarker development. It is important to note that the reported pain score during the simulated mammogram was lower than the score the participants assigned to their previous experiences. Human ability to recall pain is surprisingly accurate [25]; therefore, the difference in pain is largely attributed to the reduced compressive force used in the study and is not a result of reporting inaccuracies. Limited but sufficient force was applied during the study so that a constant force reading on the machine was achieved. The participant was in a proper, realistic postural positioning without inducing unnecessary compression. As the study did not take any image of the breast, the compressive force applied did not reach the intensities patients normally experience. The standard force ranges from 100 N to 140 N [26], whereas the forces implemented in the study range from 18.25 N to 71.60 N. It is likely that had our study applied the same degree of pressure required by common procedures, the recorded pain metrics would have been more comparable. It can be realistically hypothesized that the painful stimulus of complete breast compression would likely induce additional muscle tension and a further elevated internal stress response. Consequently, the proposed methodology may detect an even greater biomechanical response via EMG mapping. The procedure also maintained the same order of compressions, flat paddle followed by curved paddle, which may have introduced a procedural bias. Given the back-to-back nature of the compressions, the later compressions could have captured patterns corresponding to extended screening, including muscle fatigue or learning results. The influence of this effect was hopefully limited by comparing the muscle activation during compression with flat and curved paddles to the initial C2 and intermittent C3, respectively.

While the proposed methodology was not able to distinguish between paddle types or compression angles, it was able to accurately capture the positional demands associated with each of the 4 different compressions. Supplemental research is needed to detect the effects of paddle design variations through EMG. Future studies incorporating muscles more directly involved in angular positioning may better capture biomechanical differences between vertical and angled compressions. Additionally, angle-dependent effects may exist but with smaller effect sizes than currently observed, suggesting that a larger sample may be required to achieve sufficient statistical power to detect these effects. It is possible that advanced machine learning approaches could be applied to determine the effects of paddle type and other subtle machine design variations on patient discomfort. Likewise, further decomposing the measurement windows could facilitate the exploration of muscle fatigue trends not only across compressions, as examined in this protocol, but also within each individual imaging period. Such within-compression analyses could reveal shorter-term fatigue patterns that complement the broader longitudinal trends. These complex and potentially hidden relationships underscore the importance of a methodology that integrates multiple metrics across several muscles.

Future work should also expand the study population to improve external validity. Including participants with a broader range of ages, BMIs, physical health, breast densities, and demographic backgrounds would help clarify how these factors interact with muscular demand and discomfort during compression. This expanded population would help ensure that findings generalize across diverse patient groups.

As long as the routine mammogram remains a painful and stressful experience, it is crucial to understand the physiological toll the procedure has on patients. This study applied a robust,

XSL•FO
RenderX

multimetric sEMG analysis across multiple muscles to objectively characterize the physical impacts of the mammogram procedure. While subjective pain reports provide valuable patient perspectives, EMG offers critical advantages by capturing unconscious muscular compensation patterns, precise temporal responses during specific procedure phases, and quantifiable biomechanical data that patients cannot accurately self-report. By identifying the relative simultaneous activation and inactivation of specific muscles, this methodology can highlight the unique, painful demands of the procedure. In the present analysis, the deltoid and infraspinatus muscles emerged as most consistently responsive across the majority of time domain and frequency domain metrics. This finding suggests their strong potential as candidates for sEMG-based biomarkers of procedural strain. Metrics such as RMS, medianFreq, and WFL, in particular, showed robust sensitivity to compression-specific positional demands. These muscle-metric combinations, therefore, represent promising targets for future refinement of objective indicators of discomfort or biomechanical load during mammography. This metric insight, along with other takeaways on sensitive muscles, provides promising results for potentially highlighting a focus point for improvements to the mammogram procedure that would be difficult to isolate through patient feedback alone. By analyzing a wide range of metrics, the methodology can potentially provide objective pain and stress measures such as those developed in similar studies involving the development of electrophysiological biomarkers [27]. The study methodology demonstrated the sensitivity of sEMG to capture mammogram-specific muscular trends during the compressions, revealing human-machine interaction patterns that inform targeted design modifications. These objective physiological data complement subjective feedback by providing quantifiable, reproducible metrics for assessing proposed improvements to the device design and imaging protocols. Future work should confirm reproducibility through larger cohorts, expanded muscle sets, and test-retest reliability. Relating key muscle-metric patterns to patient discomfort will help establish predictive validity and support the development of sEMG-based biomarkers for mammography-induced strain.

Although women may be reluctantly willing to endure mammograms as a necessary evil, there are many good reasons to better understand and improve the procedure. First, there is the potential to enrich the quality of the medical assessment, including both the results and the patient experience. Second, improvements to the patient experience can go a long way in promoting more widespread application of the technology. Furthermore, the comprehensive methodology proposed lays significant groundwork for future research in machine-human dynamics both in and outside of the health care field. With increased human exposure to novel technologies that modify body posture and muscular kinetics, it is crucial to understand the physiological ramifications in order to allow for their safe and effective application.

Acknowledgments

The authors are grateful to all participants for their time and engagement in the study. They thank Hadleigh A. Eastman, Riley Q. McNaboe, Sarah F. Myrick, Raghavi Shanmuganathan, and Alexi Switz for assistance with recruitment and data collection. The authors also acknowledge the mammography equipment assistance provided by Hologic, Inc and technical sensor support provided by Delsys, Inc throughout the study. Similarly, the authors extend their gratitude to the DeLuca Foundation grant for their financial assistance.

Funding

This work was supported by Hologic Inc (grant AG200867) and the DeLuca Foundation (grant 240457).

Abstract

Background: In 2019, Germany introduced a unique regulatory framework for digital therapeutics (DTx), termed digital health applications (DiGAs) in Germany, with the goal of integrating evidence-based DTx into statutory health care. DTx are eligible for reimbursement by statutory health insurance if manufacturers demonstrate positive health care effects, such as improved health status or health literacy, in a controlled study setting. Although regulatory evaluation primarily relies on manufacturer-conducted studies, these studies do not fully capture how users experience and use DiGAs in everyday life.

Objective: The study aims to systematically characterize user experiences with reimbursable DiGAs by analyzing the sentiment and thematic content in publicly available app store reviews at scale to identify recurring patterns of positive and negative feedback across regulatory-relevant quality dimensions.

Methods: All DiGAs with publicly available mobile app reviews were identified via the official German Federal Institute for Drugs and Medical Devices (BfArM) directory. User reviews were extracted from the German Apple App Store and Google Play Store using a tailored Python script. Reviews were then processed using GPT-4o, which extracted up to 5 core statements per review and assigned each a sentiment label (positive, neutral, or negative) and one of ten predefined thematic categories to each statement: content, technology, cost and reimbursement, login and registration, prescription and approval, user experience and design, support, tracking and documentation, effectiveness, and overall impression, all derived from the regulatory and quality criteria applicable to DiGA certification. Classification quality was assessed through manual validation, in which each of the 3 authors independently reviewed one-third of all model outputs.

Results: In total, 44 mobile DiGAs were included and analyzed. After data extraction and cleansing, the final dataset comprised 4328 reviews containing at least one interpretable statement, resulting in 9439 interpretable statements. A systematic validation of the automated classification demonstrated exceptionally high model performance, with 99% accuracy for sentiment classification (F_1-scores of 1.00 for positive and 0.99 for negative categories) and 95% accuracy for category classification (average F_1-score of 0.95). While the categories overall impression (1233/1431, 86.2% positive) and effectiveness (1440/1609, 89.5% positive) received particularly positive feedback, users commented most negatively on the login and registration process (263/280, 93.9% negative) and technology-related aspects (563/668, 84.3% negative).

Conclusions: User feedback on reimbursable DiGAs is predominantly positive, particularly regarding perceived effectiveness, overall impression, and content. However, recurring criticism of login and registration processes, technical reliability, and prescription and approval procedures reveals persistent barriers to access and use. As many of these aspects are prerequisites rather than peripheral convenience issues, they should be treated as essential implementation requirements. Analyzed at scale with large language model-based methods, publicly available app store reviews can complement formal evaluation by providing user-centered real-world evidence for postmarket monitoring and regulatory quality improvement.

Introduction

In 2019, Germany introduced a unique regulatory framework for digital therapeutics (DTx) known as digital health applications (DiGAs), with the goal of integrating evidence-based DTx into routine care [1,2]. Under the Digital Healthcare Act (Digitale-Versorgung-Gesetz) [3], DiGAs can be prescribed by physicians and reimbursed by statutory health insurance if they are listed in an official directory maintained by the German Federal Institute for Drugs and Medical Devices (BfArM) [4]. The directory covers DTx across a range of indications, such as mental and behavioral disorders, musculoskeletal disorders, metabolic disorders, and disorders of the nervous system. This initiative aims to improve access to innovative health care technologies while ensuring their safety, quality, and effectiveness.

To qualify for inclusion, DTx must meet clinical, legal, and technical requirements, including demonstrable benefits to patient care or care structures as defined in section 139e of the German Social Code, Book V (SGB V) [3]. These so-called positive health care effects refer to either a medical benefit or to patient-relevant improvements in structures and processes. A medical benefit is defined as an effect such as an improvement in health status, a reduction of disease duration, prolonged survival, or increased quality of life. Patient-relevant structural or procedural improvements may include better coordination of the care process, easier access to health care services, or the promotion of health literacy [5]. To facilitate timely integration into routine care, the law also additionally introduced a fast-track procedure that allows provisional listing for up to 12 months while manufacturers gather evidence of positive health care effects [6,7].

Although regulatory evaluation rests primarily on manufacturer-conducted clinical studies [8,9], such studies are not designed to capture the patient-centered dimensions that determine whether a DiGA is adopted and used in everyday life [10]. For the German DiGA context specifically, it has been argued that acceptance, perceived usefulness, and usability are decisive for sustained use, yet genuine user-centeredness is not yet firmly embedded in DiGA development [11]. Usability, acceptability, and the practical feasibility of integrating an app into daily routines are key determinants of sustained engagement, yet they are only partially addressed during development and approval. To date, the actual use and adherence to a DTx have been identified as a critical but undersupported determinant of effectiveness, for which clinical practice still lacks established assessment tools [12]. Low uptake and prescription rates further underline that factors beyond clinical efficacy shape whether DiGAs reach and benefit patients [13]. As several studies emphasize, user reviews of mobile health (mHealth) apps can reveal valuable insights into real-world usability and recurring quality concerns. All these dimensions are directly relevant to the DiGA approval framework [14-17]. Analyzing user-generated feedback can therefore offer a scalable, real-world complement to clinical evidence and may surface practical barriers to adoption and sustained use.

Importantly, the regulatory framework itself recognizes the relevance of patient perspectives. Section 139e SGB V requires that the outcomes of digital health apps include patient-reported health status during usage as part of mandatory success monitoring [3]. This emphasis is mirrored in the DiGA guideline (DiGA-Leitfaden), which explicitly permits manufacturers to demonstrate positive health care effects using comparative quantitative methods drawn from the social or behavioral sciences, provided validated instruments are used [18]. This institutional acknowledgment underscores that patient experience has become a regulatory concern in the DiGA framework. App store reviews provide spontaneous, large-scale, real-world feedback across the entire DiGA landscape in a way that standardized instruments do not. While they cannot replace validated patient-reported outcome instruments, their systematic analysis can potentially reveal how DiGAs are experienced in everyday use.

To date, however, patient feedback on German DiGAs has received limited systematic attention. Uncovska et al [19] analyzed app store reviews of mHealth apps in Germany, comparing regulated DiGAs with nonregulated consumer apps using BERTopic modeling and sentiment analysis. Their work showed that DiGAs received more favorable contemporary ratings than nonregulated apps. Positive themes included customer service, personalization, and ease of use, while software bugs and cumbersome registration processes were frequent complaints across both app types. Their analysis, however, covered only 15 DiGAs and relied on data-driven topic categories that do not map onto the regulatory dimensions against which DiGAs are formally assessed. Furthermore, it was framed primarily as a comparison between regulated and nonregulated apps rather than a focused account of the user experience with DiGAs themselves.

Internationally, app store reviews have been used to examine user experience with health apps in various contexts, ranging from consumer health apps to regulated prescription DTx in the United States [20,21]. This leaves a clear gap, as to our knowledge, there is no systematic, large-scale account of how users evaluate the full range of listed DiGAs along the dimensions that are central to their regulatory assessment. To address this gap, this study analyzes publicly available DiGA user reviews from the German Apple App Store (iOS) and the Google Play Store (Android) for all approved and provisionally approved mobile DiGAs as of February 25, 2025.

Using a regulation-informed category scheme and large language model (LLM)–assisted classification, we aim to characterize how users evaluate DiGAs across dimensions relevant to regulatory assessment and to identify where regulatory expectations and lived user experience may converge or diverge.

Methods

Data Identification and Extraction

Data collection involved 2 stages: first, we identified all mobile DTx listed by the BfArM as of February 25th, 2025. Second, we used Selenium-based Python scripts (Version 4.29.0) to extract user reviews from the German Apple App Store (iOS)

XSL•FO
RenderX

and the Google Play Store (Android). Extracted data included review content, ratings, dates, developer responses, and app metadata, all stored in structured JSON format.

Category Development and Regulatory Grounding

The thematic category scheme was developed using a regulatory-driven approach. Categories were derived from legal and regulatory requirements governing DiGAs in Germany, with the aim to ensure regulatory relevance and interpretability of user-reported feedback. Specifically, we systematically reviewed the SGB V, the Digital Health Applications Regulation (DiGAV), and the official BfArM DiGA guideline [5,18]. From these sources, we identified recurring normative evaluation dimensions relevant to DiGA approval, quality assurance, and postmarket monitoring. These include requirements related to content quality, technical stability, usability, effectiveness, reimbursement, and user experience. Based on this review, 10 high-level categories were defined, and each was mapped to one or more regulatory criteria to ensure traceability between app-user feedback and legally relevant quality dimensions (Table 1). The framework was developed deductively, as the study aimed to assess user feedback against the quality dimensions that are legally binding for reimbursable DiGAs. During the human validation, the authors additionally assessed whether statements addressed aspects not covered by the framework.

Table . The 10 feedback categories, the user-reported content they capture, and their regulatory grounding.

Category	Content captured	Regulatory basis
Content	Informational, educational, and therapeutic material; evidence-based scientific soundness, up-to-dateness, readability	section 139e (2) SGB V[a]; section 5 (8) DiGAV[b]
Technology	Technical stability, software reliability, device compatibility, bugs, and system failures	section 139e (2) SGB V; section 5 (2) DiGAV; BfArM[c] guideline
Cost and reimbursement	Perceived cost; reimbursement through statutory health insurance	section 134 (1) SGB V
Login and registration	Initial access; ease of login and registration	section 5 (5) DiGAV
Prescription and approval	Obtaining or redeeming access codes; prescription, insurer approval, and diagnosis requirements	BfArM guideline (Sections 3.2.2, 2.1.2.2)
User experience (UX) and design	User interface, usability, visual, and design aspects (overall interaction beyond initial access)	section 5 (5) DiGAV
Support	Availability, responsiveness, and quality of customer or therapeutic support	BfArM guideline (Section 3.6.2.5)
Tracking and documentation	Documentation of symptoms, nutrition, activities, or behaviors	section 139e (13) SGB V (effective Jan 1, 2026)
Effectiveness	Perceived medical benefit, self-management, health literacy, and therapy adherence	section 139e (13) SGB V; section 8 (2)-(2) DiGAV
Overall impression	Overall subjective rating, perceived utility, and user trust	section 139e (13) No. 2 SGB V

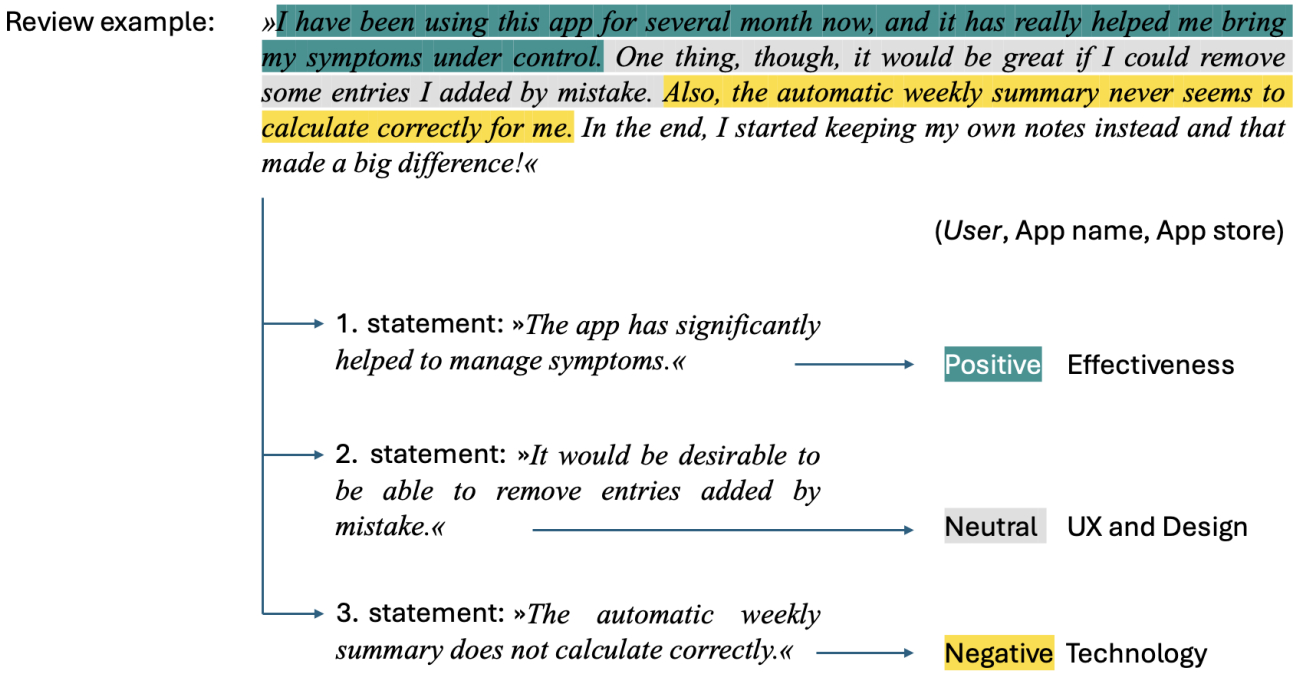
A more detailed overview of the legal sources and their mapping to categories is provided in Multimedia Appendix 1.

Model-Based Sentiment and Category Assignment

To systematically assess user sentiment, we developed a custom Python script to automate the classification process using the GPT-4o API provided by OpenAI (steps 1 - 3). GPT-4o was selected since previous research has shown that GPT-based LLMs can achieve strong zero-shot performance in sentiment classification of user-generated texts and online reviews [22]. Each user review was processed individually using a carefully structured prompt designed to guide the model toward consistent and domain-specific classification (Multimedia Appendix 2). The model was instructed to adopt the role of an expert in evaluating user experiences with DiGAs. The prompt was developed iteratively before the full-scale analysis. Initial prompt versions were piloted on a heterogeneous subset of reviews and refined through repeated inspection of ambiguous, inconsistent, or insufficiently specific model outputs. Revisions focused on clarifying category definitions, decision rules for mixed sentiment, and the required structured output format. This iterative prompt-development approach follows emerging methodological guidance emphasizing prompt specification, testing, and refinement for reliable LLM-supported classification tasks [23]. Within this role, it performed the following multistep tasks:



- Extract up to 5 core statements from each user review.
- Assign each statement a sentiment label (positive, neutral, or negative).

XSL•FO
RenderX

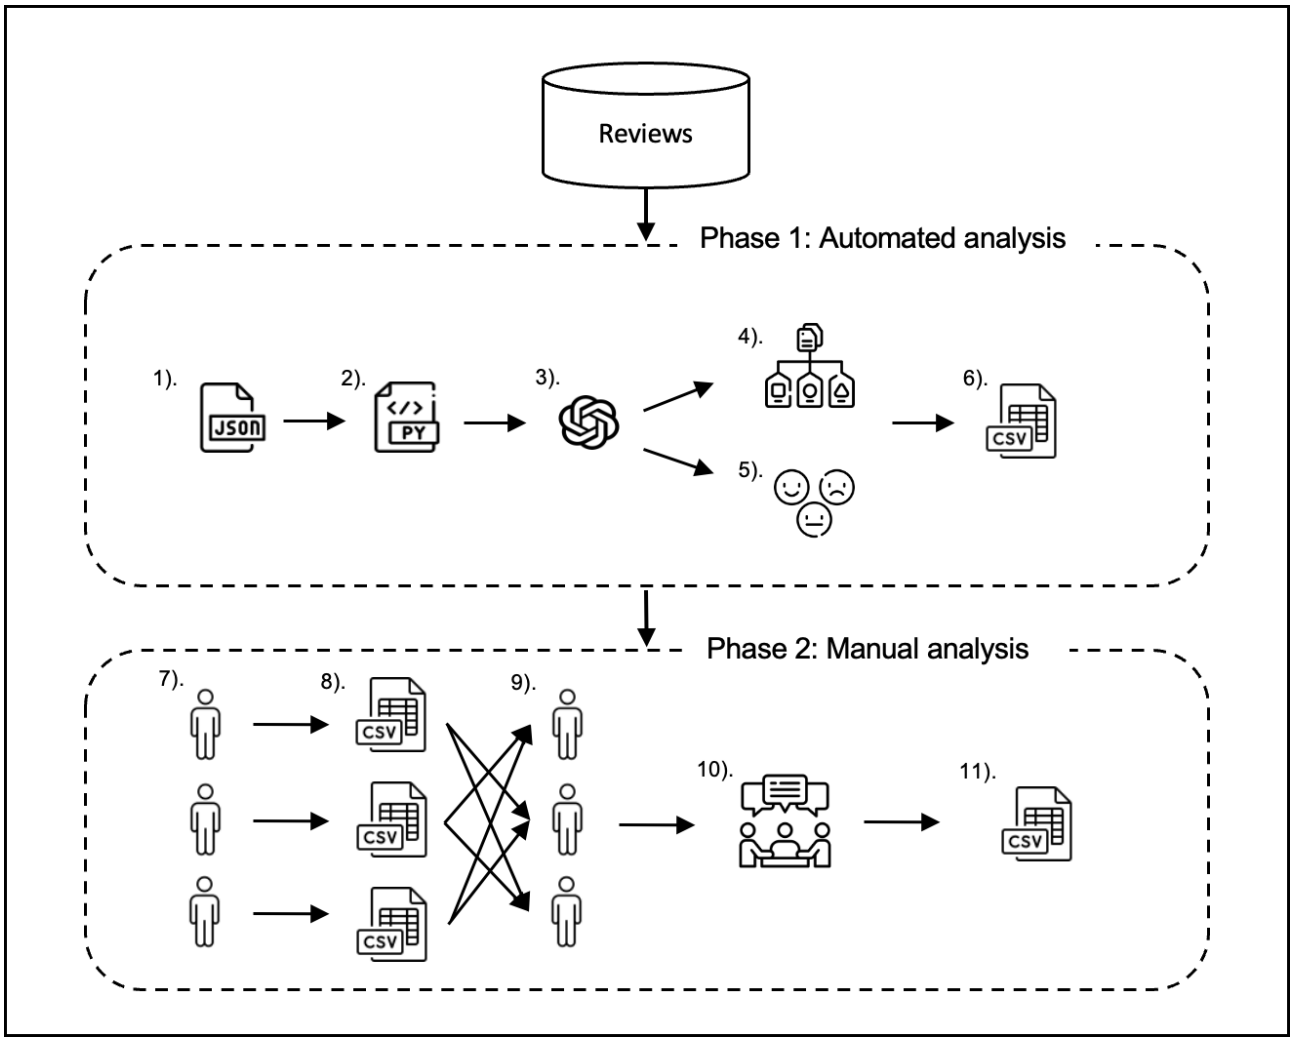
- Assign each statement to exactly one of the 10 predefined thematic categories derived from the legal and quality criteria for DiGAs (Multimedia Appendix 1).
- Merge statements that refer to the same theme and sentiment into a single, summarized expression.
- Avoid repeating partial aspects of the same issue across multiple statements.
- Limit each category to one statement per review, unless clearly distinct subtopics are present.
- Exclude overall evaluations if the review indicates that the app could not be used (eg, due to failed registration or missing insurance approval).

The model was provided with a fixed list of 10 valid categories, accompanied by specific guidance on ambiguous cases. For example, access issues after prescription or insurer approval were to be categorized as login and registration, not prescription and approval. User reviews may contain several distinct evaluative aspects. Extracting up to 5 core statements allowed the analysis to capture this multidimensionality while maintaining a consistent upper limit across reviews and preventing unusually long reviews from disproportionately influencing the dataset. Finally, the model was instructed to return its output in a standardized, structured format with numbered statements, each containing 3 elements: the *extracted statement*, *sentiment label*, and *assigned category*. A representative example was included in the prompt to enforce consistent formatting and interpretation. In order to assess whether an unsupervised topic-modeling approach could provide a suitable alternative to the predefined, prompt-based classification [24], we additionally conducted an exploratory BERTopic analysis following Uncovska et al [19]. BERTopic was applied to the complete corpus of user reviews to identify recurring themes without imposing predefined categories. The resulting topic clusters were assessed with respect to thematic coherence, clinical interpretability, and correspondence with the 10 predefined DiGA evaluation categories. In addition, we considered whether the approach could adequately represent multiple distinct issues within a single review. This exploratory comparison informed the selection of the final analytical approach. In the following processing steps, the script parsed the structured model output into a tabular dataset containing the extracted statements and their corresponding sentiment labels and thematic categories (steps 4 - 5). All results were exported in a standardized CSV format for further manual validation (step 6). By assigning the model a clearly defined expert perspective and domain logic, we ensured that the sentiment analysis aligned with both linguistic consistency and health service evaluation standards. A fictitious example of this classification process is shown in Figure 1.

Figure 1. Illustrative example of review classification process. UX: user experience.

Human Validation of Model Output

The accuracy and conceptual validity of the model-generated classifications were evaluated through a structured validation process, as shown in Figure 2. The full set of reviews, including the original review, extracted statement, sentiment label, and categories, was evenly divided among 3 authors (step 7), each of whom independently reviewed one-third of the dataset (step 8). The validation process followed a four-step protocol given below:



1. Independent review: Each model-generated statement and its assigned sentiment and category were assessed in relation to the original review. Reviewers evaluated whether the extracted statement captured a meaningful aspect of the review and whether the sentiment and category were accurate according to the predefined classification framework.
2. Flagging of inconsistencies: Statements that were incomplete, overly generic, redundant, or incorrectly classified (eg, in sentiment or category) were flagged. Each

XSL•FO
RenderX

flagged item included a brief comment and a suggested correction, if appropriate.

3. Triangulated reassessment: The 2 remaining authors independently evaluated the flagged items, providing their own classifications without being influenced by the previous assessments (step 9). This resulted in 3 independent judgments per flagged entry.
4. Consensus resolution: In cases of disagreement, the authors discussed each item until a final classification was agreed upon (step 10).

Figure 2. Overview of the 2-phase classification and sentiment analysis process, combining automated extraction and classification (phase 1) with manual validation and consensus (phase 2).

Validated statements were finalized and included in the analysis as a consolidated CSV dataset (step 11). Structurally flawed outputs (eg, empty responses or parsing errors) were reprocessed. The manual validation ensured consistency with the classification framework and enabled direct evaluation of the model on real-world data.

Data Analysis

Following the classification and validation process, a descriptive analysis was conducted. The proportions of positive, neutral, and negative statements were calculated for the full dataset and for each of the 10 categories. Data processing and descriptive analyses were performed in Python using the *pandas* library (version 2.2.3), while figures were generated using *matplotlib* (version 1.3.0). In addition, the validated statements within each category were qualitatively reviewed by the authors to identify recurring content patterns among the positive, neutral, and negative statements. The category-specific findings reported in the "Results" section, including descriptions of frequently mentioned issues, are based on this qualitative review. Because a single app accounted for a disproportionately high share of the dataset, a sensitivity analysis was performed in which all analyses were repeated after excluding this app to assess whether its disproportionate weight biased the overall results. In addition, because statements originating from the same app are unlikely to be fully independent, all analyses were additionally repeated using an app-level averaging approach. In this clustering-adjusted analysis, sentiment proportions were calculated separately for each app and then averaged across apps so that every app contributed equally regardless of the number of statements it provided.

Beyond the predefined statement-level classification, an exploratory BERTopic analysis was conducted on all included reviews using a multilingual sentence transformer model (paraphrase-multilingual-mpnet-base-v2) to assess whether unsupervised topic modeling could provide a suitable approach [24]. Topics were inspected qualitatively based on their top

XSL•FO
RenderX

terms and compared with the 10 predefined categories. Based on this assessment, BERTopic was not used for the final quantitative analysis. The full topic modeling output can be found in Multimedia Appendix 3.

Ethical Considerations

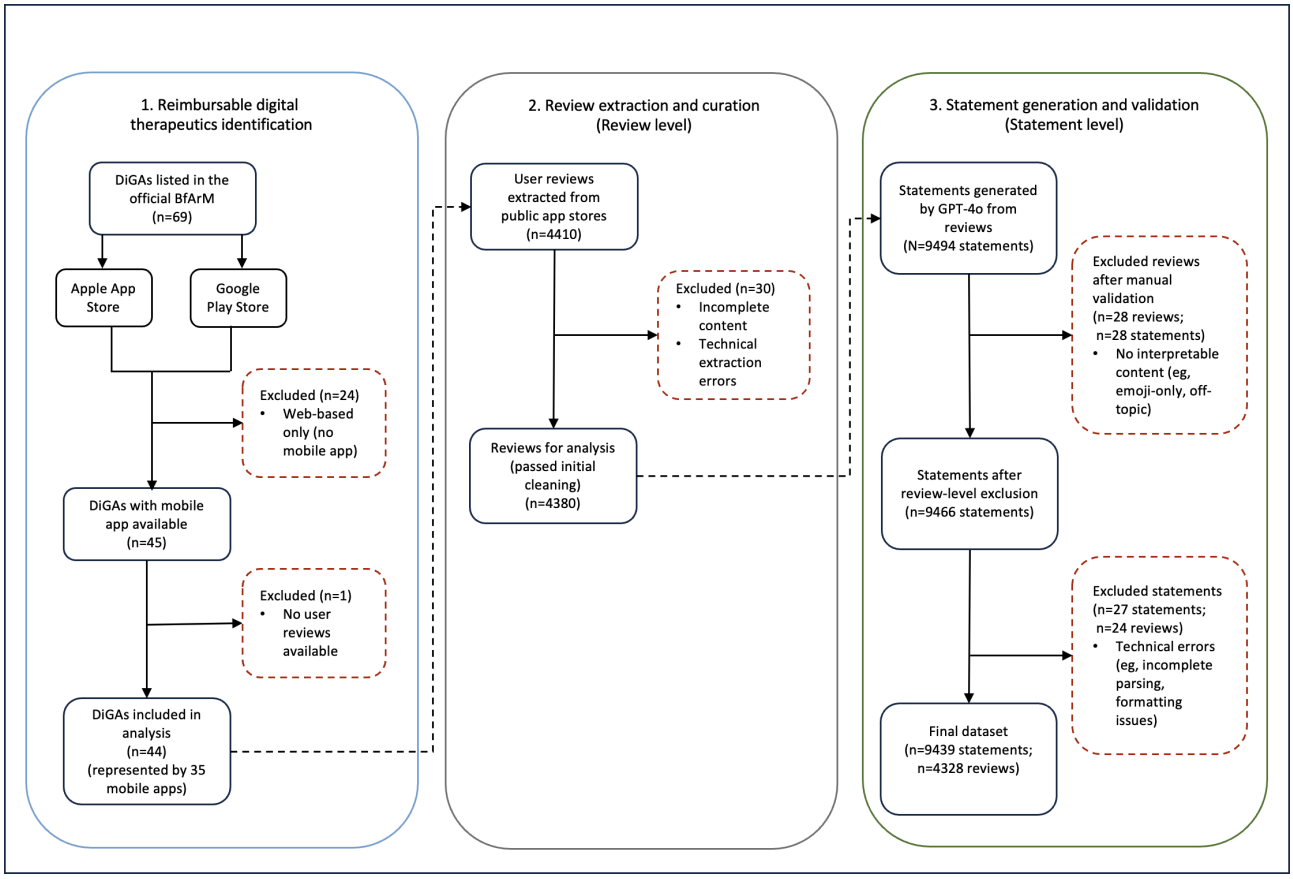
This study analyzed publicly accessible user reviews voluntarily submitted to the German Apple App Store and the Google Play Store. The study involved no interaction with review authors, no recruitment of participants, and no access to clinical records, nonpublic personal data, or other restricted information. The analysis was observational and based exclusively on publicly available product evaluations. Following the context-sensitive framework proposed by Eysenbach and Till [25], we considered not only the public accessibility of the reviews but also the nature of the online setting, the noninteractive study design, and potential risks to review authors. App store reviews were treated as publicly accessible, one-directional product evaluations rather than communications within a bounded virtual community. The reviews could be viewed without registration and did not involve an expectation of interpersonal exchange or membership in a restricted group. The analysis of publicly available app store reviews is an established approach in mHealth research and has been used to investigate user experience, usability, perceived benefits, and recurring barriers to app use [13,20-22]. To reduce potential privacy risks, analyses were conducted and reported primarily in aggregate form. No usernames, account identifiers, or other direct identifiers were included in the analytical dataset or reported in the manuscript. Because verbatim quotations may enable reidentification through search engines, no direct quotations from individual reviews are reported in this manuscript. Formal ethics review was not sought because the study involved a noninteractive analysis of publicly accessible app store reviews and did not involve the collection of nonpublic personal data.

Results

Overview of the Dataset

As of February 25, 2025, a total of 69 DiGAs were listed in the official directory maintained by the German BfArM. Of these, 45 DiGAs were available as mobile apps (iOS and Android), and 34 offered a web-based version, with several products available in both formats. Since DiGA-user reviews are only available for mobile apps distributed through public app stores, the analysis was limited to the mobile app versions of DiGAs. Web-based applications were excluded due to the lack of publicly accessible user feedback.

Although 45 DiGAs had a mobile app, 1 DiGA had no publicly available user reviews and could therefore not be analyzed. Thus, 44 DiGAs were included in the analysis. Among them, 29 (65.9%) had been permanently approved, and 15 (34.1%) were listed on a provisional basis at the time of data collection. It is important to note that several DTx share a common mobile app. For example, the *HelloBetter* app includes 6 distinct DiGAs addressing different indications (eg, chronic pain, diabetes, sleep disorders, panic, stress, and vaginismus), all delivered through the same app infrastructure. Similarly, the *Selfapy* app delivers 5 approved DiGAs (eg, for depression, bulimia nervosa, generalized anxiety disorder, and chronic pain) through a single mobile app. Accordingly, the 44 DiGAs available as mobile apps are represented by 35 mobile apps. Consequently, the app-based analysis cannot fully differentiate between user feedback for each individual DiGA when multiple products are bundled within one app. Nevertheless, all reviews associated with such apps were included in the analysis, as they reflect real-world user experiences with the respective DiGA ecosystem.



From these apps, 4410 publicly accessible user reviews were extracted via the browser-based versions of the German Apple App Store and the German Google Play Store. For the Apple App Store, only up to 10 written reviews are publicly visible per app when accessed via a browser. During data cleaning and preprocessing, 30 reviews could not be processed further due to incomplete content, parsing errors, or other technical parsing errors. These entries were excluded from the analysis. The remaining dataset of 4380 reviews was fully included in the quantitative and sentiment-based evaluation.

Validation of Model Output

From the 4380 included user reviews, a total of 9494 individual statements were extracted and systematically categorized. Each statement was assigned both a sentiment label (positive, neutral, or negative) and a thematic category. The initial classification was conducted by an LLM, followed by the manual validation. During this manual validation, 28 reviews were excluded due to irrelevance or ambiguous content. These reviews primarily included off-topic comments, incomplete sentences, and noninformative content unrelated to the DTx itself—such as emoji-only responses, promotional slogans, or vague remarks like “I want to be a hero. Greatings, Josef, “just installed,” or “don’t know yet.” In addition, 27 statements (corresponding to 24 reviews) were flagged as technically erroneous and removed. Statements addressing aspects outside the 10 predefined categories were rarely observed during validation. Together, manual-validation exclusions (28 reviews) and the technical exclusions (24 reviews) affected a total of 52 user reviews that were not included in the final dataset. As a result, the final dataset comprises 4328 user reviews containing at least one interpretable statement and a total of 9439 valid and interpretable statements. The complete data processing workflow, including all extraction, classification, and exclusion steps, is summarized in Figure 3. The complete classified dataset is provided in Multimedia Appendix 4. These 9439 statements form the basis for all subsequent quantitative analyses presented in this study. On average, a review consisted of 213.9 characters and 2.2 relevant statements. A detailed overview of the distribution of valid reviews and statements across individual apps can be found in Multimedia Appendix 4.

RenderX

Figure 3. Workflow of review data identification, extraction, cleaning, and validation. DiGa: digital health application.

Agreement Between Initial Model Output and Human-Validated Classification

To assess the reliability of the automated sentiment and category classification, a systematic manual validation was performed. Agreement between the initial GPT-4o classifications and the final human-validated classifications was high. For sentiment labels, the overall agreement was 99%, with excellent precision and recall for positive (n=6491; F_1 score=1.00) and negative statements (n=2474; F_1-score=0.99) and for neutral statements (n=474; F_1-score=o.92). The sentiment confusion matrix (Figure 4a) shows minimal misclassifications, primarily between neutral and negative labels.

For category classification, agreement between the initial model output and the final human-validated classifications was 95%, with an average F_1-score of 0.95 (Figure 4b). Most thematic agreements were consistent with human reviewers' assessments, particularly for frequently occurring categories such as *overall impression* (n=1431; F_1-score=0.96), *content* (n=2564; F_1-score=0.95), *effectiveness* (n=1609; F_1-score=0.94), and *support* (n=865; F_1-score=0.98). However, lower agreement rates were observed for categories with fewer labeled examples, such as *prescription/approval* (n=234; F_1-score=0.89) and *login/registration* (n=280; F_1-score=0.92).

XSL•FO
RenderX

Figure 4. Confusion matrices for the model-based classification: (a) sentiment and (b) category.

Distribution of Sentiments and Categories

In total, 6491 out of 9439 (68.8) statements were classified as positive, 474 out of 9439 (5.0%) statements as neutral, and 2474 out of 9439 (26.2%) statements as negative. The majority of positive statements were assigned to the category *content* (n=2001, 30.8%), followed by *effectiveness* (n=1440, 22.2%) and *overall impression* (n=1233, 19.0%). Among the 474 neutral statements, most were related to *content* (n=145, 30.6%), *UX/design* (n=83, 17.5%), and *effectiveness* (n=68, 14.3%). Negative classifications (n=2474) occurred most frequently in the categories *Technology* (n=563, 22.8%), *UX/design* (n=340, 13.7%), and *login/registration* (n=263, 10.6%) (Figure 5a). A sensitivity analysis excluding the DTx Zanadio (Sidekick Health Germany GmbH), which accounted for 1433 of 4328 (33.1%) reviews, showed a slightly lower proportion of positive statements (65% vs 68.8% in the full dataset) but did not change the overall pattern of the results, with the same categories dominating positive and negative feedback (Figure 5b).

Figure 5. Sentiment distribution per category across all apps (a) and excluding Zanadio (b).

A clustering-adjusted analysis, in which sentiment proportions were averaged across apps rather than pooled across statements, showed comparable results (64.2% vs 65.0% [3963/6098] positive statements when excluding the most frequently reviewed app) and did not change the ranking of the most positively and most negatively evaluated categories. Larger deviations occurred only in the categories cost and reimbursement and support, in which the median number of statements per app was below 5, making estimates more sensitive to individual reviews. The full comparison is provided in Multimedia Appendix 5.

In addition to the aggregated results, sentiment distributions were also analyzed separately for each individual DTx included

XSL•FO
RenderX

in the dataset. The detailed graphical breakdown of sentiment and thematic categories per app is provided in Multimedia Appendix 6 for reference. This allows a more granular exploration of potential differences in user feedback across specific DTx products, beyond the aggregated trends presented in the "Result" section.

Category-Specific Findings

The following sections provide a detailed overview of user feedback for 3 selected categories: *overall impression*, *effectiveness*, and *login/registration*. These categories were chosen due to their high frequency and relevance across the dataset. Analyses of additional categories, such as *UX/design*, *tracking/documentation*, *technology*, *support*, *prescription/approval*, *cost/reimbursement*, and *content* are provided in Multimedia Appendix 1 for reference.

Overall Impression

A total of 1431 user statements were categorized under "overall impression", providing general user feedback regarding the DTx experience. Positive reviews frequently emphasized the usefulness, clarity, and motivational aspects of the apps. Several users described individual programs as motivating, adaptable to personal needs, and worth recommending. Others highlighted that an app helped them understand and manage specific health concerns and praised its intuitive, clearly structured design, or noted that exploring the relationship between their condition and an everyday factor was insightful and that the app was easy to use. Neutral sentiments reflected initial or uncertain user experiences, with some users indicating only a tentative first impression or that they were not yet convinced. Reviews with negative statements often criticized technical problems or unmet expectations, such as poor performance and a lack of personalization due to a nonadjustable algorithm, or noted that, while an app supported the documentation of symptoms, it did not substitute for therapy and provided no personal benefit.

Login/Registration

In total, 280 user statements addressed the login and registration process. Positive feedback frequently highlighted an easy onboarding experience and simple account handling, with users describing straightforward registration, clear profile setup, and quick login as features that made it easy to get started. Neutral reviews often paired a generally positive impression with specific suggestions for improvement, such as the wish to have their login data or the email address saved to reduce repeated entry. Negative experiences primarily concerned technical login problems or authentication procedures perceived as overly complex. Some users reported losing access to their account after an update and being frustrated by having to log in repeatedly, while others described persistent login failures independent of their email provider. Several users specifically objected to a 2-step login process, which they considered unnecessary for this type of app.

Effectiveness

The category "effectiveness" received 1609 user statements, making it one of the most frequently mentioned aspects of the DTx evaluations. Many users reported positive effects on their health, highlighting improved well-being, symptom relief, or successful integration of the app into daily routines. Users described being satisfied with the range of features and reported that an app had genuinely helped them or that a sleep-focused app had improved how quickly they fell asleep and how well they stayed asleep, while praising its clear structure. Neutral reviews often reflected mixed impressions or external limitations affecting the expected effectiveness, such as finding reminders simultaneously bothersome and necessary or struggling with personal motivation despite valuing the content. Others characterized an app as a helpful first step toward understanding their condition, one that nonetheless required discipline and could not replace professional medical care. Reviews with negative statements often expressed disappointment about insufficient health improvements, with some users noting that helpful tips ultimately did not work for them. A more critical assessment reported no improvement despite full completion of the program, criticized the high cost, reimbursed by health insurance, relative to the benefits, and described the app as poorly designed and unstable.

Discussion

Principal Results

This study presents a large-scale analysis of publicly available app store reviews for reimbursable DiGAs in Germany, based on 9439 classified user statements across 44 listed DTx. Our results show that user feedback was predominantly positive with 6491 of 9439 (68.8%) classified as positive. Positive sentiment was particularly concentrated in the categories effectiveness (1440/1609, 89.5% positive), overall impression (1233/1431, 86.2% positive), and content (2001/2565, 78.0% positive), indicating that users who submitted reviews frequently expressed favorable views of the therapeutic approach and content of these apps. At the same time, 2474 of 9439 (26.2%) statements were negative, with login and registration, technology, and prescription and approval emerging as the most frequently criticized dimensions, pointing to persistent barriers in access, technical reliability, and administrative processes. The high overall classification performance of the model (99% sentiment accuracy, 95% category accuracy) supports the reliability of these patterns.

The predominantly positive overall sentiment, particularly in the categories of effectiveness and content, suggests that many users may perceive DiGAs as therapeutically meaningful and that the content quality of many apps may meet user expectations. This finding should be interpreted in light of known review behavior, as app store reviews tend to be predominantly positive overall, with praise being the most frequently expressed topic [26]. The high proportion of positive statements regarding effectiveness is therefore best understood as an indicator of perceived, self-reported benefit rather than a validated therapeutic effect. Notably, perceived effectiveness from the user perspective has also gained regulatory attention, as the app-accompanying assessment under section 139e (13) SGB V has included patient-reported health status during the DiGA use since January 1, 2026 [3].

In contrast, the high share of negative statements in the categories technology, login and registration, and prescription

XSL•FO
RenderX

and approval points to structural barriers that undermine user access and sustained engagement. Technical malfunctions and app instability are particularly concerning given that DiGAs are regulated medical devices subject to quality and safety requirements under section 139e Abs 2 SGB V. Frequent user criticism of bugs and crashes suggests a gap between regulatory certification and real-world software quality, indicating a need for improved release and quality management by manufacturers [27]. From a requirements engineering perspective, technical stability and reliable access represent basic requirements or "must-be" factors whose absence reliably generates negative feedback, regardless of, for example, an app's therapeutic value [28].

The criticism directed at login and registration processes reflects a broader tension between security requirements and usability. Multifactor authentication, while aligned with national cybersecurity standards, appears to conflict with the low-threshold access that digital regulations expect for a user population with an average age of 55-60 years [6]. Similarly, the prescription and approval category reveals user frustration with the administrative burden of the reimbursement pathway, including lengthy insurer approval processes, eligibility restrictions, and the recurring 90-day prescription cycle. Some users additionally expressed a desire to trial apps before committing to a prescription, which aligns with broader arguments in the literature for more flexible access models in DTx [12]. This concern is in line with broader critiques of the DiGA framework, in which the activation and prescription process and the lack of trial options have been identified as barriers to acceptance among prescribing physicians [11].

Compared to Uncovska et al [19], who applied unsupervised BERTopic modeling to a mixed sample of regulated and nonregulated mHealth apps, our study focuses exclusively on officially listed DiGAs and maps user feedback to a predefined framework grounded in regulatory criteria. Rather than discovering latent topics, our approach systematically evaluates user experience along dimensions that are directly relevant to DiGA approval and postmarket monitoring. This regulatory alignment allows for more targeted interpretation of findings and facilitates direct translation into policy and quality improvement recommendations. However, such reviews cannot replace formal postmarket surveillance or systematically collected patient-reported outcome measures, as they are subject to selection bias and may not represent the broader user population [8,9].

Limitations

Several methodological limitations should be considered when interpreting these findings. App store reviews are voluntary and may be affected by self-selection bias, as users with particularly positive or negative experiences may be more likely to provide feedback, whereas neutral experiences may be underrepresented [26]. The reviews are submitted without a standardized clinical or usage context. Thus, they may reflect isolated incidents rather than sustained use, and cannot be considered representative of all DiGA users. In addition, app store reviews are not a curated or audited source, and prior research has identified potentially incentivized or inauthentic reviews in app stores [29]. No additional bot detection or fraud screening beyond the app stores' own moderation was applied, and neither users' identity nor patient status could be verified. They should therefore be interpreted as complementary insights into perceived user experience and usability rather than as a replacement for formal clinical evaluation or postmarket surveillance. The validation process was not based on a fully independent blinded double-coding design. The 3 reviewers assessed and corrected model-generated statements and labels in relation to the original review rather than independently annotating all reviews from scratch. Although this enabled the validation of a large dataset, it may have introduced anchoring or acceptance effects. The reported agreement measures therefore reflect concordance between the initial model output and the final human-validated dataset, rather than an independent estimate of model accuracy or interrater reliability. The predefined category framework, while based on legal, regulatory, and quality-related criteria for reimbursable DiGAs, may not fully capture user concerns outside these dimensions, such as social support, gamification, emotional well-being, or motivational factors. As the framework was derived from regulatory requirements, it captures the quality dimensions that are legally relevant for DiGAs, but not necessarily features that go beyond these requirements and may generate particular enthusiasm among users. Identifying the latter would require an inductive coding approach, which presents a promising direction for future research. In addition, reviews were available at the level of mobile apps rather than individual DiGAs. Because several apps bundled multiple DiGAs, feedback could not always be assigned reliably to a specific product, indication, or listing status. Moreover, a single app accounted for approximately one-third of all reviews, so the aggregated findings are weighted toward the most frequently reviewed apps. A sensitivity analysis excluding this app confirmed the overall sentiment distribution and category patterns, but the pooled percentages should be interpreted with this imbalance in mind.

Finally, the analysis did not investigate the temporal development of reviews in detail. Future longitudinal analyses could assess whether technology-related complaints were transient, for example following app launches or updates, or reflected persistent barriers [30].

Comparison With Prior Work

Our findings are consistent with prior app review research showing that technical issues, registration barriers, and usability problems are recurring concerns in mHealth apps [14,19]. However, by linking user feedback to regulation-informed categories, our study adds a different perspective: it shows which aspects of the DiGA approval framework are reflected in users' real-world experience and where practical barriers persist despite regulatory certification. In this sense, the study extends prior exploratory work by demonstrating how app store reviews can be used not only to identify general user concerns, but also to generate user-reported real-world evidence relevant to postmarket monitoring and regulatory quality improvement. Similar patterns emerge in other contexts. In an analysis of app store reviews for prescription DTx cleared by the US Food and Drug Administration, access barriers, technical problems, and engagement limitations were among the most frequent themes

XSL•FO
RenderX

[20]. A thematic analysis of 13,549 reviews of mental health apps identified poor usability as the most common reason for app abandonment, along with registration requirements perceived as excessive [21]. Overall sentiment in the US sample was predominantly negative, in contrast to our largely positive findings, which may reflect differences in reimbursement or prescription pathways.

Conclusions

This study provides a large-scale overview of how users experience and evaluate reimbursable DTx in Germany, based on publicly available app store reviews. The findings show that publicly available app store reviews can reveal practical barriers that affect whether reimbursable DTx are accessible, usable, and acceptable in everyday care. Although user feedback was predominantly positive, especially regarding perceived effectiveness, overall impression, and content, recurring criticism of login and registration processes, technical reliability, and prescription and approval procedures indicates that users continue to encounter barriers at key points of access and use.

The practical relevance of these findings lies in the fact that many of the criticized aspects are not peripheral convenience issues, but basic prerequisites for sustained engagement with medical-grade digital health apps. Technical stability, reliable access, understandable onboarding, and low-threshold registration should therefore be treated as essential implementation requirements. App store reviews may help regulators, manufacturers, and researchers identify such barriers early and complement formal evaluation procedures with user-centered real-world feedback. LLM-assisted approaches can support this process by enabling large volumes of unstructured user feedback to be analyzed in a structured and scalable way. As the DiGA framework matures, systematically incorporating user-reported real-world evidence into postmarket surveillance could help ensure that regulatory certification translates into DTx that are not only proven to be effective in clinical trials but also accessible and usable in everyday care.

Acknowledgments

The authors thank the Institute of Medical Informatics and Artificial Intelligence (MIKI), Kiel University, and the University Hospital Schleswig-Holstein, for providing the infrastructure and resources that supported this work.

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: code generation, code optimization, process automation, creation of algorithms for data analysis, data analysis, proofreading and editing, and translation. GPT-4o (OpenAI) was used for automated sentiment analysis and thematic categorization of app store reviews, code generation and optimization, and language editing of the manuscript. DeepL (July 2025) was used exclusively for the translation of user review quotes from German to English. The scientific conceptualization, literature review, data interpretation, and conclusions are entirely the work of the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Funding

The authors declare no financial support was received for this work.

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information files. User names extracted from public app store reviews were replaced with pseudonyms prior to publication. A mapping table linking pseudonyms to original user names is retained by the corresponding author and is available on reasonable request. The analysis code is not publicly available, as it was developed specifically for this study and is not maintained for external use, but it is available from the corresponding author on reasonable request.

Abstract

Background: Human factors (HF), or ergonomics, which explores the interaction between humans and systems, has been used to support design in safety-critical industries such as aviation, transportation, nuclear power, and manufacturing. HF methods have the potential to support the safe design of health IT; however, the evaluation of HF methods to determine their effectiveness and feasibility in this context has been limited.

Objective: The aim of this study was to identify criteria for evaluating HF methods when applied to real-world projects and to use these to propose a framework for method evaluation.

Methods: The study design was qualitative and descriptive and involved semistructured interviews with HF experts working across health and nonhealth industries in academic and/or practitioner roles. HF experts held a relevant degree (eg, ergonomics and HF engineering) and were actively using their HF expertise. Results were thematically analyzed.

Results: A total of 21 participants took part, and interviews lasted, on average, 52 (range 39 - 103) minutes. Participants mentioned that they did not routinely evaluate methods; however, when asked how they would evaluate methods, they outlined a range of criteria to support method evaluation. Overall, 5 criteria and 28 subcriteria were identified. High-level criteria included effectiveness, efficiency, ease of use and acceptability, and impact on the solution.

Conclusions: Results from this study were used to propose a framework for evaluating HF methods used in real-world health IT projects. The framework should provide organizations with valuable information on how to optimize the application and outcomes of HF methods and build HF capability within organizations, particularly where this capability may be lacking.

Introduction

Health IT (HIT) enables the processing, storage, and exchange of health information in an electronic environment [1]. In the United States, the Meaningful Use program has led to a significant increase in the adoption of HIT, such as electronic health records [1]. Although clear benefits of HIT have been demonstrated [2,3], research has shown that many HITs suffer from poor usability [4,5]. Usability is a measure of how well a specific user in a specific context can use a product to achieve a defined goal safely, effectively, efficiently, and satisfactorily [5]. Usability can be compromised by poor design and lead to "use errors" [5-7]. The relationship between system design and safety in the context of HIT is well recognized in the literature [5,8-12]. For example, a recent systematic review found that poorly designed electronic health records were associated with usability issues such as poor data entry, lack of workflow support, and inadequate automation [13]. These issues directly contributed to medication errors, such as patient overdoses, and had other negative impacts on medication safety [13]. Human factors (HF) methods have the potential to reduce "use errors" and, in turn, improve patient outcomes [7].

The discipline of HF, or ergonomics, which explores the interaction between humans and systems, has been used to support design in safety-critical industries such as aviation, transportation, nuclear power, and manufacturing [7,14-16]. While some HF methods, particularly those focused on human-computer interaction (eg, usability testing), have been used to support the design and redesign of HIT, the use of safety-focused and systems-based HF methods in this context is limited [8,17]. HF methods commonly used in the HIT context tend to have a linear and micro perspective of potential issues

XSL•FO
RenderX

that may affect system use and user behavior, as they focus on specific problems that may be encountered by the individual user using the system rather than considering the entire sociotechnical system [8,17,18]. HF methods that apply a systems thinking lens to identify problems and risks that may arise from the interactions between components of a complex system are less commonly used in HIT design and evaluation [8,17,19,20].

Potential reasons for the limited use of HF methods include issues with the availability of HF expertise in health care, a research-practice gap, a potential echo chamber effect within health care whereby the same subset of well-known methods is used repeatedly, issues with method usability, and challenges with demonstrating the value added by HF application to justify up-front investment [10,17,20,21]. Further research is required to demonstrate the value of applying HF methods (particularly those with a systems safety focus) to HIT, supported by a robust evaluation approach or framework [22,23].

Evaluation of HF methods to determine their effectiveness and feasibility has been limited. Previous evaluations have mainly been in the context of academic studies evaluating the reliability, validity, and efficacy of some HF methods, for example, when applied by health care participants as compared with experienced HF experts [20]. Despite these studies, empirical data regarding the reliability or validity of many HF methods do not exist [24]. Several challenges associated with conducting these forms of evaluations have been cited, including challenges with recruiting enough experts to enable comparison with a gold standard, time and resource intensiveness, and limited knowledge of appropriate statistical analyses [22,24].

An additional challenge is that there is no consensus or agreement on what constitutes an effective or valuable HF method. How do HF practitioners select and evaluate methods when applying them to real-world projects as part of HF integration processes?

Although a previous paper provides suggestions on potential evaluation criteria for HF methods [18], these are not comprehensive and represent the authors' recommendations rather than findings derived from research methods. The aim of this study was to identify criteria for evaluating HF methods when applied to real-world projects and to use these to propose a framework for method evaluation.

Methods

Overview

This qualitative descriptive study was undertaken as part of a larger study that focused on HF and safety analysis methods for use in the design, redesign, and configuration of HIT. The study design involved semistructured interviews with HF experts working across health and nonhealth industries in academic and/or practitioner roles. A participant was considered an HF expert if they had a relevant degree (eg, ergonomics and HF engineering) and were actively using their HF expertise. Part 1, currently under review, explored what HF methods experts use and how they are selected. Part 2, reported here, explored criteria HF experts use or view as important to evaluate HF methods. Questions used to guide the semistructured interviews were developed by a clinical informatics professional with expertise in design, HF, and safety and quality (SA) and a HF expert (MB) and reviewed by other members of the research team with HF (TL and RB) and implementation science (AB) expertise. After collecting demographic information, the 2 main questions asked relevant to this study were "What makes a 'good' HF method to you?" and "How would you evaluate a HF method?"

Participants were recruited through a combination of purposive, opportunistic, and snowball sampling. Recruitment involved advertising the study through national HF societies and relevant working groups; promotion at an international HF and patient safety conference through networking and word-of-mouth approaches; consultation with HF experts and contacts to recommend potential participants; and a review of common HF textbooks and literature to identify HF authors who could be invited to participate. In addition, HF practitioners known to the research team were directly approached. Suitable participants interested in the study, including those identified by the investigators, were invited to take part in the study via email. Recruitment continued until thematic saturation was reached, that is, no new themes were emerging from the data [25].

The interviews, conducted by SA, occurred via videoconferencing, except for one, which was face to face. Deidentified content from the interview transcripts was independently analyzed by 2 investigators with expertise in HF and qualitative analysis (SA and RB) using a general inductive approach [26]. Each investigator independently coded data for the first 5 interviews and then met to discuss findings and reach consensus on a high-level framework to support the documentation of codes into themes and subthemes. For the remainder of the interviews, each investigator continued to independently assign text to the agreed themes and subthemes using the framework and, at the end of this process, met to discuss any further discrepancies until consensus was reached [27]. Overall, the 2 investigators were generally consistent in their coding and identification of themes and subthemes. Disagreements were minor and resolved via discussion until consensus was reached.

Ethical Considerations

Ethics approval was obtained from the University of Sydney's Human Research Ethics Committee. All participants provided informed consent and agreed to be audio-recorded. All transcripts were de-identified prior to data analysis. All participants provided informed consent and agreed to be audio-recorded.

Results

Participant Demographics

A total of 21 participants took part, and interviews lasted, on average, 52 (range 39 - 103) minutes. Table 1 describes the demographics of the 21 participants.

XSL•FO
RenderX

Table . Characteristics of the participants included in the interviews (N=21).

Core industry and core role		Participants, n	Within industry category, %	Within total participants, %
Health (n=14)				
	Academic	9	64	43
	Practitioner	2	14	10
	Academic and practitioner	3	21	14
	Total	14	100	67
Nonhealth (n=7)				
	Academic	2	29	10
	Practitioner	5	71	24
	Academic and practitioner	0	0	0
	Total	7	100	33

How Should HF Methods Be Evaluated?

Participants explained that they did not routinely evaluate methods; however, when asked how they would evaluate them, they outlined a range of criteria to support method evaluation (Table 2). High-level criteria included effectiveness, efficiency, ease of use and acceptability, and impact on the solution. Other criteria, such as validity, reproducibility, and reliability, were mainly mentioned by academic participants rather than practitioners. Overall, 5 criteria and 28 subcriteria were identified.

XSL•FO
RenderX

Table . Criteria for human factors (HF) method evaluation, as reported by participants.

Criteria and subcriteria	Example quotes
Effectiveness	
1.1 Effectiveness in identifying usability issues	• [N]ice to see whether or not the amount of usability issues related to patient safety. [P2]
1.2 Effectiveness in identifying safety issues	• [N]ice to see whether or not the amount of usability issues related to patient safety. [P2] • ...there's a primary metric that matters most like which method uncovered the most safety issues in advance of implementation or which method uncovered the more severe safety issues [P9]
1.3 Ability to achieve intended impact, change or goal	• What value did it add? Like? Do you feel like added value to the project? Do you feel like it gave you the right answers or the right tools to get to the answers that you wanted? [P16] • Does it make the change that you envision?...And that has to do with your final goal [P6]
1.4 Generates recommendations that are useful and easy to implement	• Does it generate recommendations [that] are easy to implement? And that then do [they] get implemented and lead to risk management? [P7] • [T]he other thing that's really important to us in terms of criteria is going beyond analysis and figuring out a method that can actually produce useful information, and actionable information for redesign for change, for implementation, whatever you want [P11]
1.5 Ability to identify micro, meso and macro (systems) level considerations that have safety implications	• [Y]ou might do an overarching review of the technology in the context of the people using it in the context of the work in the workplace and then on the basis of that, deploy specific things that are the micro, meso, or macro level, to understand a bit more [P7]
1.6 Method's effectiveness in understanding the dynamic nature of the system	• And another important thing is to continue to collect data about the use of the system, what I call the dynamic safety of an application. [P13]
1.7 Ability to cover the required domain areas/constructs (eg, usability, safety, workload, situational awareness, and decision-making)	• And then I think it's the core human factors constructs. It's kind of like, what's the impact on situational awareness, workload? Usability, and decision making, are probably some key constructs that you might want to check [P21]
1.8 Overall usefulness	• [T]he other thing that's really important to us in terms of criteria is going beyond analysis and figuring out a method that can actually produce useful information, and actionable information for redesign for change, for implementation, whatever you want [P11]
Efficiency	
2.1 Demand on time and resources (e.g.eg, workload)	• How fast it was... how much time [and] how much budget it came under. [P16]
2.2 Cost required	• Is it cost effective? [P6]
2.3 Overall efficiency	• It's to look at the efficiency of the methods [P4]
Ease of use and acceptability	
3.1 Ease of use	• Is it usable, based on some objective standard usability? Or is it more usable than the alternative? [P7] • [Y]our method should be easy to use... not too demanding in human resources in training, and not too costly [P1] • [E]ase of use of the method and the ease of understanding the tools from the people who participate [P13]
3.2 Learnability	• How quick it was to learn [P16]

XSL•FO
RenderX

Criteria and subcriteria	Example quotes
3.3 Utility and acceptability of the method	• The types of questions that make sense are acceptability. You know, utility...in [a] very basic sense, we applied this in this way, what did we learn, we learned something new [P7]
3.4 Overall satisfaction of those applying the method	• [E]ase of use of the method and the ease of understanding the tools from the people who participate [P13]
3.5 Participant experience	• [E]ase of use of the method and the ease of understanding the tools from the people who participate [P13] • [W]e asked participants to give us feedback on the method...I think that's an important source of feedback and evaluation of the method, what do they think about it? [P11]
3.6 Likely adoption of the method based on complexity and learnability	• If you develop a very complex method, it may be the best one to identify all the problems that could lead to a risk for the patient. But...nobody's applying it [P1]
3.7 Adoption of the method by non-HF experts	• [T]alked about giving away ergonomics. And in a lot of the things that we've done that has been our goal when we leave, can they actually do things on their own? Even if it's a little bit more simple than the way we would do it? [P11]
3.8 Whether the method met expectations	• And another important thing probably is to clarify, the time needed to apply one method and the expected outcome, like a sort of table of the expectation that one can have through the application of that method, because too often, people look at the ergonomist, either those with the silver bullet in the hand, or those with some annoying requirements to be applied in the design process. [P13]
3.9 Ability of the method to be adapted	• [D]evelop questions that can be added into evaluation about the potential adaptation of these methods [P7]
Impact	
4.1 Impact on patient safety and other outcomes	• [If] you've got a goal of patient safety...the main criterion should be the risk to the patient... the likelihood of patient safety issues...if you want that your method is used, if you want to make it to be used by vendors and hospital later...analyze their human factors or risk, relate the human factors related risks of EHR [electronic health record] [P1] • Is the whole system in total more safe? [P6]
4.2 Impact on end user workflows and workloads	• [Y]ou can also identify workload issues that will slow down the care process even if it doesn't threaten directly patient [P1]
4.3 End user satisfaction (of the health information technology)	• The satisfaction of the end users also could be analyzed [P1]
4.4 Adoption of the system or tool by end users	• Is it used? Is it actually used? By all your users? [P6]
4.5 Impact on redesign (ie, whether changes or improvements were made)	• So when we redesigned the document, how many of those many, many vulnerabilities or problems were identified in the document? How many of those were we able to address? So, you know, having concrete impact on design, I think is a big issue. [P11]
Other	
5.1 Preestablished validity	• I think these reliability and validity studies are really important [P7]
5.2 Reproducibility of results	• [D]id you align to see if you meet that standard? ...and then do all these things that are for measurements, I think it must be reproducible [P9]
5.3 Reliability if applied by different people (interrater reliability)	• I think these reliability and validity studies are really important [P7]

XSL•FO
RenderX

Participants commented on challenges with quantitatively evaluating methods using the criteria identified and suggested a more qualitative, self-assessment–based evaluation; for example:

> *We usually sit down when we've concluded a project as part of the HF team and we will talk about the methods we used and how we feel they performed, whether we had any pitfalls, whether we wished we had something different, or we've done something different.* [P16]

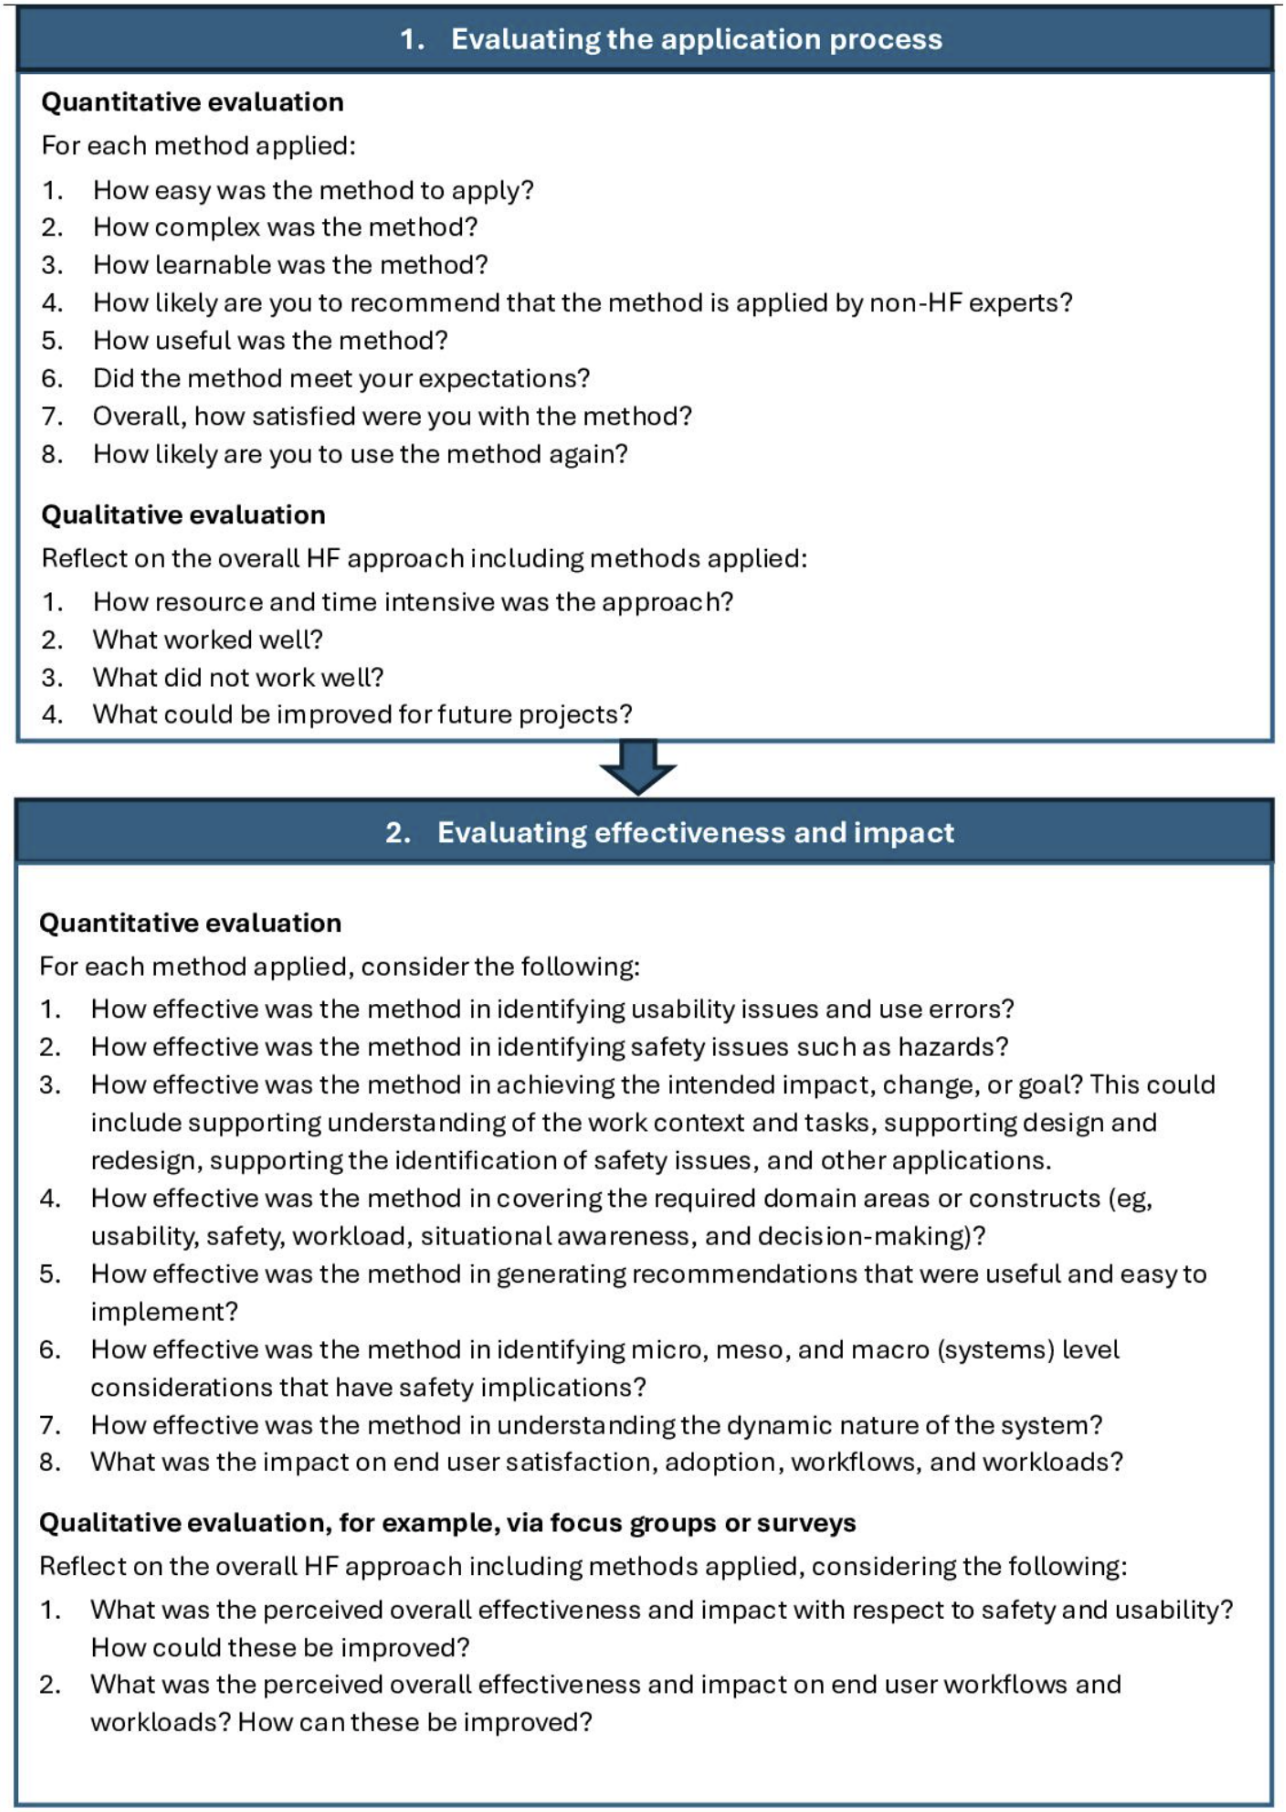
Discussion

This study identified 5 high-level criteria and 28 subcriteria to support the evaluation of HF methods in real-world HIT projects, as reported by HF practitioners across health and nonhealth industries.

Although previous studies have evaluated HF methods by focusing on validity and reliability [23], this study is the first of its kind to identify a broad range of evaluation criteria for HF methods, as recommended by HF practitioners. There is some overlap between our criteria and those developed by Waterson et al [18], which focused on the evaluation of systems-based methods. As such, this study adds to findings generated by Waterson et al [18] by confirming some of the criteria identified in this previous work. This includes outcomes of the method, the method's robustness, the method's usability and support requirements, aspects related to work domains, and aspects related to different levels (ie, individual, team, and organizational) [18].

Our study adds to this by identifying new criteria, particularly those related to operationalized usability, adoption, and other impacts on users (eg, workload); outcome-focused effectiveness, including the link between usability and safety; and more nuanced consideration of system-level considerations (micro, meso, and macro). Furthermore, the findings from our study offer a combined quantitative and qualitative approach to evaluation, with a focus on actionable insights and bridging theory and practice. These points highlight the value of exploring the views of a range of HF experts working across different industries [18].

Our study also elaborates on the method's effectiveness in understanding the dynamic nature of the system, which is aligned with systems safety thinking that defines safety as a dynamic, emergent property of how system components interact with each other [19,28-30]. A dynamic system is a complex and adaptive system that changes behavior due to interactions between system components [31-33]. As such, the safety of a system can change over time and is impacted by many variables, such as human performance, resources, and events at particular points in time. This is consistent with a study that aimed to evaluate methods, such as the functional resonance analysis method, using resilience characteristics as indicators of core safety factors [34].



Participants commented on challenges with quantitatively evaluating methods and suggested that a more qualitative approach could be used. This is generally aligned with other literature that suggests that outcome-based quantitative evaluation is not widespread and can be resource intensive [18]. Furthermore, demonstrating the impact of methods can be difficult, as system usability and safety are influenced by a range of factors outside of the method itself [18]. While many factors influence outcomes, health organizations may still benefit from using measures, for example, the number of usability and safety issues identified and user satisfaction scores, to evaluate whether applying methods results in detection of usability and safety issues. Where possible, comparative evaluation to demonstrate that applying methods is better than not applying any method may also be of value. Although such approaches may lack the academic rigor of reliability and validity studies, they may increase an organization's degree of confidence in HF methods and, therefore, willingness to invest in them. Such evaluation may help health staff and managers develop business cases for the application of HF, help organizations reflect on strategies to enhance the use of methods (eg, organizational support), and refine when and how HF methods are applied to deliver the most value within the context of challenging and complex HIT projects. This type of evaluation could occur through self-reported Likert-scale ratings (as done by Waterson et al [18]); reflective qualitative discussions, as suggested by participants in this study; and other relevant metrics.

This study had several limitations. The recruitment process relied on interested experts volunteering to participate, so the sample may have been biased and our results may not represent the views of all HF experts. We included both health and nonhealth participants, as well as practitioners and academics, but did not compare the views of participants from different groups. Although our sample size was modest, we continued interviews until thematic saturation was reached, which is the norm in qualitative research.

We used participant responses and systems safety knowledge to propose a framework for evaluating HF methods in the context of real-world HIT projects (Figure 1). By covering both process- and outcome-based evaluation, this framework loosely aligns with other evaluation frameworks, such as those used in quality improvement and program evaluation [35,36]. While we also recommend further reliability and validity academic studies to validate the robustness of HF methods in the HIT context, our proposed framework offers a subjective yet structured approach for HF method validation that can be applied by organizations to real-world HIT projects where HF methods have been used. The framework, which we recommend be applied flexibly depending on the nature of the project and the resources available, should provide organizations with valuable information on how to optimize the application and outcomes of HF methods and build HF capability within organizations, particularly where this capability may be lacking.

Abstract

Background: Although chronic pain (CP) is highly prevalent, current modalities are not sufficient to address the needs of people living with this condition. Pharmacological treatments for CP can have severe side effects and increased likelihood of patients overdosing or developing addiction. Behavioral treatments are often indicated for the treatment of CP, but barriers to treatment are common. Virtual reality (VR)–based interventions have shown promise as an effective and potentially accessible form of treatment for CP. However, previous research on VR interventions for people living with CP has not often included diverse populations, including racial and ethnic minority groups and people with low socioeconomic status.

Objective: This study aimed to gauge the interest of patients with CP in participating in a hypothetical study of at-home VR for CP and to identify predictors of interest. Patients were recruited from a low socioeconomic and racially and ethnically diverse community.

Methods: A total of 48 participants living with CP were recruited from an electronic medical record database, a research participant database, and a pain clinic, and they completed surveys about demographics, pain levels, technology use, and knowledge of VR. Bivariate testing was used to determine which, if any, of the aforementioned variables were associated with interest in a hypothetical study of at-home VR for CP. Stepwise logistic regression models predicting interest were built based on bivariate testing. Finally, we used a thematic analysis framework to analyze an additional open-ended question about reasons for interest in participating in a VR intervention for CP.

Results: Despite low technology use and little knowledge and experience with VR, results showed high interest (42/48, 88%) among patients in participating in a hypothetical study of at-home VR for CP. More frequent email use and using Facebook demonstrated nonsignificant trends toward interest in participating in a VR clinical trial for pain (P=.06 for email use and P=.06 for Facebook use). In stepwise multivariate models controlling for pain score, Facebook use was predictive of being somewhat or very interested in participating in a VR clinical trial for pain (P=.047). Open-ended responses tended to cite the novelty of VR and desperation for pain relief as reasons for participants' interest.

Conclusions: We found high interest in participating in a clinical trial of VR despite low use of technology and low knowledge of VR. Future fully powered studies should seek to confirm the effectiveness of VR treatments for people with CP, especially people from lower socioeconomic, and racially and ethnically diverse backgrounds.

Introduction

Chronic pain (CP) affects an estimated 50.2 million adults in the United States [1], and it remains one of the most common reasons people seek medical care [2]. Individuals who live in poverty, have less than a high school education, and are on public health insurance are more likely to have high-impact CP [3]. Moreover, CP is linked to numerous adverse physical and mental health outcomes [3].

Despite the burden of CP, there is no gold standard treatment, and current options are insufficient for many people living with CP. Many medications, such as antidepressants and antiepileptic drugs, have severe side effects [4]. Patients are often dissatisfied with conventional pharmacological pain treatment, reporting that CP continues to affect their health, relationships, happiness, and quality of life [5]. Opioid medications can be ineffective and carry significant risk for patients, including the potential for addiction and overdose [6,7]. Nonpharmacologic options are recommended for treating CP, but barriers to accessing them are common, including lack of availability, distance to travel, and high cost of treatment [8].

In numerous studies, patient participants seek new, innovative treatment options for CP. Virtual reality (VR) is a promising new category of therapeutic options for pain management without many of the drawbacks of conventional CP treatments. VR is effective in the treatment of acute pain [9], and emerging evidence suggests it can be effective in the treatment of CP [10]. Additionally, portable VR headsets can be used at home or in a clinic, potentially increasing availability and accessibility of treatment. Interventions involving VR may also become more affordable and more widely available compared with other current treatments as the cost of such technology continues to decrease [11,12].

As VR technology develops, the need for robust study is paramount. Nonetheless, racial and ethnic minority groups and individuals of lower socioeconomic status (SES) may face barriers to entering new VR clinical trials due to preexisting disparities in pain clinical trial enrollment and, potentially, due to low interest in technology interventions [13]. Most VR clinical trials for individuals with CP in the United States to date have included samples primarily composed of non-Hispanic White, high-SES participants [14,15].

To ensure effectiveness in all populations and to ensure equity, further clinical studies of diverse patient populations are necessary. As part of preparations for recruiting participants to a pilot study of VR for CP, we conducted a cross-sectional study of patients with CP in a low SES and racially and ethnically diverse county. The survey was aimed at identifying patients' interest in participating in a hypothetical at-home VR trial and factors associated with interest.

Methods

Overview

We conducted a cross-sectional study using telephone and in-person surveys among patients with CP to evaluate interest in participating in a study of VR for pain management and to examine factors associated with interest.

Ethical Considerations

The study was approved by the Albert Einstein College of Medicine and Montefiore Medical Center Institutional Review Board through the Office of Human Research Affairs (2021-13108**)**. Oral informed consent was obtained over the telephone at the time of the interview. Identifying data was omitted if not essential and are not published in this manuscript. Participants were reimbursed US $10 in electronic gift cards for their time at the conclusion of the survey.

Participants

We recruited patients with CP in the Bronx, New York, both over the phone and in person. Bronx County is the poorest county in New York State and has the lowest internet adoption rates of any borough in New York City [16]. One-third of the Bronx population is Black or African American, 55% is Hispanic or Latino, and 9% is non-Hispanic White [17]. The median household income is US $45,517, with 27.7% of the Bronx population living in poverty [17].

Recruitment and Eligibility

There were 3 methods used for recruitment. First, we used hospital databases to identify potential participants based on *International Classification of Diseases, Tenth Revision (ICD-10)* codes. Second, we used a separate database that consisted of patients with CP that had completed previous research studies at our institution and consented to be recontacted for future research opportunities. Potential participants were identified from these 2 databases and contacted over the phone. Third, patients were recruited in person from a general medicine CP clinic. To be eligible to complete the survey, patients had to be aged at least 18 years, speak English fluently, and be able to provide consent for themselves.

Data Collection

Data were collected between August 2021 and December 2022 and deidentified for analysis. Participants completed the following questionnaires.

Sociodemographic Questions

We asked participants about their age, highest educational level, and race and ethnicity. Educational level was dichotomized into 2 groups: less than high school education and high school education or higher.

Pain Questions

We asked participants about their CP using the Pain, Enjoyment of Life, and General Activity (PEG) scale [18]. The PEG scale is a brief 3-item scale that assesses pain intensity and interference. The 3 questions assess pain on average in the past week, how much pain has interfered with their general activity, and how much pain has interfered with their enjoyment of life. Answer choices for each of the 3 questions were given on a 0- to 10-point scale, where 0 was "no pain" or "it does not interfere" and 10 was "pain as bad as you can imagine" or "it completely interferes." The PEG score is calculated using the mean of the answers to the 3 questions. Additionally, we asked

XSL•FO
RenderX

participants about the level of bodily pain they had experienced in the past week. The answer choices were “none,” “very mild,” “mild,” “moderate,” “severe,” and “very severe.” We also asked participants about all locations where they experienced pain for at least the last 3 months.

Media and Technology Usage Scale

We asked participants about their technology use and attitudes about technology using the Media and Technology Usage Scale [19]. This scale measures (1) the use frequency of a variety of technology and media types and (2) attitudes toward technology. There are 11 usage subscales representing smartphone use, general social media use, internet searching, emailing, media sharing, SMS text messaging, video gaming, online friendships, Facebook (Meta Platforms) friendships, phone calling, and watching television. Answers to questions related to these 11 subscales are scored on a 10-point frequency scale: 1=never, 2=once a month, 3=several times a month, 4=once a week, 5=several times a week, 6=once a day, 7=several times a day, 8=once an hour, 9=several times an hour, 10=all the time. Notably, the smartphone usage scale described above reflects using functions of the smartphone, such as apps, and does not reflect using the smartphone for calling or texting; calling and texting are represented in separate scales. Attitudes toward technology are rated on a 5-point Likert-type scale ranging from 1 (strongly disagree) to 5 (strongly agree). Questions in this domain include (1) positive attitudes toward technology, (2) negative attitudes toward technology, and (3) anxiety or dependence on technology.

VR Questions

In total, we asked 6 questions about VR. First, we asked participants a set of four questions about their experience and perception of VR: (1) whether they had ever heard of VR, (2) whether they had used a VR device, (3) whether they had heard of VR being used to treat pain, and (4) whether they thought VR could work for treating pain. Participants could answer yes or no for the first 3 questions and had the additional option of answering not sure for the fourth question. A fifth question asked if participants would be interested in participating in a hypothetical study of at-home VR for CP and could answer that they were “not interested,” “somewhat interested,” or “very interested.” A sixth question was an open-ended question for participants to provide reasons for their interest or lack of interest.

Data Analysis

All participant data were included in the analysis. Information about gender was extracted from the electronic medical record. We calculated descriptive statistics (mean, median, and SD) for the PEG score, sociodemographic measures, and each of the subscales on the Media and Technology Usage Scale.

Our dependent variable was interest in participating in a hypothetical at-home VR study for CP. For this outcome, we dichotomized responses as “not interested” vs “somewhat interested” or “very interested.” While our dependent variable is subjective, in this open-ended survey, we were testing interest in participating in a future trial; therefore, we felt a subjective outcome was best suited for this study as there are many factors that may ultimately influence a decision to participate in a clinical trial, including availability, location, and incentives. Sociodemographic information, PEG score, pain location (back pain vs no back pain, knee pain vs no knee pain, and hip pain vs no hip pain), and the Media and Technology Usage Scale subscales were independent variables. We ran bivariate tests to determine whether independent variables were associated with patient interest in a hypothetical VR trial. For hypothesis testing in bivariate models, we set the double-sided α to .05. We created multivariate regression models using a stepwise approach. We identified variables a priori, including age, gender, and PEG score, to be included in the initial model regardless of significance. Additional covariates associated with the outcome in bivariate analyses at $P<.20$ were sequentially added to the model. Final model selection was guided by theoretical relevance, model fit, and statistical significance.

To summarize open-ended responses about participants’ interest in a VR trial, we coded responses using a thematic analysis framework. We reviewed codes and developed categories to reflect responses. After each response was categorized, we tabulated categories quantitatively. Where possible, we present illustrative text reflecting categories.

Results

Demographic and Survey Outcomes

Sociodemographic Variables

Of 693 participants contacted, 215 (31%) were successfully reached. Among those successfully reached, 124 (57.7%) declined, and 43 (20%) did not meet the inclusion criteria. The most common reason for exclusion in this study was only speaking Spanish (n=41, 15% of successful contacts). Of 172 potential participants, our final sample consisted of 48 (27.9%) individuals who met the inclusion criteria. The mean age of participants was 58.5 (SD 11.3) years. Of the participants, 32 (67%) were female and 16 (33%) were male. About half (n=23, 47.9%) of the participants had a high school education or less. About one-fifth (n=9, 19%) of participants were non-Hispanic White; 15 (31%) were Black; 18 (38%) were Hispanic; and 6 (13%) were Asian, Native Hawaiian or other Pacific Islander, or other. Please see Table 1 for detailed demographics.

Table 1. Survey participant characteristics (N=48).

Characteristic	Total cohort (n=48)	Interested (n=42)	Not interested (n=6)	*P* value
Age (y), mean (SD; 95% CI)	58.5 (11.3; 55.2-61.9)	58.5 (11.1; 55.0-61.9)	58.7 (13.5; 44.5-72.8)	.97
Gender, n (%; 95% CI)				.99
Woman	32 (67; 52.5-78.9)	28 (67; 51.0-79.9)	4 (67; 29.6-90.9)	
Education, n (%; 95% CI)				.45
High school or less	23 (48; 34.3-62.0)	21 (50; 35.3-64.7)	2 (33; 9.7-70.0)	
Race or ethnicity, n (%; 95% CI)				.99
White, non-Hispanic	9 (19; 10.3-32.0)	8 (19; 9.8-33.6)	1 (17; 3.0-56.4)	
Black, non-Hispanic	15 (31; 19.7-45.4)	13 (31; 19.0-46.3)	2 (33; 9.7-70.0)	
Hispanic	18 (38; 24.9-52.0)	16 (38; 24.7-53.8)	2 (33; 9.7-70.0)	
Other	6 (13; 5.6-25.6)	5 (12; 5.0-26.1)	1 (17; 3.0-56.4)	
Pain severity, n (%; 95% CI)				.89
Moderate or higher	39 (81; 67.4-90.3)	34 (81; 66.7-90.1)	5 (83; 36.5-99.1)	
Pain intensity (PEG[a] score), mean (SD; 95% CI)	6.31 (2.4; 5.61-7.01)	6.17 (2.5; 5.40-6.93)	7.28 (1.9; 5.31-9.25)	.30
Texting use, mean (SD; 95% CI)[a]	5.7 (1.9; 5.2-6.2)	5.8 (1.8; 5.2-6.3)	5.1 (2.9; 2.1-8.1)	.45
Smartphone use, mean (SD; 95% CI)[b]	4.2 (1.9; 3.6-4.7)	4.3 (1.9; 3.7-4.9)	3.3 (1.6; 1.6-5.0)	.21
Email use, mean (SD; 95% CI)[b]	4.4 (2.2; 3.8-5.0)	4.6 (2.2; 4.0-5.3)	2.8 (2.1; 0.6-5.0)	.06
Internet use, mean (SD; 95% CI)[b]	3.6 (3.0-4.2)	3.6 (3.0-4.3)	3.3 (1.3-5.3)	.75
Facebook user[c], n (%; 95% CI)	25 (2; 52.1; 37.9-66.0)	24 (2; 57.1; 41.0-71.9)	1 (2; 16.7; 3.0-56.4)	.06

[a]PEG: Pain, Enjoyment of Life, and General Activity.

[b]Use is rated 1 to 10 on the Media and Technology Usage Scale, with higher values representing more use. The scale is as follows: 1=never, 2=once a month, 3=several times a month, 4=once a week, 5=several times a week, 6=once a day, 7=several times a day, 8=once an hour, 9=several times an hour, 10=all the time.

[c]Participants were asked if they have a Facebook account.

Pain Measures

The mean PEG score was 6.31 (SD 2.4), and 39 (81%) participants reported having pain that was at least moderate. Lower back pain was the most common pain site (n=30, 63%), followed by knee pain (n=17, 35%) and hip pain (n=14, 29%).

Media and Technology Usage Scale

The mean texting usage subscale score was 5.7 (SD 1.9), reflecting text message use between several times a week and once daily. The mean phone use was 5.6 (SD 1.8), again reflecting calling or receiving calls from others between several times a week and once daily. The mean smartphone usage subscale was 4.2 (SD 1.9), which reflects using smartphone functions about once per week. The mean email use was 4.4 (SD 2.2), and the mean internet use was 3.6 (SD 2.0), with both reflecting nondaily use of these technologies. Of the 48 participants, about half (n=25, 52%) reported using Facebook. Participants generally reported mixed attitudes toward technology; mean subscale scores on positive attitude scales with technology were 3.8 (SD 0.8), reflecting a stance approaching agreement; mean subscale scores on negative attitude scales were 3.1 (SD 1.0), reflecting a neutral stance; and mean subscale scores on anxiety or dependence on technology were 2.8 (SD 1.1), reflecting a neutral stance approaching disagreement that participants were anxious or dependent upon technology.

VR Questions

Of the 48 participants, about two-thirds (n=31, 65%) had never heard about VR, 41 (85%) had never tried a VR device, and 2 (4%) had heard about VR being used to treat pain. A small minority of participants (n=7, 15%) thought that VR could work for treating pain, with a majority (n=38, 79%) reporting being unsure. Despite this, about two-thirds (n=31, 65%) of participants were “very interested” in participating in a hypothetical study of at-home VR for CP, and an additional 11 (23%) were “somewhat interested.” As we had defined our primary outcome, interest in VR, as either “very interested” or “somewhat interested,” most participants (n=42, 88%) met the outcome. Only 6 (13%) participants reported not interested in participating in a hypothetical study of at-home VR for CP.

Factors Associated With Interest in Participating in a VR Trial

Relationships between (1) more frequent email use and (2) Facebook use and interest in participating in a VR clinical trial for pain approached statistical significance and were subsequently included in stepwise multivariate models (email subscale score among interested vs not interested participants:

XSL•FO
RenderX

4.6 vs 2.8; *P*=.06 and Facebook use among interested vs not interested participants: 24/42, 57% vs 1/6, 17%; *P*=.06). Age, gender, race, education, pain severity, pain location, smartphone use, and internet use were not predictive of being somewhat or very interested in participating in a VR clinical trial.

We examined predictors of interest across a series of multivariate models. Variables identified a priori included gender, age, and PEG score. These were added to a baseline model along with email use and Facebook use, which were identified through bivariate analyses. The initial model (model 1) was not statistically significant overall (*P*=.14). None of the individual predictors reached significance, though Facebook use approached significance (odds ratio [OR] 9.50, 95% CI 0.68-132.21; *P*=.09). After simplification (model 2: email use, PEG score, and Facebook use), the overall model became statistically significant (*P*=.04), and Facebook use remained a consistent predictor, although it did not reach statistical significance (OR 8.56, 95% CI 0.69-106.38; *P*=.10). In the final reduced model (model 3: PEG score and Facebook use), the model retained statistical significance (*P*=.04), and Facebook use emerged as a statistically significant predictor of VR interest (OR 11.37, 95% CI 1.04-124.81; *P*=.047).

Open-Ended Qualitative Survey Responses: Reasons for Interest in VR

We collected 47 open-ended responses describing reasons for interest or lack of interest in participating in a VR clinical trial. We categorized responses into 7 separate categories. Two categories were related to interest: (1) interest in a new treatment modality and (2) desperation for pain relief. Four categories were related to lack of interest: (1) doubts about VR as a pain treatment, (2) fear of COVID-19, (3) scheduling and traveling concerns, and (4) lack of more information. Three coded responses could not be labeled as interest or lack of interest and instead were marked as "other." The most common category was interest in a new treatment modality (27/47, 58%), followed by desperation for pain relief (9/47, 19%). The most common category representing lack of interest was doubts about VR as a pain treatment (3/47, 6%), followed by scheduling and traveling concerns (2/47, 4%). A sample quote reflecting a participant's interest was as follows:

> *You never know what will work. There's always advancements and new things that they discover outside of pills. I'm open to anything.*

A sample quote reflecting a participant's lack of interest was as follows:

> *My pain can only be helped by a doctor. No way virtual reality works for pain. If your boss is telling you that then they are lying.*

Discussion

Principal Findings

In this telephone survey of 48 persons with CP, we found that, despite a lack of experience with and knowledge of VR, most participants were interested in a study of at-home VR for CP. In this racially and ethnically diverse sample, we found relatively infrequent use of smartphones, email, internet, and social media. Additionally, we found mixed evidence that technology use was predictive of interest in participating in a clinical trial for VR. In open-ended responses, reasons for interest tended to cite new treatment modalities and the high burden of CP. These results indicate that the desire for new and innovative technological interventions exists even among people with CP with relatively low technology use.

Our results did not find patient-level barriers to participating in technology-oriented clinical trials, including a lack of trust. Prior studies have indicated that mistrust of research institutions and investigators is a significant attitudinal barrier to research participation reported by African Americans [20]. Overall, non-Hispanic Black and Hispanic individuals exhibit much higher levels of medical mistrust than their White counterparts [21]. Nonetheless, our qualitative data did not suggest that mistrust was a major barrier for participants. Other patient-level systemic barriers, such as scheduling and transportation, were more prominent in open-ended responses. These barriers may restrict participation in clinical research, and any trial that seeks diverse participation should consider efforts to reduce systemic barriers in recruitment procedures.

By contrast, institutional barriers and researcher-level barriers can be a prominent systemic reason for exclusion in clinical trials. Institutional barriers can include inadequate or untimely reimbursement of participants, insufficient attention to research important to communities of racial and ethnic minority people, and challenges with institutional review boards and community partnerships [22]. Researcher-level barriers can include bias, among many other factors. A notable form of bias in pain research is the underrecognition of pain in minorities by physicians [23]. The belief that Black persons feel less pain than White persons remains prevalent among US physicians, leading to inadequate treatment recommendations and possibly lower referral to pain research [23,24]. Perceptions that individuals from certain racial and ethnic groups are challenging or not ideal study candidates also remain prevalent and lead to less diverse participation [25]. In this study, one important researcher-level barrier participants encountered was that we required English proficiency. Because we were conducting a cross-sectional survey of interest in participation in a VR trial, we elected to only include people who could participate in future VR studies. As of 2025, none of the current US Food and Drug Administration–approved devices for CP are available in Spanish.

The high level of interest in VR in this study implies that institutional and researcher-based systemic barriers could be more prominent for this population than patient-level barriers. Previous literature in other intervention modalities has been mixed on this topic. When given the opportunity to participate in clinical research, some studies show that racial and ethnic minority groups are as likely to participate as White populations, whereas others report the opposite [26-29]. One overarching conclusion of the literature to date is that opportunity to participate or interest in participating alone is often not enough, as actual participation still lags due to a myriad of factors. Ensuring that research opportunities are relevant and significant to populations of interest is absolutely critical, as is lowering

XSL•FO
RenderX

systemic barriers to participation, such as by providing off-hour availability or transportation reimbursement.

Additionally, our results challenge the perception that a population characterized by low technology use has less interest in participating in clinical trials involving technology. We found mixed evidence that technology use was related to interest in VR. Though we found that Facebook use was associated with VR interest in multivariate models, other proxy measures for technology use, including internet use, were not similarly related. We theorize that, perhaps aside from technological familiarity, participants who maintained social ties on the internet may have a particular interest in technological solutions to their CP. For the entire sample, the high interest we observed may also reflect ongoing frustration with the treatment options provided by the health care system among patients with CP. In our open-ended responses, some participants indicated that they were desperate for pain relief and willing to try novel interventions. The extent to which participants feel more comfortable with technology-based research compared to traditional clinical research involving medications or other medical interventions, owing to historic mistrust and inequities of traditional research, is unclear and warrants further research.

Health care systems that adopt VR into routine pain management can increase patient interest and subsequent participation through increased exposure. For example, the Veterans Health Administration (VHA), the largest integrated health care system in the United States, is in the early stages of VR adoption for CP, with patients showing high levels of interest [30]. The VHA has established an Office of Healthcare Innovation and Learning and a specific VA Immersive Program, which has supported literature reviews, conferences, and innovative pilot programs in VR studies [31]. However, because of unique payment incentives, public and private hospital systems lag behind the VHA in technology adoption [32]. Nonetheless, there are new financial options to sustain VR care. Although VR for CP is not routinely covered by Medicare, VR devices can be covered if they are declared reasonable and necessary [33]. Reimbursement through Medicare may lead to increased adoption in private health care systems, such as ours at Montefiore, and affiliated public hospitals that serve diverse populations.

Limitations

The primary limitation of this study is the lack of generalizability of our sample to the patient population. Our sample was small and hospital based, which may have introduced response bias. Some participants may have previously participated in clinical trials. Additionally, we were unable to reach many of our potential participants, and as such, we enrolled a relatively small proportion of patients we attempted to contact. Our telephone response rate is similar to recruitment rates in other studies we have conducted, but there may have been selection bias in the participants that responded to our phone call. However, the directionality of the bias is unclear; patients who answer telephone calls and use telephones more often may be less technologically savvy compared with those who communicate more with friends and relatives via SMS text message or email. By contrast, as observed in our previous studies and those of others withing our health care system and community [34], patients with economic challenges may not have consistent telephone access or consistent telephone numbers and may represent groups that are less technologically savvy. Additionally, we estimated engagement in clinical trial activities by asking about subjective interest, which may overestimate intent to participate because of response bias. We did not assess negative interactions with the health care system and how these may have affected interest in VR clinical trials. Nonetheless, to our knowledge, this is the first study to gauge the level of interest in a VR clinical trial among a predominantly Hispanic and Black patient population with CP.

Conclusions

Patient populations of low SES and racial and ethnic minority groups are not sufficiently included in pain clinical trial recruitment. In this study, we found high interest in participating in a VR study for CP despite low technology use and lack of knowledge of VR, underscoring the importance of not underestimating patient willingness to engage with innovative treatments for CP. Further research is necessary to include diverse populations to ensure equity and effectiveness of VR, especially considering the high burden of CP among these populations. Addressing language accessibility and structural challenges, such as transportation and Medicare or Medicaid reimbursement, will be essential to ensure inclusive clinical trial recruitment and adoption of VR for CP.

Abstract

Background: Telemedicine has rapidly expanded; however, standardized, telemedicine-specific patient-reported experience measures tailored to outpatient workflows are limited in many settings.

Objective: This study aimed to develop and psychometrically validate the Telemedicine Service Experience Questionnaire (TSEQ) for Chinese outpatients using telemedicine services.

Methods: We conducted a web-based survey among outpatients who completed a telemedicine consultation at Peking Union Medical College Hospital between July 1, 2021, to August 31, 2021, and who had used telemedicine services, using an adapted Chinese Patient Experience Questionnaire that encompasses 15 questions across 4 dimensions, to investigate patients' telemedicine consultation experiences. Item generation was informed by a literature review, workflow mapping, and expert review. We evaluated the factor structure using exploratory factor analysis and confirmatory factor analysis on the full sample with cross-validation. Reliability was assessed using Cronbach α and item-total correlations.

Results: In total, 3338 participants completed the survey (mean age 45.3, SD 17.8 y; n=2182, 65.4% female participants; n=1827, 54.8% with college education or above). The exploratory factor analysis of the final 14-item scale resulted in 4 factors. After scrutinizing the content, these factors were labeled "Service Efficiency," "Post-treatment," "Information Guidance," and "Humanistic Care," and they demonstrated good internal consistency (Cronbach α values of 0.876, 0.840, 0.962, and 0.876, respectively). Moreover, as the average variance extracted values were greater than 0.5 and the composite reliability values were greater than 0.7, the TSEQ scale has high convergent validity. Our findings suggest that the psychometric properties of the 14-item TSEQ are valid and reliable for assessing telemedicine service experience among Chinese outpatients.

Conclusions: The TSEQ demonstrates a stable multidomain structure with satisfactory reliability and validity for evaluating outpatient telemedicine service experience in China. The instrument can support routine quality monitoring and guide targeted workflow improvements. Future studies should validate the TSEQ in multisite and postpandemic samples and examine measurement invariance across key subgroups.

Introduction

With the rapid development of information technology and the popularization of the internet, telemedicine services are becoming an innovative approach in the medical field [1] and are being used in a variety of settings, including psychiatric counseling [2], home health care services [3], intensive care units [4], and emergency stroke care [5], to provide patients with efficient and convenient medical care. In recent years, the worldwide COVID-19 outbreak has accelerated the spread and adoption of telemedicine services in health care [5]. Faced with the constraints of outbreaks and the need for prevention and control, telemedicine services protect patients, clinicians, and communities from exposure. In addition, they provide a platform where physicians and patients can interact using smartphones or webcam-enabled computers, regardless of time or location

XSL•FO
RenderX

[6]. Particularly in China, a vast country with rural areas and dispersed populations, telemedicine services hold great potential and advantages in addressing the unequal distribution of health care resources and improving the quality of medical services [7]. The Chinese government has explicitly included telemedicine services as a key area in the development of the national health care system. In 2018, the National Health Commission of China launched the Action Plan for Further Improvement of Medical Services (2018 - 2020). The program encourages medical institutions and research institutes to strengthen innovative research and development and vigorously promotes the integration of telemedicine technology with medical resources to facilitate the gradual development of telemedicine [8].

As an emerging health care model, patient satisfaction with telemedicine services is an important indicator of the quality of telemedicine services and an important driving force for the development of telemedicine services. Collecting and analyzing patient feedback can help medical institutions and decision-makers to comprehensively understand patients' demands and expectations, improve and optimize service quality, attract more patients to accept telemedicine services, and promote their wide application in health care. Studies have shown that the use of telemedicine services will only expand if patients and health care professionals are at least as satisfied with telemedicine services as they are with in-person visits [9]. In addition, highly satisfied patients are likely to have higher medication adherence, leading to better health outcomes [10].

Several studies have been conducted to explore the satisfaction with telemedicine services, such as the Telemedicine Satisfaction and Usefulness Questionnaire [11], Telemedicine Satisfaction Survey [12], and Telehealth Usability Questionnaire [13]. Nevertheless, telemedicine-specific, psychometrically validated patient-reported experience instruments tailored to Chinese outpatient workflows remain limited. In China, the scales currently available for measuring telemedicine service satisfaction are mainly based on the extension and improvement of traditional health care service satisfaction scales and lack sufficient consideration of the specific characteristics and unique features of telemedicine services [14]. For example, these scales may not fully capture telemedicine-specific processes (eg, digital information guidance, postconsultation payment and medication delivery, and privacy or security concerns).

To address this gap, we developed the Telemedicine Service Experience Questionnaire (TSEQ), using various items adapted for patient satisfaction surveys among Chinese outpatients. Our primary objective in this paper was to assess the appropriateness of the TSEQ scale as an instrument to measure patient satisfaction across a broad range of outpatient populations in China. Rather than measuring technology usability alone, the TSEQ is designed to capture the service-process experience across the entire outpatient telemedicine journey, including preconsultation guidance, interaction quality, and postconsultation processes (eg, payment and medication delivery), which are particularly salient in platform-based telemedicine services. Accordingly, the objectives of this study were to (1) develop the TSEQ for Chinese outpatient telemedicine services; (2) evaluate its underlying factor structure using exploratory and confirmatory factor analyses; and (3) assess its reliability and validity, including internal consistency and convergent validity.

Methods

Data Collection and Sample

Our research focuses on users of hospital apps at Peking Union Medical College Hospital, a leading medical institution renowned for its comprehensive health care services and advanced medical technology. Data were collected through a web-based questionnaire from July 1, 2021, to August 31, 2021. Eligible participants were adults (aged ≥18 years) who completed a telemedicine consultation and provided informed consent. We excluded responses with substantial missing data, implausibly short completion times, or duplicate submissions where applicable. Convenience sampling was used, which is common in psychometric validation studies. In this study, patients who fully completed the TSEQ questionnaire were included (N=3337). The survey window was selected because telemedicine services at the study hospital had reached stable operational routines and sufficient user volume for psychometric evaluation. As this study focuses on instrument development and validation, the 2021 dataset provides an appropriate foundation to examine the factor structure and reliability and validity of the TSEQ.

Ethical Considerations

A web-based informed consent was obtained before the survey via WeChat. Participants were allowed to withdraw from the survey at any time. All interviews of the survey were kept confidential and anonymous. This study was approved by the Peking Union Medical College Hospital Ethics Committee (S-k1545). Responses were collected anonymously (or deidentified), and no directly identifiable personal information was stored. Data were stored on secure servers with restricted access limited to the research team. Participants did not receive any compensation for participation in this study.

Measures and Scale Development

The TSEQ was adapted from the Chinese Patient Experience Questionnaire (CPEQ; refer to Multimedia Appendix 1 for details) [15]. The CPEQ consists of 2 sections: part A includes 9 questions that collect basic demographic information of the participants, such as age, sex, employment status, and type of insurance and part B comprises 22 questions across 5 dimensions and is designed to comprehensively evaluate patient experience. On the basis of expert discussions on the CPEQ, we developed a 15-item questionnaire for telemedicine service experience, focusing on self-efficacy, information guidance, and humanistic care. Every question was assessed using a 5-point Likert scale (5=strongly agree, 4=agree, 3=unsure, 2=disagree, and 1=strongly disagree). The newly formed TSEQ is presented in Multimedia Appendix 2.

The validation and reliability of the TSEQ are the cornerstones of our research's second objective. We assessed the instrument's internal consistency and test-retest reliability, alongside its validity, to ensure it measures the intended constructs. An

XSL•FO
RenderX

open-ended question was included at the end of the questionnaire to capture valuable, unstructured feedback from the respondents.

Statistical Analysis

Descriptive statistics were used to summarize and describe the demographic characteristics of the participants, such as age, sex, occupation, and education. Categorical variables (eg, sex, occupation, and education) were presented as numbers (percentages), and continuous variables (eg, age) were reported as mean (SD).

Exploratory Factor Analysis

Exploratory factor analysis (EFA) was first performed to explore the number of factors and the factor loading of each item using maximum likelihood estimation, which is the default estimator in Mplus (version 7.0; Muthén & Muthén). Before the factor analysis, Bartlett test of sphericity was usually used to examine whether these variables were independent of each other and suitable for factor analysis. In this study, we computed 1-factor, 2-factor, 3-factor, and 4-factor measurement models using EFA. To identify the model structure, we used a series of indicators such as χ^2, *df*, Tucker-Lewis index (TLI), comparative fit index (CFI), Akaike information criterion, Bayesian information criterion [1,16], standardized root mean square residual (SRMR), and root mean square error of approximation (RMSEA) to evaluate the goodness-of-fit statistics. Acceptable model fit was defined by the following criteria: TLI>0.90, CFI>0.90, SRMR<0.05, and RMSEA<0.08 [17-19].

During EFA, items were considered for removal if they exhibited low factor loadings (eg, <0.40), substantial cross-loadings, low commonalities, weak item-total correlations, or conceptual redundancy. The refined structure was then tested using confirmatory factor analysis (CFA), and model fit indices guided the final scale specification.

Model Validation Using CFA

Following EFA, we conducted the CFA to verify whether the hypothesized structure from EFA was consistent and valid. CFA is a statistical technique used to evaluate the effectiveness of the measurement model and examine the relationship between measured variables and underlying latent constructs or factors. In this study, first-order factors were verified for the dimensions of telemedicine service experience, and a second-order model was established to explain the relationships among multiple first-order factors. We computed and compared the overall fit coefficients, χ^2/df, RMSEA, CFI, TLI, and SRMR of CFA models to remove inappropriate items and confirm the ideal model results. Moreover, the model fit was evaluated using the standardized factor loadings and R^2.

Reliability and Validity

To assess the reliability of CFA-confirmed models, we further computed Cronbach α and split-half reliability coefficients (SRCs) for the total questionnaire, final questionnaire, service efficiency (F1), post-treatment (F2), information guidance (F3), and humanistic care (F4). With regard to the reliability of a research instrument, statistical theory has determined that Cronbach α should be >0.7 [20,21]. Correlation analysis was used to investigate the correlation between the first-order factors and Chinese patients' overall satisfaction and willingness to recommend. Finally, a validity test was conducted to verify the validity of the newly proposed Chinese adaptation of the patient experience measurement instrument by estimating the factor loadings to examine the relationships between observed variables and latent constructs that we wanted to measure. Standard factor loadings >0.70 were considered the criterion for convergent validity [22].

Results

Sociodemographic Characteristics

Among the 3337 participants, the mean age was 45.3 (SD 17.8) years. The majority were female (n=2182, 65.4%), had completed a bachelor's degree or higher education level (n=1827, 54.8%), paid using health insurance (n=2292, 68.7%), and were seeking medical care outside their local area (n=1372, 41.1%; Table 1).

Table 2 presents the performance scores for the 15 individual items of the TSEQ in this study. These items primarily focus on various aspects of hospital services, including waiting times, service convenience, the communication style of physicians, and the respect and privacy protection afforded to patients during their medical visits. The average scores for each item generally range between 4.2 and 4.6, indicating that most respondents are satisfied with the services provided by the hospital and that the scores demonstrate relatively high consistency. These findings support further development of the scale for the EFA and the CFA.

Table . Performance scores for the 17 individual items of the Telemedicine Service Experience Questionnaire.

Question number	Item	Value, mean (SD)
Q1	The waiting time for on-site registration was acceptable.	4.2 (1.0)
Q2	The waiting time for consultation with physicians was acceptable.	4.5 (0.8)
Q3	The consultation length was acceptable.	4.5 (0.7)
Q4	The waiting time for a planned examination was acceptable.	4.5 (0.7)
Q5	The waiting time for payment was acceptable.	4.6 (0.6)
Q6	The waiting time for medicine delivery was acceptable.	4.6 (0.6)
Q7	It was convenient to access self-service information inquiry devices.	4.5 (0.7)
Q8	Medication instruction services provided by the hospital can meet needs.	4.5 (0.7)
Q9	Physicians discussed my condition and care patiently.	4.5 (0.8)
Q10	Physicians explained examination results to me patiently.	4.5 (0.8)
Q11	Physicians discussed treatment with me patiently.	4.5 (0.8)
Q12	I was treated with respect and dignity during this visit.	4.5 (0.8)
Q13	My privacy has been fully protected during this visit.	4.6 (0.6)
Q14	All the medical staff was kind to me during this visit.	4.5 (0.8)
Q15	I got help from medical staff as soon as I had problems.	4.5 (0.8)

EFA Findings

The results of the EFA indicated that the Bartlett test of sphericity yielded a χ^2 value of 785.966 (df=51; P<.001; Kaiser-Meyer-Olkin value=0.950; Table 3), suggesting that the dataset used was suitable for factor analysis. Through this analysis, we successfully established a 4-factor structure, with these factors collectively explaining 78.49% of the total variance (Multimedia Appendix 3). This indicates that the TSEQ tool exhibits good structural validity, accurately reflecting various aspects of patient experiences in remote health care services.

Table . Fit indices for the exploratory factor analysis model.

Model	χ^2 (df)	Tucker-Lewis index	Comparative fit index	Akaike information criterion	Bayesian information criterion	Standardized root mean squared residual	Root mean squared error of approximation (90% CI)
One-factor	9637.302 (90)	0.754	0.789	77359.640	77634.715	0.086	0.178 (0.175-0.181)
Two-factor	2597.384 (76)	0.923	0.944	70347.720	70708.377	0.028	0.100 (0.096-0.103)
Three-factor	1262.718 (63)	0.956	0.974	69039.054	69479.177	0.021	0.076 (0.072-0.079)
Four-factor[a]	*785.966 (51)*	*0.967*	*0.984*	*68586.302*	*69099.780*	*0.016*	*0.066 (0.062-0.070)*

[a]Italicized text indicates the selected final model.

Of the 15 items, 14 loaded meaningfully onto 1 of the 4 factors, with factor loadings ranging from 0.38 to 0.89. However, one item (item 12: “Physicians discussed my condition and care patiently”) had cross-loadings on factors 2 and 4. Despite this, considering the importance of this item, we did not remove it

XSL•FO
RenderX

in the EFA stage. The EFA resulted in a 4-factor solution that explained 79.00% of the variance (Table 4).

Table . Results of the exploratory factor loadings matrix.

Item number	Item	Factor loading			
		Factor 1	Factor 2	Factor 3	Factor 4
Q1	The waiting time for on-site registration was acceptable.	*0.689* [a]	0.038	−0.147	0.018
Q2	The waiting time for consultation with physicians was acceptable.	*0.670*	0.162	−0.053	0.037
Q3	The consultation length was acceptable.	*0.707*	−0.033	0.153	0.004
Q4	The waiting time for a planned examination was acceptable.	*0.744*	−0.019	0.102	0.002
Q5	The waiting time for payment was acceptable.	0.279	−0.024	*0.517*	0.092
Q6	The waiting time for medicine delivery was acceptable.	0.021	0.065	*0.887*	0.006
Q7	It was convenient to make an appointment for a planned examination.	*0.607*	0.021	0.083	0.052
Q8	Medication instruction services provided by the hospital can meet needs.	*0.521*	0.180	0.221	−0.026
Q9	Physicians discussed my condition and care patiently.	0.005	*0.875*	0.001	0.069
Q10	Physicians explained examination results to me patiently.	0.072	*0.928*	0.000	−0.032
Q11	Physicians discussed treatment with me patiently.	−0.011	*0.902*	0.030	0.055
Q12	I was treated with respect and dignity during this visit.	−0.001	*0.444*	0.000	*0.523*
Q13	My privacy has been fully protected during this visit.	0.273	0.186	0.048	*0.382*
Q14	All the medical staff was kind to me during this visit.	−0.001	0.054	0.033	*0.860*
Q15	I got help from medical staff as soon as I had problems.	0.266	−0.025	−0.017	*0.662*

[a]Italicized factor loadings indicate the highest loading for each item and were used to assign the item to the corresponding factor.

CFA Findings

In the CFA, it was observed that the modification index for item 12 was excessively high across the 4 factors (>200; Multimedia Appendix 4). After its removal, the model fit improved in the CFA model. Therefore, the final model excluded item 12 (Table 5).

XSL•FO
RenderX

Given the 4 factors derived from EFA, an interpretation focusing on items with higher factor loadings for each factor, and their comparison to the TSEQ, was performed by the panel (Table 6). Factor 1 was labeled "Service Efficiency," as it consisted of 6 items dealing with the convenience of telemedicine services. The second factor, consisting of 2 items, was called "Post-treatment," as the content involves the time spent on medication dispensing and payment processes. Factor 3 comprised 3 items that captured information-related elements of telemedicine services; therefore, the title of this factor was "Information Guidance." Finally, the 3 items in factor 4, which involve the physician's' attitudes toward patients, were labeled "Humanistic Care."

Table . Overall model fit coefficients for the confirmatory factor analysis model.

Model fit index	Ideal standard	Common standard	Model results	Results after excluding item 12	Second-order model	Conclusion (first-order model)
χ^2/df[a]	<3	<10	23.33	18.70	30.30	Model not ideal
Root mean square error of approximation	<0.08	<0.1	0.082	0.073	0.094	Model ideal
Comparative fit index	>0.9	>0.8	0.959	0.968	0.946	Model ideal
Tucker-Lewis index	>0.9	>0.8	0.948	0.960	0.933	Model ideal
Standardized root mean square residual	<0.08	<0.1	0.035	0.030	0.047	Model ideal

Q15	0.846	0.716
Second-order model and indicators		
Service efficiency (F1)[c]	0.936	0.876
Post-treatment (F2)	0.826	0.683
Information guidance (F3)	0.820	0.672
Humanistic care (F4)	0.940	0.883

[a]The *P* values for the standardized factor loadings are all <.001.

[b]Q1-Q15 denote questionnaire items, the full wording of which is provided in Table 4.

[c]F1-F4 denote the 4 factors of the second-order model.

Internal Consistency and Validity

As presented in Table 7, the final instrument obtained a Cronbach α coefficient of 0.946 and an SRC value of 0.872 for the total sample. The 4 factors—service efficiency, post-treatment, information guidance, and humanistic care—each obtained Cronbach α coefficients ranging from 0.840 to 0.962, and their SRC values were 0.877 (6 items), 0.840(2 items), 0.965 (3 items), and 0.892 (3 items), respectively. These results demonstrate that the TSEQ has good internal consistency.

The correlation coefficients between overall satisfaction and the 4 factors—service efficiency, post-treatment, information guidance, and humanistic care—were 0.941, 0.781, 0.857, and 0.901, respectively. All the correlations were statistically significant at the .01 level and demonstrate good internal validity. Moreover, as the average variances extracted values were >0.5 and the composite reliability values were >0.7, the TSEQ scale demonstrated high convergent validity (Table 7).

XSL•FO
RenderX

Table . The evidence for the reliability and validity of the Telemedicine Service Experience Questionnaire (TSEQ) scale and 4 factors.

Variable	Correlation[a]				Internal consistency		Convergent validity	
	TSEQ	Service efficiency (F1)	Post-treatment (F2)	Information guidance (F3)	Cronbach α	Split-half reliability coefficients	Average variances extracted	Composite reliability
TSEQ (14-items, mean)	—[b]	—	—	—	0.946	0.872	—	—
Service efficiency (F1)	0.941	—	—	—	0.876	0.876	0.567	0.886
Post-treatment (F2)	0.781	0.805	—	—	0.840	0.840	0.725	0.841
Information guidance (F3)	0.857	0.667	0.520	—	0.962	0.962	0.896	0.962
Humanistic care (F4)	0.901	0.760	0.624	0.788	0.876	0.876	0.714	0.882

[a]All Pearson correlation coefficients were statistically significant (P<.001).

[b]Not applicable.

TSEQ Scoring

The TSEQ measures each item on a 5-point Likert-type scale, ranging from 1 (“strongly disagree”) to 5 (“strongly agree”). Calculating a total score involves summing the response scores for all 14 items of the TSEQ. The total score ranges from 14 to 70, with higher scores indicating higher levels of telemedicine service experience. The Chinese version of the questionnaire is shown in Multimedia Appendix 5.

Discussion

Principal Findings

This study developed and validated the TSEQ, an instrument for measuring telemedicine service experience in Chinese outpatients, based on the CPEQ [15]. In this study, EFA produced a revised 4-factor solution for the TSEQ, leading to modifications in the 5 domains of the CPEQ. Telemedicine services offer convenient medical solutions and effectively tackle the issue of uneven distribution of medical resources, especially in remote and rural areas [23,24]. The global COVID-19 pandemic has recently accelerated the adoption and expansion of telemedicine [25,26]. Importantly, our study does not aim to re-establish the well-known advantage that telemedicine reduces geographic barriers. Instead, it contributes a validated, telemedicine-specific patient experience instrument and highlights which service-process dimensions matter in Chinese outpatient telemedicine workflows. In particular, the emergence of a distinct “post-treatment” domain (eg, payment timing and medication delivery) reflects operational features that are often underrepresented in traditional in-person satisfaction tools and provides actionable targets for quality improvement. Our findings contribute to global efforts to standardize patient-reported evaluation of telemedicine quality. Although the TSEQ was developed for Chinese outpatient workflows, its domain-based structure may inform telemedicine service monitoring in other settings, subject to appropriate cross-cultural adaptation and validation.

In this analysis, the final instrument comprises 4 factors with 14 items, designed to evaluate patient satisfaction with telemedicine services and identify areas for service improvement. The EFA supported the viability of a 4-factor model. Compared to previous studies, the EFA uniquely identified “payment timing (item 5)” and “medicine delivery (item 6)” as a new single factor, while grouping “It was convenient to make an appointment for a planned examination (item 7)” and “Medication instruction services provided by the hospital can meet needs (item 8)” under the first factor, service efficiency. Notably, the item “I was treated with respect and dignity during this visit (item 12)” was originally categorized under “Humanistic Care” in the CPEQ framework but was removed in this study. This change may be attributed to the fact that patients using telemedicine services are more focused on the quality and efficiency of the service and may not experience significant nonverbal communication cues such as eye contact, body language, and tone of voice, which are typically present during face-to-face interactions with health care professionals [24,27].

Additionally, although “privacy and security risks (item 13)” showed lower factor loadings in the EFA, these aspects were still included in the TSEQ due to their critical importance in the telemedicine context [28,29], where patient privacy and security are paramount. Telemedicine also introduces challenges, including technology barriers, digital literacy gaps, privacy or security concerns, and constrained clinician-patient communication. By quantifying patient experience across distinct service domains, the TSEQ can help hospital identify where telemedicine workflows fail to meet expectations and prioritize targeted improvements.

Furthermore, CFA validated the 4-factor structure of the questionnaire. According to the pre-established CFI, and RMSEA thresholds, the second-order model can be considered acceptable. Only the χ^2 test revealed a bad fit for the second-order model, likely due to the large sample size [30]. All standardized factor loadings were statistically significant (all P<.001) and ranged from 0.729 to 0.953. On the basis of

XSL•FO
RenderX

the CPEQ [15], our study has introduced a second factor, defined as "post-treatment," further demonstrating that the efficiency of posttelemedicine services also affects overall patient satisfaction. Analysis of the internal consistency of the Chinese version of the TSEQ showed that the Cronbach α of the entire scale was 0.95, indicating excellent scale reliability. All scales demonstrated good internal consistency, with Cronbach α of >0.80, indicating moderate to good test-retest reliability [30,31]. Moreover, CFA revealed strong correlations among the 4 factors, and further exploration of the relationships among the 4 factors confirmed satisfactory convergent validity based on the average variances extracted and composite reliability values [32,33].

The majority of participants in our study were female (2182/3337, 65.4%) and had completed bachelor's degree or higher education level (n=1827, 54.8%). Nearly half (n=1372, 41.1%) of the participants were seeking medical care outside their local area. The composition of our study population underscores the broad relevance of our findings. This diversity is essential for understanding the multifaceted patient experiences within telehealth services, emphasizing the need for inclusive and accessible health care solutions that cater to varied demographic segments [30,33].

The TSEQ offers actionable value for routine quality monitoring and continuous improvement in outpatient telemedicine services. In practice, health care professionals and platform administrators can integrate the TSEQ as a brief postvisit feedback tool embedded within the telemedicine workflow (eg, immediately after consultation or after completion of postconsultation steps). Domain-level scores can be visualized in a dashboard to identify specific bottlenecks and track trends over time, enabling a closed improvement loop of "measure-diagnose-intervene-reassess." For example, low scores in interaction-related domains may prompt targeted clinician training (eg, communication clarity and shared decision-making in remote settings), whereas low scores in the post-treatment domain can inform workflow redesign for payment, prescription processing, and medication delivery or collection. The TSEQ can also support benchmarking across departments, specialties, or service lines to prioritize resource allocation and evaluate the impact of operational changes. At the policy level, aggregated TSEQ indicators may complement use metrics by capturing patient-centered service quality; helping health systems move from "telemedicine adoption" to "telemedicine performance"; and guiding standards for service transparency, privacy protection, and equitable access for digitally disadvantaged groups.

Limitations

Several limitations should be acknowledged. First, this study relied on self-reported survey responses collected immediately after telemedicine use, which may be subject to social desirability bias, recall bias, and common method variance. Second, participants were recruited using a convenience sampling approach from a single hospital setting, which may limit generalizability to other regions, health care tiers, and telemedicine platforms, especially where service workflows, payment pathways, and medication dispensing or delivery arrangements differ. Third, the sample characteristics may not fully represent telemedicine users with limited digital access or lower digital literacy; therefore, our estimates of service experience may be upwardly biased for populations facing stronger technology barriers. Fourth, data were collected during mid-2021, when telemedicine use and patient expectations were shaped by the COVID-19 pandemic context; experience patterns may shift in postpandemic periods when patients have broader choices between in-person and remote visits. Fifth, the cross-sectional design precludes assessment of temporal stability (eg, test-retest reliability), responsiveness to service improvements, and longitudinal predictive validity. Finally, although we established overall psychometric properties, formal measurement invariance and differential item functioning across key subgroups (eg, age, sex, education, allopatry treatment, and previous telemedicine experience) were not the primary focus of this manuscript and warrant further validation in multisite and postpandemic samples.

Conclusions

In conclusion, this study developed and psychometrically validated the TSEQ for Chinese outpatients. The final instrument demonstrated a stable multidomain structure, indicating that it can be used to capture key dimensions of patients' telemedicine service experience in routine outpatient care. By providing domain-specific scores, the TSEQ enables health care institutions and platform administrators to identify actionable targets for quality improvement, particularly in end-to-end workflow components that are salient in telemedicine settings (eg, communication processes and postconsultation services). Future research should validate the TSEQ in multisite and postpandemic samples, assess test-retest reliability and responsiveness to service changes, and examine measurement invariance or differential item functioning across key subgroups to support broader implementation and benchmarking.

Acknowledgments

The authors thank all study participants and staff members involved in data collection for their contributions.

Abstract

Background: Despite increasing recognition of human factors in technologically advanced manufacturing, psychological resilience remains an underexplored dimension. Existing studies often rely on generic instruments that fail to capture the specific adaptive challenges faced by workers in high-tech environments. There is a growing need for context-sensitive tools capable of assessing resilience in line with the human-centric vision of Industry 5.0.

Objective: This study aimed to develop and conduct a preliminary evaluation of the Change Adaptation Resilience Evaluation Questionnaire for Industry 5.0 (CARE-QI 5.0), a multidimensional instrument designed to assess individual and contextual factors contributing to psychological resilience among workers in high-tech manufacturing settings.

Methods: The questionnaire was developed through a 4-phase process: literature review, expert evaluation, focus groups with operators, and pilot testing within 2 manufacturing companies. CARE-QI 5.0 conceptualizes resilience as a higher-order construct comprising 2 second-order dimensions—individual resilience and contextual resilience—further articulated into 18 first-order subscales. Internal consistency and intersubscale correlations were assessed using data from a sample of workers employed in the mechanical and packaging industries in Northeastern Italy.

Results: Findings on the 84 items showed good internal consistency across all subscales and meaningful patterns of intercorrelation. External validity showed that problem-solving self-efficacy, cognitive flexibility, and problem-oriented coping were positively associated with both individual-based resilience and a wide range of contextual resources, including support given by organizations, colleagues, and family, as well as openness to change. In contrast, perseverance in the face of difficulties was linked to cognitive inflexibility, avoidance, and seeking change, suggesting the presence of rigid or less adaptive coping functioning.

Conclusions: CARE-QI 5.0 provides a theoretically grounded and context-sensitive tool for assessing psychological resilience as a multidimensional construct in technologically evolving manufacturing environments. By integrating both individual and contextual protective resources, this instrument captures key adaptive processes relevant to Industry 5.0 scenarios, where human-technology interaction plays a central role. While further psychometric validation is needed, including confirmatory factor analysis and measurement invariance testing, CARE-QI 5.0 shows promise for both theoretical and research use. It can support organizations in monitoring workers' adaptability and well-being, guiding targeted interventions and training strategies that align with workers' resilience profiles and their technological experience.

Introduction

Background

The manufacturing field constantly faces multiple challenges arising from the elevated production standards imposed by the global market, which increasingly demand high levels of customization and product quality [1]. Within this scenario, the integration of advanced industrial automation and collaborative robotics technologies (eg, cobots) constitutes one of the most significant transformations introduced by Industry 4.0, aimed at enhancing production efficiency through smart and interconnected systems [2]. Despite these technological advancements, manufacturing industries continue to encounter substantial barriers, including difficulties in technological

XSL•FO
RenderX

implementation, as well as insufficient human worker integration into automated systems [3,4]. This limited human-technology integration obstructs the shift toward more adaptive and resilient manufacturing environments, where human-robot interaction (HRI) is expected to play a key role in improving operational flexibility, safety, and decision-making processes [5]. In this context, the human contribution in manufacturing production systems remains a critical factor in shaping production performance and machinery effectiveness [6]. A growing body of literature displays the pivotal mediating role played by Human Capital in technologically advanced firms, facilitating the maximization of both labor output and productivity [7,8]. Concurrently, the effectiveness of human-robot collaboration (HRC) has been strongly linked to increased individual performance, which is largely supported by key human factors [9]. In this context, the development of a new theoretical framework on HRI is considered essential to fostering production systems that are not only more efficient but also more flexible and resilient [10]. Within this evolving paradigm, the role of workers has become increasingly central not only in supporting long-term economic growth through efficient production practices but also in activating resilience strategies that support organizations to recover from potential disruptions [11]. In response to these emerging needs, Industry 5.0 suggests a fundamental shift from a system-centered to a human-centered perspective, keeping the HRI at the core of a collaborative process model [5]. This human-centric vision further emphasizes the importance of human well-being and the preservation of a supportive working environment by promoting the principles of sustainability and resilience [12,13]. Among these principles, resilience stands out as a critical benchmark, defined as the capability to adapt and flexibly cope with vulnerabilities and disruptive changes while maintaining industrial productivity [12]. In this framework, manufacturing workers emerge as the key to such resilience. Through their involvement in HRI processes, they become pivotal agents in supporting both production efficiency and organizational adaptability [14]. To optimize productivity and efficiency within complex industrial environments, several studies converge on the idea that Industry 5.0 can holistically improve workers' well-being and safety by integrating advanced technologies and a human-centered approach [15-17]. This perspective gives rise to the concept of Operator 5.0, a professional figure who goes beyond mere technical skills, by embracing a self-resilience–oriented mindset. Within this framework, *psychological resilience* refers to the individual's ability to emotionally cope with crises and stressors, often supported by advanced technological tools, whereas *cognitive resilience* refers to the operator's ability to sustain mental focus under stressful conditions, thereby reducing the likelihood of error during production processes [18]. Accordingly, Operator 5.0 is not merely a user of technology but also a carrier of psychological resources essential to flourish in hybrid HRC settings, making resilience a key competence in the definition of the Industry 5.0 paradigm.

Recent research examines various dimensions of manufacturing resilience, with particular emphasis on systemic and technological resilience. Nonetheless, despite the increasing recognition of human factors, psychological resilience remains a relatively underexplored area within manufacturing contexts [19]. Existing studies rely on non–sector-specific assessment tools and tend to lack longitudinal or mixed methods designs, which limits their ability to adequately capture the dynamic and evolving nature of resilience in high-tech workplaces [20]. This reveals a crucial gap in the current literature, particularly concerning the potential impact of Industry 5.0 technologies, such as collaborative robots, on workers' psychological resilience. Addressing this gap is pivotal to developing more integrated and context-sensitive assessment frameworks that not only promote human well-being but also enhance workplace adaptability and responsiveness in increasingly manufacturing settings.

Theoretical Background and Current Research Gaps in Resilience at Work

Although various theoretical perspectives on resilience have been proposed, the concept is widely understood as a dynamic and evolving process shaped by individuals' ongoing interactions with their environment [21]. Despite the absence of unanimous consensus upon definition, conceptualization, and measurement frameworks, most assumptions in the literature underline 2 foundational concepts: adversity, typically defined as negative events or circumstances quantitatively associated with adaptive difficulties, and positive outcomes, understood as the capacity to recover or exceed prior levels of psychological functioning following adversity [22]. The American Psychological Association [23] defines resilience as "the ability to adapt in the face of trauma, adversity, tragedy or even significant ongoing stressors." Among the personal resources that support resilient functioning in complex and evolving work environments, 2 constructs have emerged as particularly relevant: change adaptation, the perceived ability to effectively respond to and integrate workplace changes [24], and cognitive flexibility, the capacity to adjust mental strategies and reframe stressful events [25,26]. Both have been linked to improved emotional regulation and adaptive behavior under pressure [26] and can be considered essential components of resilience in technological contexts. Within this framework, protective factors play a fundamental role in promoting resilience by increasing the likelihood of a positive adaptation following exposure to stressors [27]. According to Windle [28], protective factors are pivotal in defining resilience and are typically classified into 2 categories. Internal positive factors refer to intraindividual characteristics that foster resilience and are specific to each individual [29]. These include several traits, such as positive self-perception, self-regulation, cognitive abilities, adaptive coping strategies, and stress inoculation [27,30]. In contrast, external positive factors encompass supportive social and environmental conditions derived from an individual's immediate surroundings [29], such as strong social support (eg, positive relationships from family and friends) and community cohesion [27,30]. These resources affect how individuals perceive and deal with challenges, especially in work-related settings [31].

Increasingly, the literature suggests that resilience cannot be fully understood through the analysis of individual or contextual factors apart, but rather through their dynamic interaction. This is especially relevant in complex and high-pressure environments, such as advanced manufacturing. In such

XSL•FO
RenderX

contexts, resilience emerges as a multilayered construct, where personal cognitive-emotional resources and organizational or social support systems are deeply intertwined. As highlighted in recent research [20], considering both dimensions simultaneously allows for a more accurate understanding of how workers adapt and thrive amidst organizational change, technological disruption, and operational stress.

In line with this perspective, in this study, psychological resilience is conceptualized as a multidimensional and context-sensitive capacity that enables workers to cope with stress, adapt to changes related to technological and organizational demands, and maintain effective functioning in complex and evolving manufacturing environments [20]. More specifically, resilience is framed as a higher-order construct encompassing 2 interrelated domains: individual resilience (eg, self-efficacy, cognitive flexibility, and change adaptation) and contextual resilience (eg, social support and organizational resilience). These dimensions jointly influence workers' capacity to adapt to technological and organizational challenges in advanced manufacturing settings, forming an integrated conceptual model that underpins the development of the Change Adaptation Resilience Evaluation Questionnaire for Industry 5.0 (CARE-QI 5.0) [20]. These dimensions were selected as theoretically grounded components of resilience rather than independent constructs, in line with evidence highlighting the role of both individual resources and contextual protective factors in influencing adaptive functioning under stress [21,27,28]. Given these distinctions, work-related resilience can be broadly considered as the capacity to cope with and overcome adversity in occupational settings, emerging stronger and more competent as a result [32]. While existing research has addressed both individual and environmental dimensions of resilience, there is currently no unified theoretical model specifically tailored to industrial work environments. Despite the growing interest in resilience within high-tech manufacturing settings, the literature lacks psychometrically validated tools designed to assess resilience in such contexts [20]. To date, only Babamiri [33] has developed a tool related to HRI. However, it comprises only 3 items and fails to capture resilience as a multidimensional construct. In light of these limitations, this study introduces a new psychometric instrument: CARE-QI 5.0, specifically developed to assess and conceptualize psychological resilience in advanced manufacturing environments aligned with the principles of Industry 5.0.

Aims

The overarching aim of this study was to develop and conduct an initial evaluation of the CARE-QI 5.0, a new multidimensional self-report instrument designed to assess psychological resilience among industrial workers in high-tech manufacturing environments. In line with the human-centric principles of Industry 5.0, this study pursued the following objectives:

- To conceptualize and operationalize psychological resilience in technologically advanced manufacturing contexts by integrating personal and contextual protective factors derived from existing theoretical and empirical frameworks.
- To develop and refine a context-sensitive set of items through a mixed methods approach that included expert review and focus group feedback, thereby enhancing the semantic clarity and contextual relevance of the instrument.
- To pilot the revised questionnaire in real-world high-tech industrial settings, evaluating its preliminary psychometric properties, including internal consistency, interitem correlations, and subscale coherence.

Methods

Participant Recruitment

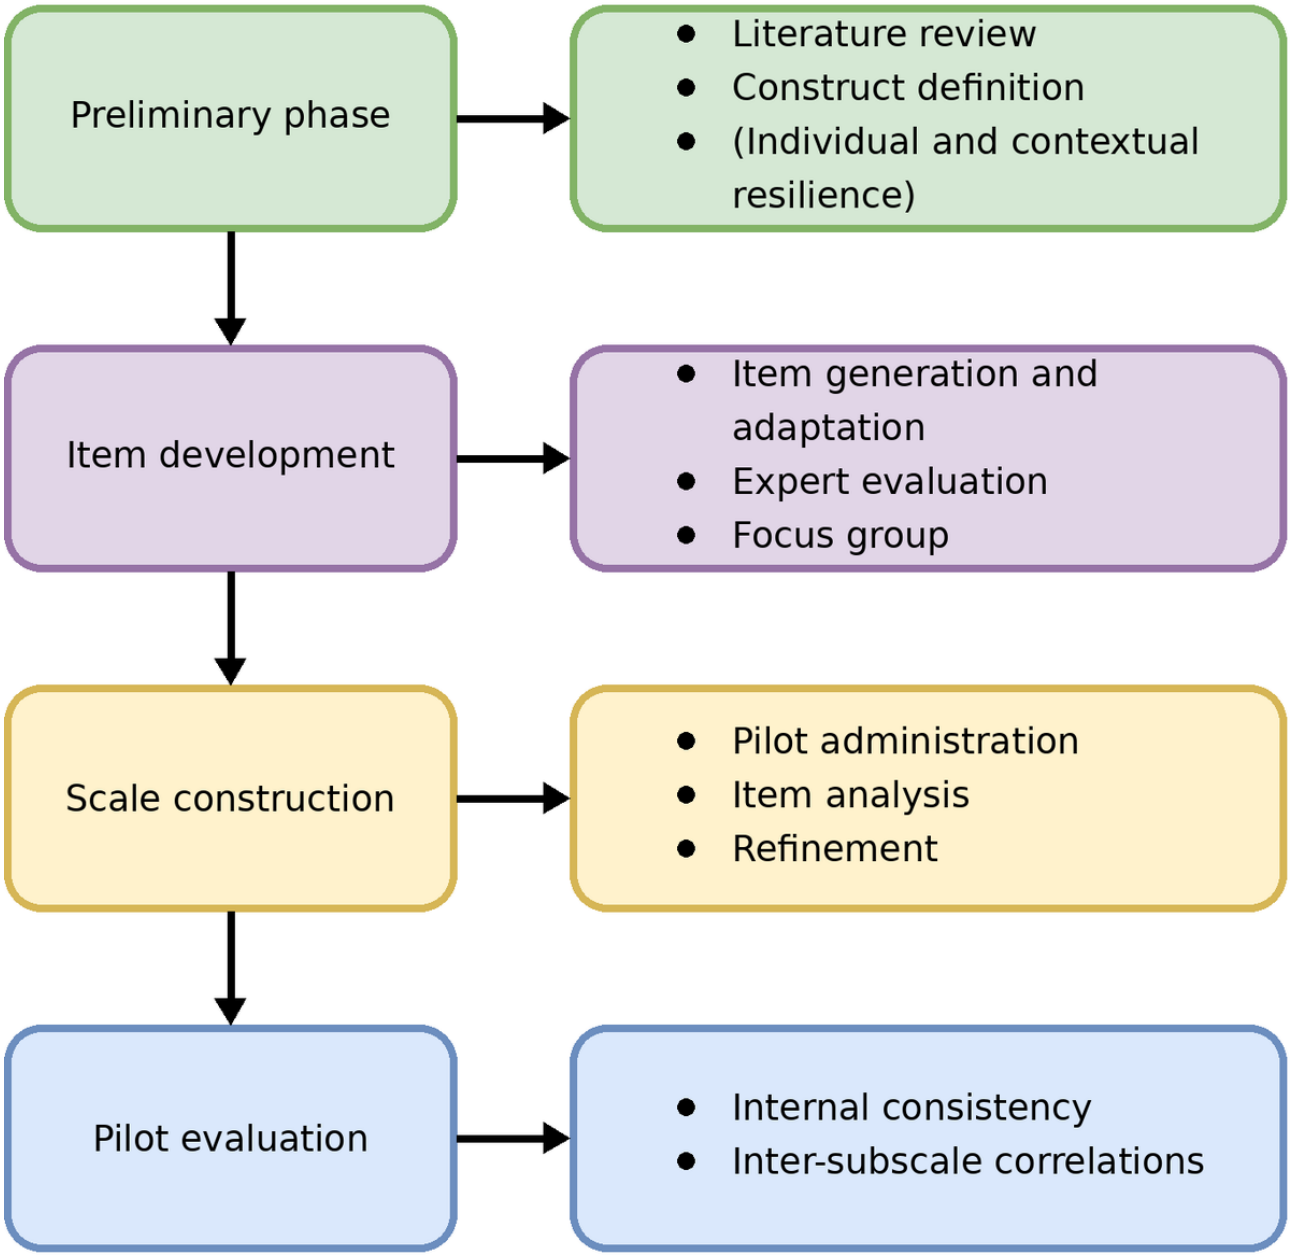
Participants were recruited from 2 distinct manufacturing companies located in Northeastern Italy, both operating in technologically advanced production sectors. One company specializes in the design and production of high-precision mechanical components primarily for the pharmaceutical and packaging industries, while the other is a leading provider of flexible packaging solutions, focusing on innovation, sustainability, and advanced printing technologies for food and consumer goods.

For the focus group phase, inclusion criteria were established to ensure representativeness and alignment with the study's aims. Specifically, participants were required to (1) be operators in high-tech companies, (2) ensure a balanced distribution by gender and age, and (3) be fluent in Italian to guarantee full comprehension and effective participation in the qualitative discussions.

For the pilot testing phase, a separate group of workers was recruited. Inclusion criteria for this phase included being operators employed in high-tech manufacturing companies and being fluent in Italian.

It is important to note that the participants involved in the focus groups differed from those who later took part in the pilot testing phase. This methodological separation was implemented to ensure that insights gathered during the qualitative development of the questionnaire did not bias its subsequent evaluation during pilot administration [34].

Ethical Considerations



All participants were recruited voluntarily through internal company communications (eg, human resources announcements and mailing lists) as well as via digital and paper flyers specifically created for the purposes of this study. Informed consent was obtained from all participants electronically at the beginning of the digital questionnaire, prior to their involvement. No compensation was provided to participants. Data were collected and stored in compliance with applicable privacy regulations, ensuring the confidentiality and anonymity of participants' data. Data collection procedures complied with the ethical standards outlined in the Declaration of Helsinki [35] and received 2 separate approvals from the Ethics Committee of the University of Padova (protocol 871-c, 2025 for the focus group sessions and 991-b, 2025 for the pilot administration).

Design

An exploratory sequential mixed methods approach was used for the development of the CARE-QI 5.0 questionnaire, following established best-practice guidelines and scale development and validation frameworks [34,36-38]. This comprised a structured, multiphase process encompassing construct definition, item generation, expert evaluation, target population feedback, and pilot psychometric evaluation. The item development process followed an iterative refinement logic, in which they were not strictly retained or excluded based on a single quantitative criterion but were progressively revised, reworded, or replaced across phases, integrating expert judgment and feedback from the target population [34,36-38]. In line with these guidelines, the overall procedure is summarized in Figure 1, comprising 4 key stages.

Figure 1. Development process of the CARE-QI 5.0 following best-practice guidelines for scale development.

First, we conducted a comprehensive literature review across academic databases to identify core constructs and relevant existing instruments. Drawing on these results, we generated and contextually adapted questionnaire items from validated sources. Next, the initial version of the instrument underwent expert review to assess content validity. Third, following item refinement, 2 separate focus groups, lasting 60 minutes each, were conducted with workers from 2 different manufacturing companies to obtain qualitative feedback on item clarity and comprehensibility. Finally, pilot administration of the revised digital questionnaire was conducted as part of a case study, allowing for initial preliminary evaluation aimed at exploring the psychometric properties of the instrument in a real-world industrial context. The digital survey also collected information on participants' sociodemographic, occupational, and technology-related characteristics. Specifically, data were gathered on sex, age, job tenure, job role, work tasks, type of contract, technology readiness level (basic, intermediate, and high), frequency of technology use from 1 ("never") to 5 ("always"), years of experience with such technologies, and

XSL•FO
RenderX

whether they had received any related training. The duration of the compilation was approximately 25 minutes. The 4 major phases are specifically described step by step.

Literature Review for Instrument Development

A deductive strategy for the selection of main constructs was applied, following established methodological guidelines [38]. This process involved a comprehensive review of existing theoretical models and empirical literature through Scopus, Web of Science, PubMed, and Google Scholar. This was followed by a series of iterative brainstorming sessions among the authors to identify the most relevant dimensions of psychological resilience. The selection of main constructs for the questionnaire aimed to provide a comprehensive and representative theoretical structure of worker resilience within advanced manufacturing contexts, in line with Industry 5.0 principles. Items were selected and adapted from validated instruments to ensure theoretical coherence and psychometric robustness, rather than being developed ex novo [34,36,38]. The selection of constructs and items followed a theory-driven approach, conceptualizing them as interrelated components of resilience rather than independent measures. In this framework, resilience was defined as a multidimensional construct influenced by the interaction between individual resources and contextual factors in technologically evolving work environments [20]. Accordingly, each dimension of the questionnaire was derived from established psychometric tools commonly used in psychological research [34-39]. Preference was given to tools that have been validated on Italian populations or adapted to the Italian sociocultural context by reporting good or excellent internal consistency values (Cronbach $\alpha \geq 0.70$) in their validated Italian versions. Items were viewed and selected through a comparative process among the authors of this study. During this phase, items that were most representative of each specific subdimensional construct within the broader model were selected. For each construct, priority was given to items that demonstrated both theoretical clarity and contextual relevance. Subsequently, the authors proposed a context-specific readaptation of the selected items, in line with high-tech manufacturing environments.

Experts' Evaluation: Item Clarity Assessment

The first version of the CARE-QI 5.0 questionnaire was assessed by 3 experts in work and organizational psychology as well as HRI, who independently gave feedback regarding the clarity and comprehensibility of each item, without being informed of the questionnaire's underlying factor structure. The assessors rated each item dichotomously (yes or no), reporting if it was clear or unclear by further providing qualitative comments to suggest any changes. Experts also provided open-ended comments to improve the semantic alignment of the items with the target population.

Two Focus Groups

Two focus group sessions were conducted within 2 manufacturing companies known for their high-tech machinery usage, by implementing the guidelines described by Freeman [39]. This inductive approach, which involves collecting opinions from the target population to corroborate item clarity and their contextual relevance, is recognized as a pivotal step for the questionnaire development and validation process [40,41]. The facilitator (GB) read each item aloud while the text was projected on a monitor, and 2 observers (AV and ST) took notes of the participants' nonverbal expression. The questionnaire was implemented on the *Qualtrics* platform (Qualtrics International Inc). Participants were asked to indicate whether the item was clear, unclear, or ambiguous by responding "yes" or "no" accordingly. This phase was inspired by cognitive interviewing [42], integrating a hetero-directed evaluation. The evaluation primarily focused on participants' judgments of item clarity, but it was also enriched by their spontaneous comments. Although no formal probing scripts or structured think-aloud protocols were used, participants frequently shared their interpretations, suggested alternative wordings, and pointed out ambiguities. These qualitative insights offered valuable information about comprehension processes. All observations were audio recorded and transcribed verbatim to identify potential sources of misunderstanding and to refine the wording of the questionnaire items.

The Pilot Administration

Following the item pool refinement, the CARE-QI 5.0 was administered through a pilot session to the same abovementioned recruited companies. The main purpose of this validation step concerned the examination of the internal validity of the questionnaire, which was filled out using the *Qualtrics* platform. Data were collected over a 2-week period. All items were scored on a 5-point Likert scale, ranging from 1 ("totally disagree") to 5 ("totally agree").

Data Analysis

Statistical analyses were progressively conducted across each phase of the refinement process. As such, each version of the questionnaire integrated adjustments derived from the previous step, with the goal of enhancing item clarity and contextual relevance.

For the experts' evaluation phase, item clarity and comprehensibility were assessed using an agreement index based on dichotomous judgments (clear or unclear) provided by 3 experts. For each item, we calculated the proportion of experts who rated it as clear. Items receiving full agreement (3/3 experts; 100% agreement) were retained without modification, whereas items with lower agreement were revised based on the experts' qualitative feedback. Expert agreement was used to identify items that could be retained without modification, whereas items not reaching full agreement were further refined rather than discarded, in line with the iterative process [34,36,38].

For the focus groups, both quantitative and qualitative analyses were performed. Frequencies and percentages were computed for each item to identify potential comprehension issues, and content analysis was applied to summarize key themes from participants' feedback.

In the pilot phase, all statistical analyses were performed using RStudio (Posit, PBC) [43]. Descriptive statistics were computed for each item and each subscale of the CARE-QI 5.0 questionnaire.

XSL•FO
RenderX

Internal consistency was assessed using Cronbach α and McDonald ω total coefficients, calculated separately for each subscale. For each α estimate, the corresponding 95% CI (lower and upper bounds) was also computed to evaluate the stability and precision of internal consistency estimates.

Pearson correlation coefficients (*r*) were calculated to assess interitem correlations within each subscale to evaluate internal coherence and identify potentially misfitting items. In addition, item-total correlations were examined to verify the contribution of each item to its respective subscale.

Furthermore, intersubscale Pearson correlations (*r*) were computed to explore the relationships among the identified dimensions of the questionnaire. This step aimed to preliminarily assess the internal structure and construct validity of the tool, consistent with the hypothesized hierarchical model of CARE-QI 5.0. Moreover, the subscales were correlated with age, job tenure, technology readiness level (basic, intermediate, and high), frequency of technology use, and years of experience with such technologies. The strength of interfactor relationships was interpreted based on Cohen's [44] guidelines, where *r* values of 0.10, 0.30, and 0.50 are considered small, medium, and large effects, respectively. In addition, intersubscale correlations exceeding $r>0.85$ were interpreted as potential indicators of construct overlap, suggesting that the associated dimensions may be measuring substantially similar or redundant constructs [45].

Results

Results of the 4 Phases

Across the different phases of the study, the CARE-QI 5.0 was developed by integrating and adapting items derived from multiple validated questionnaires, which were progressively refined throughout the process. The results of each development phase are summarized in Tables 1-7. Specifically, Table 1 reports the initial item pool derived from the literature review and existing instruments, Tables 2 and 3 present the results of the expert evaluation and subsequent refinement of the selected items, Tables 4 and 5 describe the characteristics of the pilot sample and the technologies used, Table 6 reports the reliability analyses, and Table 7 presents the final set of questionnaires and subscales included in the CARE-QI 5.0 for the pilot phase. Moreover, item selection and refinement followed an iterative process across the 4 study phases. As illustrated in Figure 2, the initial pool of 82 items was first evaluated by experts, resulting in a subset retained without modification (n=32), and the remaining items were revised based on qualitative feedback. Subsequently, theoretically driven modifications were introduced, including the replacement of the Emotional Style Questionnaire (ESQ; 12 items) with the Coping Orientation to the Problems Experienced (COPE-NVI; 21 items), leading to an expanded pool of 91 items. This version was then evaluated through focus groups, which informed further wording refinements and contextual adaptations. The final version administered in the pilot phase comprised 91 items.

Literature Review

A comprehensive literature review led to the identification of a set of individual and contextual constructs empirically associated with resilience in organizational settings. Personal factors refer to internal dispositions and cognitive-emotional resources that individuals mobilize when facing adversity, such as self-efficacy, locus of control, emotion regulation strategies, and cognitive flexibility [24-30]. Conversely, contextual factors pertain to environmental resources and systemic support mechanisms, such as perceived social support and organizational adaptability, that fall outside the individual's direct control but critically shape their capacity for resilience [29,31].

Accordingly, the CARE-QI 5.0 scale was developed by organizing these constructs into 2 higher-order dimensions under the overarching factor of resilience: (1) personal factors, comprising the subdimensions of self-efficacy, locus of control (internal and external), emotion regulation strategies, change management and adaptation, and cognitive flexibility; and (2) contextual factors, comprising social support and organizational resilience. This theoretical model informed the development of an initial item pool consisting of 82 items, all distributed across the identified subdimensions. The selection of the underlying measurement tools for each construct was based on their conceptual alignment with the target population (ie, industrial workers), empirical validity, psychometric soundness, and adaptability to high-tech occupational contexts. Table 1 summarizes the constructs, the original instruments, Cronbach α values (all >0.70), and the first set of the selected subscales for the development of CARE-QI 5.0.

In particular, for the cognitive flexibility dimension, items were adapted from the Multidimensional Psychological Flexibility Inventory (MPFI) [50], which originally includes 6 first-order factors loading onto two higher-order constructs: flexibility and inflexibility. In this study, only these two broader domains were retained, omitting the subfactors, to provide a more parsimonious and context-sensitive model tailored to high-tech manufacturing environments.

Furthermore, the Social Support (SS) dimension was constructed by integrating items from three validated instruments to represent distinct sources of support relevant to workplace dynamics: (1) 4 items were drawn from the Italian version of

XSL•FO
RenderX

the Multidimensional Scale of Perceived Social Support [51], assessing support from family and friends; (2) 6 items from the Health and Safety Executive Stress Indicator Tool (SIT) [52] measured support from colleagues and supervisors or managers; and (3) 3 items from the Survey of Perceived Organizational Support [53] addressed support from the organization. This integrated approach allowed for a multidimensional and occupationally relevant operationalization of perceived social support.

Experts' Evaluation: Item Clarity Assessment

As summarized in Table 2, expert judgments were used to assess item clarity and comprehensibility. Of the 82 items originally included across 7 questionnaires, 32 items (39%) achieved full expert agreement on clarity. Notably, the SS questionnaire showed the highest agreement, with 85% of its items (11/13) rated as fully clear. In contrast, the ESQ [47] presented significant issues, with only 1 (8%) of 12 items receiving unanimous agreement. Experts provided extensive qualitative feedback regarding the ESQ's lack of contextual relevance and overly complex phrasing, especially in relation to workplace dynamics. As a result, the ESQ was removed from the battery and replaced with the COPE-NVI [55] (21 items), which better aligns with the aim of assessing emotional regulation strategies within occupational contexts and demonstrates solid internal consistency [55]. These revisions, theoretically driven and supported by experts' feedback, were made prior to pilot testing and are reflected in the final pool of 91 items. Table 3 reports the second set of questionnaires used in the development of CARE-QI 5.0.

Focus Groups

Participants of the Focus Groups

A total of 18 operators participated in 2 focus groups (mean age 49.22, SD 9.95 y). The sample was evenly split by sex (50% male and 50% female). Participants had an average job tenure of 29.53 (SD 12.04) years, with a range from 1 to 37 years. Most participants were Italian (n=13, 72.2%), while the remaining 5 (27.8%) were foreign nationals fluent in Italian.

The first focus group consisted of 8 participants (men: n=7, 87.5%), with a mean age of 45.9 (SD 12.12) years. The second group included 10 participants (women: n=8, 80%), with a mean age of 51.9 (SD 6.63) years.

Results Emerged From the Two Focus Groups

The overall clarity assessment indicated that 90.7% of the items were rated as clear by participants, while only 9.3% were identified as unclear. Suggestions for improvement primarily concerned wording adjustments to better reflect the manufacturing context. In particular, participants recommended avoiding the use of anglicisms (eg, *routine* and *feedback*) and suggested replacing generic terms such as "organization" with "company" to increase contextual relevance. Specific concerns emerged regarding the MPFI [50], whose items were perceived as ambiguous in distinguishing between work-related and personal domains. To address this, all MPFI items were reformulated to remove references to the workplace, ensuring they referred solely to individual characteristics across contexts.

Pilot Administration

Participants of the Pilot Study: Sociodemographic and Occupational-Related Characteristics

Table 4 presents the sample's sociodemographic and occupational-related characteristics.

A total of 44 participants completed the revised version of the questionnaire as part of the pilot administration. Age data were available for 43 (97.7%) participants (mean age 45.12, SD 11.74 y). No participants were excluded from the analyses. Most participants were Italian men (n=29, 65.9%) and had a mean job tenure of 18.42 (SD 8.55) years. The majority worked as operators (n=40, 90.9%), *while technicians (*n=4, 9.1%) were less represented. Assembly was the most common task (n=17, 38.6%), followed by welding (n=2, 4.5%), picking (n=2, 4.5%), and product quality control (n=2, 4.5%). Most participants had an open-ended contract (n=33, 75%), with fewer on interim (n=4, 9.1%), fixed-term contract (n=4, 9.1%), part-time contracts (n=1, 2.3%), or other types of contract (n=2, 4.5%), such as employee leasing and work under an independent contractor agreement.

Technology Characteristics

As reported in Table 4, regarding technology readiness, 63.6% reported an intermediate level, 27.3% reported a basic level, and only 9.1% reported a high level. On average, participants reported using technology frequently in their work (mean 3.93, SD 1.17) and had been working with such technologies for an average of 15.63 (SD 8.91) years. The majority had received training (n=33, 75%) for using such technologies within their workplace. Moreover, Table 5 presents the technology used for working. Among the wide range of technologies reported by participants, the most frequently used were robotic assembly lines (n=16, 36.36%) and measurement instruments for calibration and testing (n=16, 36.36%), followed by semimanual machining stations (n=12, 27.27%) and pillar drills or similar drilling or tapping machines (n=12, 27.27%). Other commonly mentioned technologies included loading and unloading robots (n=11, 25.00%), assembly tables (n=9, 20.45%), testing machines (n=9, 20.45%), and automated material handling systems such as conveyors and trolleys (n=9, 20.45%).

Reliability of the CARE-QI 5.0 Subscales

As presented in Table 6, most factors demonstrated acceptable to excellent reliability. Internal consistency was assessed using both Cronbach α and McDonald ω_total. Specifically, alpha coefficients ranged from 0.63 related to the Positive attitude subscale of the COPE-NVI scale (COPE-PA) [55] to 0.94 related to the Skill-based Resilience of the Self-Evaluation of Resilience scale (SEOR-SR) subscale, with CIs generally supporting the stability of internal consistency.

However, the internal (LOC-INT) and external (LOC-EXT) locus of control subscales yielded suboptimal reliability estimates. In particular, the analysis of LOC-INT revealed a negative α coefficient (α=−.04, 95% CI −0.845 to 0.420), suggesting problematic item intercorrelations. LOCL3 ("*A well-prepared person always finds a satisfying job"*) showed a negative correlation with LOCL1 (r=−0.27) and a very weak

XSL•FO
RenderX

correlation with LOCL2 (r=0.05). When LOCL3 was removed, internal consistency improved (α=.48) but still did not reach an acceptable threshold. Moreover, the LOC-EXT showed a low reliability (α=.595, 95% CI 0.287 to 0.759). On the basis of both statistical evidence and conceptual considerations, specifically, the deterministic and potentially externally oriented nature of LOCL3's content, which aligns more with Levenson's [56] depiction of external reinforcement expectancies than with Rotter's [57] original definition of internal locus of control, both the LOCL-INT and LOCL-EXT subscales were excluded from the final version of the resilience scale. A similar issue emerged in the "Confidence to persevere in the face of difficulties" (α=.087, 95% CI −0.452 to 0.309) subscale (OSES-CD) of the Occupational Self-Efficacy Scale (OSES) [46]. Correlational analysis revealed that item OSES8 ("*When unexpected problems happen at work, I don't handle them very well*") was negatively associated with all other items in the factor (eg, OSES8-OSES7, r=−0.15; OSES8-OSES9, r=−0.33), suggesting an inconsistency in directionality. Although the item was conceptually intended to be reverse scored, this transformation had not been applied prior to the initial analysis. After correcting this and reverse-coding OSES8 of the OSES, the internal consistency of the OSES-CD subscale improved substantially (α=.84), supporting its inclusion in the final structure of the scale. Moreover, the MPFI-CF showed a lower ω value compared to α, suggesting that the scale's internal consistency may be partially influenced by its multidimensional structure (acceptance and committed action as distinct but related facets). Despite this, the scale was retained due to its theoretical centrality in resilience models [58]. The global CARE-QI 5.0 score showed excellent reliability (α=.95; ω=0.90). At the domain level, both dimensions demonstrated good to excellent internal consistency. Specifically, both individual and contextual resilience showed excellent reliability (α=.93; ω=0.84; and α=.96; ω=0.96, respectively).

The final pool items were 85. Table 7 presents the third and final set of questionnaires used in the development of CARE-QI 5.0.

To further enhance the transparency of item-level functioning, a supplementary table (Table S4, Multimedia Appendix 1) was included reporting corrected item-total correlations and the change in internal consistency coefficients (Cronbach α and McDonald ω) if each item were deleted. This information provides a detailed overview of the contribution of each item to the internal consistency of its respective subscale.

Description and Contextual Relevance of CARE-QI 5.0 Subscales

Overview

To enhance interpretability within Industry 5.0 contexts, each subscale is briefly defined in relation to workers' adaptive functioning in technologically advanced environments [12]. The full item catalog (Italian and English versions), together with their original sources and type of adaptation, is reported in Table S1 in Multimedia Appendix 2. All items were derived from validated instruments and adapted following a theory-driven approach [34,36-38]. Adaptations varied depending on the source scale and included contextual modifications to the work environment (eg, for ACS and COPE), minor linguistic and semantic refinements (eg, for OSES and SEOR), and temporal reframing from past to present to ensure consistency in item format (eg, for MPFI) while preserving the original construct content.

Self-Efficacy (OSES-PS and OSES-CD)

The self-efficacy subscales reflect workers' perceived capability to manage complex and unpredictable work demands [59]. In Industry 5.0 environments, characterized by increasing HRI and system variability, *problem-solving self-efficacy* supports rapid decision-making and operational continuity, whereas *confidence in persevering* reflects persistence under prolonged uncertainty and disruptions [18,21,46].

Coping Strategies (COPE-AV, COPE-PA, COPE-PO, and COPE-SSS)

The coping strategy subscales represent behavioral and cognitive responses to stressors [60]. In high-tech manufacturing contexts, *problem-oriented coping* is particularly relevant for actively managing technological challenges and workflow disruptions, whereas *avoidance and positive attitude* may reflect regulatory processes that vary in adaptiveness depending on situational demands [61,62]. Seeking social support is critical in collaborative environments where problem-solving relies on interpersonal coordination [31].

Change Management and Adaptation (ACS-PTC, ACS-STC, and ACS-PRTC)

These dimensions capture workers' orientation toward change, a core requirement in Industry 5.0 systems characterized by continuous technological evolution [12]. For example, *openness and proactive engagement with change* have been associated with better adjustment to organizational transformation and innovation [24].

Cognitive Flexibility (MPFI-CF and MPFI-CINF)

Cognitive flexibility is a central resilience mechanism that enables individuals to adapt to changing demands and regulate emotional responses under stress [25,27]. In contrast, *cognitive inflexibility* reflects rigid cognitive patterns that may hinder adaptation, particularly in complex and dynamic technological environments [25,27].

Social Support (SS Subdomains)

The social support subdomains represent a key contextual resource for resilience, influencing both emotional regulation and adaptive functioning [28,32,51-53]. In Industry 5.0 environments, where teamwork and human-technology collaboration are central, support from colleagues, supervisors, and organizations facilitates trust and fluency [63].

Organizational Resilience (SEOR-SR and SEOR-IR)

The organizational resilience subscales refer to the capacity of organizations to adapt and sustain functioning under disruption events [11]. In Industry 5.0, this includes investment in training, skill development, and adaptive work structures that support effective human-technology integration and collective problem-solving [14,54].

XSL•FO
RenderX

Descriptives of the Items and Subscales

Table S2 in Multimedia Appendix 3 reports the descriptive statistics (mean, SD, skewness, and kurtosis) for each item and corresponding subscale of the newly developed CARE-QI 5.0 resilience questionnaire.

Overall, item means ranged from 1.80 to 4.25, suggesting a moderate-to-high endorsement of most items. Several items exhibited moderate negative skewness, indicating a tendency toward higher agreement levels. For example, OSES2 ("When I face difficulties at work, I remain calm because I can rely on my abilities") and item SS7 from the supervisors/managers subscale ("My direct supervisor provides what I need to perform my job effectively") showed pronounced negative skewness (−1.46 and −1.12, respectively), suggesting a potential ceiling effect. Some items also demonstrated leptokurtic distributions, such as OSES2 (kurtosis=5.47), indicating clustered responses around the mean.

At the subscale level, total means ranged from 1.94 (COPE-AV) to 3.94 (COPE-PO), highlighting notable variability in the endorsement of different resilience dimensions. Specifically, higher means were observed for problem-solving self-efficacy (OSES-PS=3.92), problem-oriented coping (COPE-PO=3.94), and cognitive flexibility (MPFI-CF=3.71), whereas lower scores characterized avoidance strategies (COPE-AV=1.94) and confidence to persevere in the face of difficulties (OSES-CD=2.07).

Interitem Correlations Within Subscales and Their Relationships With Total Scale Scores

Interitem correlation analyses within each subscale were conducted to evaluate the internal homogeneity of the items and are reported in Table S3 in Multimedia Appendix 4. Overall, most items showed moderate to strong correlations with one another within their respective subscales, supporting their coherence in measuring the same latent constructs.

However, for the Acceptance of Change Scale (ACS) [49], item ACS12 ("I am aware of the changes and modifications occurring in my workplace") displayed weak correlations with the other items in the Positive Reaction to Change (ACS-PRTC) subscale. Its removal led to an increase in internal consistency (from α=.666 to .673), suggesting limited contribution to the underlying construct. On the basis of both statistical evidence and conceptual clarity, ACS12 was excluded from the final version.

Thus, the final items included in the CARE-QI 5.0 were 84.

Interrelationships Between the CARE-QI 5.0 Subscales: Preliminary Evidence of Structural Coherence

As illustrated in Figure 3, problem-solving self-efficacy (OSES-PS) was positively associated with individual-based resilience (SEOR-IR), as well as with perceived support from the organization, colleagues, and family, cognitive flexibility (MPFI-CF), predisposition to change (ACS-PTC), and problem-oriented coping strategies (COPE-PO).

XSL•FO
RenderX

Figure 3. Correlations between the subscales of the Change Adaptation Resilience Evaluation Questionnaire for Industry 5.0. ACS-PRTC: positive reaction to change; ACS-PTC: predisposition to change; ACS-STC: seeking to change; COPE-AV: coping orientation to problems experienced-avoidance strategies; COPE-PA: coping orientation to problems experienced-positive strategies; COPE-PO: coping orientation to problems experienced-problem oriented; COPE-SSS: coping orientation to problems experienced-seeking social support; MPFI-CF: cognitive flexibility; MPFI-CINF: cognitive inflexibility; OSES-CD: Occupational Self-Efficacy Scale-confidence to persevere in the face of difficulties; OSES-PS: Occupational Self-Efficacy Scale-problem solving; SEOR-IR: Self-Evaluation of Resilience-individual-based resilience; SEOR-SR: Self-Evaluation of Resilience-skill-based resilience; SS-Coll: Social Support-colleagues; SS-Family: Social Support-family; SS-Friends: Social Support-friends; SS-ORG: Social Support-organization; SS-S/M: Social Support-supervisors/managers; TechnoFreq: frequency of technology use; TechnoYears: years of experience with technology.

The dimension of perseverance in facing difficulties (OSES-CD) showed positive correlations with cognitive inflexibility (MPFI-CINF), seeking to change (ACS-STC), positive attitude (COPE-PA), and avoidance strategies (COPE-AV), indicating a less adaptive pattern of coping.

Both positive attitude and avoidance coping strategies were positively associated with cognitive inflexibility. Additionally, positive attitude was also positively correlated with support from the organization and colleagues and with positive reaction to change (ACS-PRTC); conversely, avoidance was positively associated with support from managers or supervisors.

Problem-oriented coping strategies (COPE-PO) were significantly and positively related to both dimensions of organizational resilience (SEOR-SR and SEOR-IR), support from the organization, colleagues, and family, cognitive flexibility, and 2 subdimensions of change management and adaptation (ie, ACS-PRTC and ACS-PTC).

The ACS-PTC subscale was positively correlated with support from colleagues, family, and friends and with cognitive flexibility. The ACS-STC dimension showed positive associations with seeking social support (COPE-SSS) and perceived support from friends, individual-based resilience, and both dimensions of cognitive (in)flexibility. The positive reaction to change dimension (ACS-PRTC) was positively associated with skill-based resilience (SS-Coll), support from colleagues and family, and cognitive flexibility.

Cognitive flexibility itself was positively related to skill-based resilience, as well as to COPE-SSS, the support from organization, colleagues, and friends, reinforcing its central role in adaptive functioning.

XSL•FO
RenderX

Interrelationships Between the CARE-QI 5.0 Subscales and Occupational and Technology Variables

As shown in Figure 3, age was negatively associated with perceived social support from supervisors or managers and with individual-based resilience (SEOR-IR). In contrast, it showed positive correlations with both experience in using technology (TechnoYears) and job tenure. Job tenure was negatively correlated with skill-based resilience (SEOR-SR), while it was positively associated with technological experience. Technology readiness was positively related to both technology use frequency (TechnoFreq) and experience (TechnoYears). Moreover, technology use frequency was positively associated with support from friends. In addition, experience in using technology was negatively correlated with individual-based resilience, as well as with perceived support from supervisors or managers and COPE-SSS.

Discussion

Principal Findings

The overarching aim of this study was to develop and preliminarily evaluate the CARE-QI 5.0, a multidimensional self-report instrument designed to assess resilience in manufacturing environments. The scale is grounded in a global score of resilience, with a dual-factor model, that conceptualizes adaptability as the result of 2 interrelated components: individual resilience (eg, self-efficacy, coping strategies, cognitive flexibility, and change management and adaptation) and contextual resilience (eg, perceived social support and organizational resilience). This framework reflects the human-centered and sustainable vision of Industry 5.0, where the technological transformation of production systems must be accompanied by the promotion of workers' well-being, agency, and psychological adaptability [12].

In particular, this human-centered shift involves increasing forms of HRI and HRC, which require operators to adapt not only to new tools but also to novel relational dynamics with intelligent technologies. Understanding how workers psychologically respond to such transitions is therefore crucial for the sustainable integration of advanced automation.

To ensure theoretical and contextual robustness, the development of the questionnaire followed a 4-phase mixed methods approach: (1) a literature review, (2) expert review, (3) focus groups with manufacturing workers, and (4) a pilot administration aimed at assessing the internal consistency and the correlational structure of the instrument.

Insights From the Preliminary Evaluation of the CARE-QI 5.0

Building on the literature review, a panel of psychologists and HCI experts was involved in a structured content and semantic evaluation of the selected items. This expert review phase was instrumental in validating the proposed dual-factor model of resilience, encompassing both individual and contextual resources, and in defining the preliminary structure of the CARE-QI 5.0. Items that did not meet minimum thresholds for clarity, comprehensibility, or contextual appropriateness were modified or excluded. In particular, although the ESQ was theoretically consistent with core resilience dimensions [47], it was considered too abstract and insufficiently grounded in the lived experiences of industrial workers. Consequently, ESQ-derived items were replaced with items from the COPE-NVI [55], a tool offering a more concrete and behaviorally oriented operationalization of coping strategies and previously validated in occupational settings [55].

Participants generally confirmed the clarity of the items (with over 90% rated as "clear") but also highlighted the presence of language that was either too abstract or unfamiliar, including anglicisms and psychologisms. On the basis of their suggestions, numerous items were reworded to improve operational clarity, and the wording of certain scales, such as cognitive flexibility, was adjusted to ensure their applicability to daily work tasks, interpersonal relations, and problem-solving in the manufacturing context. This process enhanced both the ecological validity and the practical usability of the CARE-QI 5.0 instrument in Industry 5.0 settings.

The pilot testing phase provided evidence of satisfactory internal consistency for the vast majority of subscales, with Cronbach α and McDonald ω coefficients ranging from acceptable to excellent. Notably, at the global level, the CARE-QI 5.0 demonstrated excellent reliability (α=.95 and ω=0.90), suggesting that the overall instrument shows strong internal consistency. At the domain level, both dimensions showed good to excellent reliability: individual resilience (α=.93; ω=0.84) and contextual resilience (α=.96; ω=0.96), further supporting the structural coherence of the instrument. Notably, the cognitive flexibility scale showed a lower ω value compared to alpha, which may reflect the multidimensional structure of the scale, as it comprises acceptance and committed action as theoretically distinct yet related aspects of psychological flexibility. Despite this, the scale was retained, given its theoretical centrality in resilience models: cognitive flexibility, intended as the ability to adapt one's cognitive repertoire in response to changing demands, has been consistently identified as a core component of psychological resilience, particularly in technologically evolving work environments where continuous adaptation to new tools, processes, and roles is required [58]. Only the locus of control dimensions did not meet the reliability threshold and were therefore excluded from the final structure of the questionnaire, which now includes 84 items across the individual and contextual domains. Correlational analyses further supported the structural coherence of the instrument. All intersubscale correlations remained below the critical threshold of r=0.85, indicating an absence of multicollinearity and acceptable discriminant validity. On the basis of Cohen's [44] guidelines, most associations between dimensions fell within the small to moderate range, suggesting related yet distinct constructs, consistent with a hierarchical model of resilience.

Internal Structure and Construct Validity

To assess construct validity, correlations between resilience dimensions and sociodemographic variables were also examined. As expected, age was positively associated with both technological experience and job tenure; yet age was negatively associated with individual-based resilience and perceived

XSL•FO
RenderX

support from supervisors or managers. Similarly, technological experience was negatively related to individual-based resilience and to seeking social support and perceived support from supervisors, suggesting that increased exposure to technology in the workplace may not necessarily be coupled with perceived psychosocial support or internal resilience resources. Conversely, technology readiness was positively associated with both technology use frequency and experience, and the frequency of technology use was positively related to support from friends, indicating that digital engagement may reflect more socially integrated or voluntary patterns of use.

From a psychological perspective, problem-solving self-efficacy emerged as a construct deeply embedded in adaptive functioning. Its positive associations with individual-based resilience, cognitive flexibility, support from key relational and organizational sources, predisposition to change, and problem-oriented coping strategies reinforce its role as a central competence underpinning resilient responses. This pattern reflects a flexible and agentic configuration, in which confidence in one's problem-solving abilities coexists with openness to change and access to supportive contexts. In contrast, the perseverance in facing difficulties (OSESCD) showed a more complex and potentially maladaptive profile. While traditionally viewed as a marker of resilience, its positive associations with cognitive inflexibility, avoidance, positive attitude, and seeking to change, in the absence of links with organizational support or self-efficacy, suggest a form of rigid perseverance, more closely aligned with resignation or effortful persistence than with adaptive coping. This interpretation can be supported by the content of the OSESCD items (eg, "I avoid trying new things when they seem too difficult"), which may reflect passivity or learned helplessness, particularly under conditions of perceived threat or low external support.

A particularly nuanced picture emerged around avoidance and positive attitude strategies, which were both positively associated with cognitive inflexibility but also with cognitive flexibility. This dual alignment underscores their ambivalent nature: while they may serve immediate emotion-regulation functions, their adaptiveness likely depends on the broader cognitive-emotional configuration in which they operate [61]. When enacted within a flexible mindset and embedded in supportive environments, they may contribute to adjustment. However, when embedded in rigid cognitive structures, they risk becoming maladaptive coping habits, promoting disengagement or illusory optimism [62,64].

In line with this dynamic perspective, cognitive inflexibility was largely uncorrelated with external resources (eg, organizational resilience and social support) but was positively associated with rigid or passive profiles, including perseverance in facing difficulties, avoidance, and positive attitude. This reinforces its conceptualization as a marker of limited adaptability, associated with reduced access to both internal and external regulatory mechanisms.

Conversely, cognitive flexibility emerged as a central protective factor, positively linked to both skill- and individual-based resilience, seeking social support and perceived support from colleagues and the organization, and openness to change across all 3 change-related subdimensions. Its wide-ranging associations suggest a pivotal role in integrating coping strategies, relational support, and openness to innovation, especially in complex and evolving work environments, such as those characterizing advanced manufacturing. Problem-oriented coping strategies aligned consistently with cognitive flexibility, resilience dimensions, and social-organizational support, highlighting their embeddedness in broader adaptive networks rather than standing as isolated traits.

Taken together, these findings support a process-oriented view of resilience, which emerges not from single traits or isolated strategies but from the dynamic interplay of flexible cognition, effective coping, change orientation, and social-organizational resources. The value of any strategy appears to depend less on its nominal category and more on how it functions within broader patterns of adaptation and support.

Technology Readiness and Implications for Psychological Resilience

In addition to the psychometric evaluation of CARE-QI 5.0, the pilot phase provided valuable insights into workers' technological exposure, which is a critical contextual factor for interpreting resilience in Industry 5.0 environments [12]. Most participants reported an intermediate (63.6%) or basic (27.3%) level of technology readiness, with only a small subset (9.1%) indicating high readiness. Nevertheless, technology use in daily operations was generally frequent (mean 3.93, SD 1.17), and workers reported an average of over 15 years of experience (mean 15.63, SD 8.91) with advanced manufacturing technologies. The most commonly used tools included robotic assembly lines and precision measurement instruments (both reported by 36.36% of the sample), followed by semimanual machining stations and pillar drills (each 27.27%). A diverse array of technologies was also mentioned, including loading and unloading robots (25.00%), assembly tables, testing machines, and automated material handling systems (each 20.45%). Although less prevalent, the use of collaborative robots (6.82%) and AI-assisted systems, such as MES platforms and real-time monitoring tools, suggests an ongoing, albeit gradual, transition toward more integrated HRC scenarios. Notably, the majority of participants (n=33, 75%) had received specific training for using these technologies, highlighting the importance of organizational investment in upskilling as a facilitator of technological adaptation. This finding reinforces the conceptualization of resilience as an interaction between individual resources and contextual supports, thereby underscoring how technological competence, fostered through structured training, may serve as a protective factor in high-tech industrial settings. Correlational analyses offered further insight into the psychological significance of these technological variables. Technology readiness was positively associated with the frequency of technology use and years of technological experience.

Practical Implications

The CARE-QI 5.0 seems to be a robust and innovative tool for assessing psychological resilience in organizational settings, especially those undergoing significant technological and

XSL•FO
RenderX

structural changes. Developed within the theoretical framework of Industry 5.0, the instrument embraces a human-centered approach that acknowledges the complexity of workers' experiences in increasingly automated and digitized environments.

CARE-QI 5.0 is further characterized by a multidimensional structure, conceptualizing resilience as a higher-order factor composed of 2 second-order domains: individual resilience and contextual resilience. These domains are in turn articulated through a series of first-order subdimensions, including self-efficacy, coping strategies, cognitive flexibility, change management and adaptation, perceived social support, and organizational resilience. This layered architecture enables a comprehensive yet nuanced evaluation of workers' adaptive capacities, considering not only internal dispositions but also the quality of their social and organizational environment. Such a structure is particularly relevant in light of the challenges posed by Industry 5.0 transformations, which involve close interaction between human operators and advanced technologies, such as collaborative robots [20], real-time monitoring systems, and intelligent automation. These changes impact not only task demands and technical skills but also workers' psychological adaptability, stress regulation, and relational dynamics. CARE-QI 5.0 can therefore serve as a valuable instrument for diagnosing resilience profiles and for monitoring how employees adjust to innovation over time. Its use may inform targeted interventions aimed at strengthening both personal and systemic protective resources. Clinical and work and organizational psychologists, HRC experts, and HR departments may use the tool to detect early signals of psychological difficulties, map areas of risk or resilience, and tailor actions to support workers' well-being. Moreover, CARE-QI 5.0 enables organizations to move beyond generic wellness initiatives and adopt evidence-based strategies for promoting sustainable human performance. By identifying which dimensions of resilience are most challenged in a given context, or reduced change readiness, companies can enact specific and measurable improvements in their work environment and organizational culture.

Therefore, CARE-QI 5.0 provides not only a means of assessing workers' adaptability but also a strategic foundation for building more resilient, inclusive, and future-ready workplaces in alignment with the social and technological principles of Industry 5.0.

Limitations and Future Directions

Despite its promising contributions, this study presents several limitations that should be considered, also for future research. First, the psychometric evaluation of the CARE-QI 5.0 remains preliminary. While internal consistency and intersubscale correlations provided initial evidence of structural coherence, no factor-analytic validation was conducted. Given the scale's multidimensional structure, with resilience conceptualized as a general construct composed of 2 higher-order domains (individual and contextual resilience) and multiple first-order subdimensions, future research should use exploratory factor analysis and confirmatory factor analysis, including second-order and bifactor models, to test the hierarchical configuration of the instrument. Second, the sample was small and drawn from a specific regional and sectoral context, namely, manufacturing companies located in Northeastern Italy, primarily within the mechanical and packaging sectors. While these sectors represent relevant use cases in Industry 5.0 transitions, the limited scope may restrict the generalizability of the findings. Further research is needed to assess the applicability and cultural fit of the instrument in other manufacturing domains among a large sample size. Third, an additional limitation concerns the expert review phase. The panel included a small sample size (n=3 experts), which limits the stability and interpretability of item-level agreement estimates. Moreover, the expert evaluation focused exclusively on item clarity and comprehensibility, without formally assessing item essentiality. As such, the current findings should be considered preliminary with respect to content validity. Notably, this limitation was partially mitigated by the inclusion of focus groups with target users, which provided complementary evidence on item comprehensibility and contextual appropriateness. Future research should involve a larger panel of subject matter experts (eg, 5 - 10 or more) and adopt more robust content validity procedures, including the use of indices such as the Content Validity Index, or Aiken V, ideally accompanied by CIs. Future validation efforts should also assess multiple aspects of content validity, including relevance and comprehensiveness, potentially integrating both experts' judgment and feedback representatives of the target population. Finally, although qualitative methods (eg, expert review and focus groups) contributed to the linguistic and contextual refinement of the items, no analysis of measurement invariance was conducted. To ensure that the CARE-QI 5.0 functions equivalently across key demographic groups (eg, gender, age, and professional role), future studies should assess its psychometric stability and fairness using multigroup confirmatory factor analysis.

Conclusions

This study contributes to the growing effort to develop context-sensitive tools for assessing psychological resilience within the evolving landscape of contemporary manufacturing. Through a mixed methods approach with several processes, encompassing theoretical review, expert evaluation, focus groups, and pilot testing, the CARE-QI 5.0 was developed as a multidimensional instrument, grounded in a dual framework of individual and contextual resilience.

Preliminary findings support the internal consistency and conceptual distinctiveness of its subdimensions, revealing the dynamic interplay between personal coping resources, cognitive adaptability, and perceived social-organizational support in shaping workers' capacity to respond to organizational and technological transitions. Correlational analyses suggest that constructs, such as problem-solving self-efficacy, cognitive flexibility, and support from supervisors and colleagues, form core adaptive clusters, while other patterns, such as rigid perseverance and avoidance strategies, highlight the risk of maladaptive coping when flexibility and support are lacking.

By capturing both individual dispositions (eg, self-efficacy and openness to change) and environmental supports (eg, social support and organizational culture), CARE-QI 5.0 offers a

XSL•FO
RenderX

comprehensive and integrative framework for evaluating psychosocial adaptability in high-tech, human-centered contexts. This makes the instrument especially relevant to the principles of Industry 5.0, where technological innovation is increasingly intertwined with sustainability, inclusion, and well-being.

While further psychometric validation and cross-contextual applications are needed, CARE-QI 5.0 holds promise as both a research instrument and a practical tool for high-tech manufacturing environments. It can assist organizations in mapping resilience profiles, guiding the design of targeted interventions, and promoting psychosocial sustainability in technologically advanced workplaces. In doing so, it supports a vision of industrial innovation that places psychological adaptability and human value at the core of progress.

Acknowledgments

We extend our sincere gratitude to the 2 companies and all participating operators for their valuable contribution to this study. Moreover, we thank the 3 independent experts for their suggestions in ameliorating the CARE-QI 5.0: Serena Tassoni, Valeria Orso, and Luca Menghini. No generative artificial intelligence tools were used at any stage of the manuscript preparation or writing process.

Funding

The research is funded within the project CARE-QI 5.0 - Change, Adaptation, Resilience, Evaluation Questionnaire for Industry 5.0: Strumento di valutazione per un'industria resiliente, within the framework of the Ecosystem INEST-Interconnected Nord-Est Innovation (PNRR) project. Notably, the content of the manuscript represents exclusively the authors' point of view, neither the European Union nor the European Commission should be considered accountable for its content.

Abstract

Background: The OA Coach mobile app was developed to support individuals with knee osteoarthritis in self-managing their condition. The app aims to fill a current gap in the osteoarthritis mobile app field by combining key features such as symptom tracking, objective activity tracking, educational modules, and encouragement notifications underpinned by behavior change theory.

Objective: The aim of this study was to describe the development of the OA Coach mobile app and assess its usability in a 6-week feasibility study.

Methods: The app was designed in consultation with consumers, rheumatologists, physiotherapists, and osteoarthritis researchers. The app prototype contained four screens: (1) a home screen to track goals and activities, (2) a progress page, (3) a learning page with self-directed modules, and (4) an inbox for communication with the study team. For the feasibility study, 30 participants were recruited between March and April 2024 from a database of osteoarthritis trial participants or through the Osteoarthritis Chronic Care Program at Royal North Shore Hospital, Sydney, Australia. Participants were eligible if they were aged 45 years or older, had knee pain ≥4 on an 11-point numerical pain rating scale and knee stiffness lasting <30 minutes in duration, or stiffness >30 minutes and diagnosed with knee osteoarthritis through a health care provider or radiographs. Participants were provided access to the app and asked to interact with it daily for 6 weeks. Outcomes were assessed through online questionnaires or through mobile app data. The primary outcome was usability, assessed using the mHealth App Usability Questionnaire (MAUQ). Secondary outcomes included computer self-efficacy and osteoarthritis knowledge. The quantitative data were summarized descriptively. Qualitative feedback was collected through open-ended survey responses and discussed within the research team to improve the app.

Results: A total of 30 participants completed the study. There was a 1:1 ratio of male to female participants, with an average age of 66.9 (SD 9.1) years and a mean pain level of 6.0 (IQR 5.0-6.8) on an 11-point numerical pain rating scale. Twenty-nine responses from the MAUQ were available for analysis. Most statements scored >5 out of 7 ("somewhat agree"), indicating that the app was easy to use. The mean satisfaction score for the app on the MAUQ was 4.7 (SD 2.0) out of 7. Qualitative feedback from participants indicated the need for clear instructions on how to use and navigate the app, improved structure and integration of the exercise program, and improved tailoring of osteoarthritis education and support.

Conclusions: Overall, the OA Coach app was well accepted by participants. Based on participant feedback, the app will be revised to improve aspects of clarity, ease of use, and personalization. The updated app will be tested against other methods of care delivery in a randomized controlled trial.

mobile app; osteoarthritis; digital health; physical activity; self-management

Introduction

Osteoarthritis is the most common form of arthritis and a leading cause of disability worldwide. With the current population growth and aging, the number of Australians living with osteoarthritis is expected to increase, impacting over 3.11 million by the year 2040 [1]. There is no cure for osteoarthritis, and the current management strategies focus on alleviating symptoms. The core treatments for osteoarthritis include education for self-management, physical activity, and exercise [2,3]. These core treatments are appropriate for all individuals with osteoarthritis, regardless of the severity of their symptoms [2].

Many people with osteoarthritis do not receive appropriate care [4]. For example, surgical referral is often prioritized over nondrug treatments, despite conservative, nondrug care being strongly recommended in international guidelines for osteoarthritis management [4-6]. The use of digital health, combined with behavior change techniques (BCTs), may help to improve access to appropriate osteoarthritis care. BCTs (eg, feedback, self-monitoring, and reinforcement) are observable, replicable, and irreducible components of interventions designed to alter or redirect causal processes that regulate behavior [7]. Physical activity interventions that use BCTs are more effective in chronic disease populations [8], and physical activity interventions that include BCTs through digital health have been shown to increase physical activity in people with osteoarthritis in the short term [9]. Digital health is broadly defined as the use of technologies such as wearables, mobile phones or apps, and websites for the treatment, prevention, and maintenance of health [10]. The World Health Organization has identified digital health as a global priority. Greater adoption of digital health initiatives will support accessible, equitable, and universal access to quality health services, as well as strengthen and scale up health promotion, disease prevention, management, and rehabilitation [11]. The COVID-19 pandemic has further accelerated the use of these technologies, and digital health is being increasingly used for the management of knee osteoarthritis [12-16]. Compared to traditional care, the use of digital health care has provided similar improvements in pain and function in osteoarthritis and back pain populations (systematic review of 23 studies, n=4994 participants) [17]. Our research group also found similar results in individuals following knee replacement (systematic review of 17 studies, n=2188 participants) and in a recent randomized controlled trial (n=102 participants) where participants received a combination of digital interventions (exercise mobile app, activity tracker, and online health coaching) [15,18]. In Australia, the majority of households have access to the internet (88%), even in remote and very remote settings (77%). Of those with internet access, 91% have access to a laptop, desktop, or smartphone [19], highlighting the potential to scale up effective digital interventions for osteoarthritis management. Access to evidence-based osteoarthritis care through a digital mobile health app could be a potential solution for low-cost and accessible care.

Mobile apps designed to support the management of osteoarthritis exist; however, no osteoarthritis-specific app has measured or monitored physical activity objectively [20]. As increasing and maintaining physical activity levels is a core aspect of osteoarthritis management, it is important that reliable measures of physical activity are incorporated into these apps. Previous studies have suggested that participants tend to inaccurately report their adherence to exercise and physical activity during home-based programs [21,22]. A recent systematic review also found that existing mobile apps for osteoarthritis management lack quality information, structured exercise programs, and scientific testing [20].

We developed a mobile app called OA Coach to support individuals with osteoarthritis in self-managing their condition. OA Coach aims to fill a current gap in the osteoarthritis mobile health field by combining key features such as symptom tracking, objective activity tracking (step count and sleep), tailored educational modules, and encouragement notifications, all underpinned by behavior change theory and developed with experts in osteoarthritis. The primary aim of this paper was to outline the development of the OA Coach mobile app and examine the usability of the app in participants with knee osteoarthritis in a 6-week feasibility study. Secondary outcomes include changes in knee symptoms, physical activity, sleep, feelings of depression, anxiety, stress, and osteoarthritis knowledge after app use.

Methods

Mobile App Prototype Development

The OA Coach app was co-designed with a multidisciplinary team including osteoarthritis researchers, rheumatologists, physiotherapists, and consumers living with osteoarthritis. The app prototype was developed by Vulsen, a developer with expertise in developing mobile apps for chronic disease management [23,24]. The study team (VD, NB, JE, SK, DJH) tested the mobile app prototype for approximately 2 weeks. A 1-hour co-design workshop was also held with 6 consumers with lived experience of osteoarthritis to gather initial feedback regarding the features and visual aspects of the app prototype. Co-design participants were given access to the mobile app to download onto their personal devices 1 week prior to the workshop. In the workshop, a brief overview of the app was presented, followed by the participants mapping likes or dislikes and potential areas for improvement for the app and a group discussion. Following alpha-testing, issues with the functionality or content of the app were relayed to the developer for resolution prior to the 6-week feasibility study.

Mobile App Features and Functionality

Details on the main features of the app are summarized in Textbox 1. An overview of the Home, Progress, and Learning pages is displayed in Figure 1. The app's log-in page required

XSL•FO
RenderX

participants to enter their date of birth and answer questions about their knee pain (pain severity, stiffness duration). This information was used to make a clinical diagnosis based on the National Institute for Health and Care Excellence guidelines [25], which then determined access to the app. Following this, participants were prompted to complete questions about their weight, height, sleep, mood, and current activity levels in order to trigger corresponding educational modules targeted to the users' needs. For example, if a participant's BMI was above a healthy range or the questionnaire responses indicated poor sleep, participants would be assigned the "Weight Management" or "Sleep" modules, respectively.

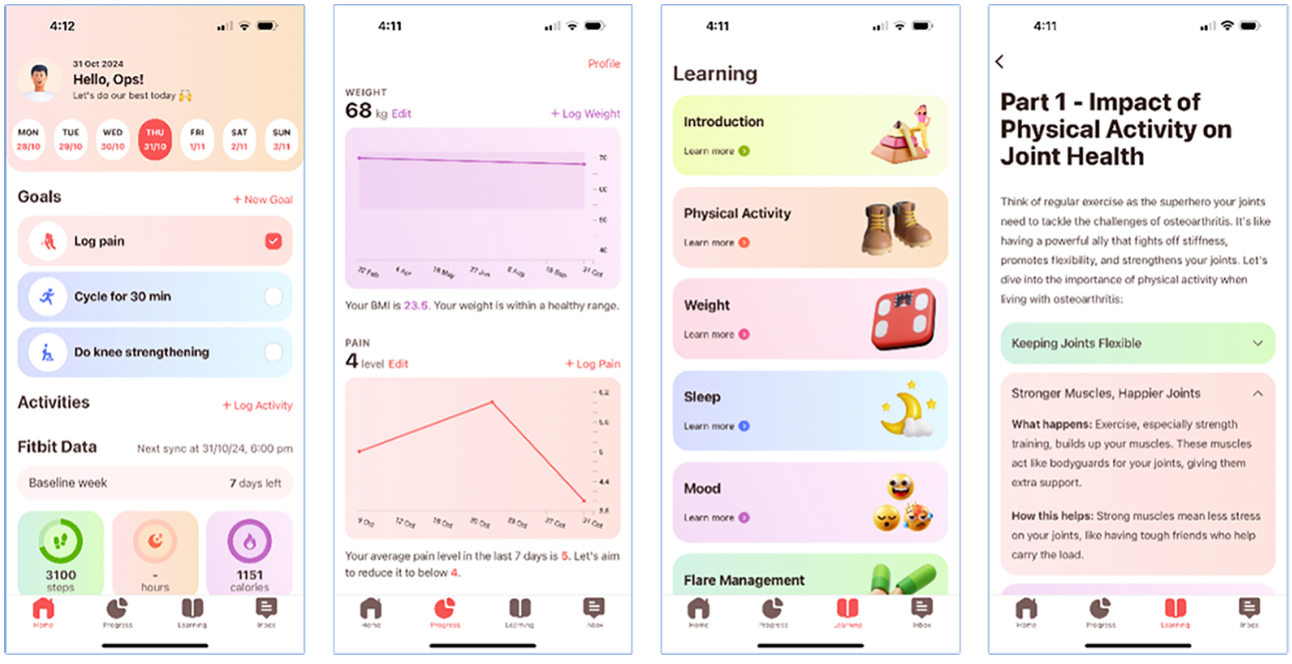
Textbox 1. Functionalities associated with each feature of the OA Coach app prototype.

Home screen

- Participants prospectively set personal goals (eg, related to physical activity, exercise, meditation) during the registration process of the app, which are displayed as a checklist on the home screen under Goals.
- Questionnaires for mood and sleep, and logging of pain scores, will also appear under Goals.
- Fitbit data, including the number of steps, hours slept, and number of calories burned, are displayed.

Progress

- Weight is tracked in kilograms. BMI is calculated with the user's height inputted at registration and displayed at the bottom of the graph. If the user's BMI is between 18.5 and 24.9 kg/m^2, it will display "Your weight is within a healthy range." Otherwise, the graph will say "Let's aim to reach a healthy weight range between X kg and X kg."
- Knee pain over the past 24 hours is tracked on a 0 - 10 numerical rating scale, where 0 represents no pain and 10 represents extreme pain. The average pain over the past 7 days is displayed at the bottom of the graph.
- Sleep and step count data are automatically populated with Fitbit data.



Learning

- Seven learning modules related to the core aspects of osteoarthritis management are displayed (introduction to osteoarthritis, physical activity, weight, sleep, mood, osteoarthritis flare management, and exercise). Each module, apart from physical activity, has 3 units: "Educational resources: Learn the basics, Self-guided help: Digging deeper, and Expert help: Getting more help."
- If participants experience an episode of a pain flare, they will be prompted by a notification to complete the Flare Management module. Similarly, if they have an episode of low mood or sleep, they will be prompted to complete the Mood or Sleep modules, respectively. These modules will appear initially as a pop-up notification and then on participants' Home page in the Goals section.

Messaging

- Initially set up for study staff to send one-way messages to participants related to their progress. The messages are sent from a custom dashboard and appear for participants in the messaging tab, which displays messages in a format similar to text messages on a mobile phone. Participants will also receive a push notification on their phone home screen alerting them to the new message.

Exercise plans for the app were displayed under the "Learning" page. The page included a brief introduction to knee-strengthening exercises, including the benefits of exercise, how to complete the exercise programs (warm up, joint specific exercises, cardiovascular endurance exercises [if possible], warm down), how to assess difficulty and progression, and frequency of program. Separate plans for individuals with good mobility, moderate mobility, and limited mobility were presented, with 3 progressions within each plan. Each exercise plan included instructional photos and descriptions as well as suggested dosage. Participants were free to choose a plan which best aligned with their current mobility status.

Participants were also provided with an activity tracker to wear for the duration of the study. The app requires that participants wear the Fitbit tracker to collect baseline data on sleep and physical activity levels in order to generate appropriate goals. The step and sleep count data are displayed on the "Home" and "Progress" pages of the app. The generated goals are displayed under the "Goals" heading on the "Home" page.

Behavior Change Theory

Behavior change theory was used to help motivate users to increase their physical activity and sleep levels, as well as complete tasks such as logging pain scores or completing surveys. BCTs, such as goal setting, feedback on behaviors, and graded tasks, were integrated into the setup process and push notifications. Participants were asked to set goals during the initial setup process of the app, where they were asked about their current exercise and physical activity levels in a questionnaire. Their responses were used to create weekly goals. For example, if a participant enjoyed playing a sport once a week, a goal would automatically be created to increase the frequency of the sport to align with the World Health Organization physical activity guidelines for older adults [26]. Feedback on behaviors, as well as graded tasks, was provided to participants as push notifications for meeting their step goal at the end of the day. Self-monitoring of pain levels and body weight was also encouraged through notifications and logged in the "Progress" page of the app, along with sleep and step count data. Further details of various OA Coach features mapped to the Behavior Change Taxonomy are outlined in Multimedia Appendix 1.

Feasibility Study Design

The feasibility study involved providing the OA Coach mobile app to study participants for 6 weeks to assess the usability of the developed app. The protocol for the feasibility study was registered on the Australian and New Zealand Clinical Trials Registry before commencement (registry number: 12623001223628). The results of this study are reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) checklist (Checklist 1).

Ethical Considerations

Ethical approval was granted by the Northern Sydney Local Health District Human Research Ethics Committee (2023/ETH02288). Participant eligibility was assessed using an online survey, and participants who passed the screening survey provided electronic consent through a Research Electronic Data Capture e-consent form.

Participants

Potentially suitable participants were identified by rheumatologists and physiotherapists within the Osteoarthritis Chronic Care Program at Royal North Shore Hospital, Sydney, Australia, and were provided with a link to the eligibility screening survey. Participants from past clinical trials who had consented to be contacted about future research studies were also emailed and invited to participate in the study.

Individuals were eligible for the study if they were aged 45 years or older, had knee pain ≥4 out of 10 on an 11-point Numerical Pain Rating Scale (NPRS; where 0 represents "no pain" and 10 represents "worst imaginable pain"), and experienced knee stiffness lasting no longer than 30 minutes after rising from bed in the morning. Participants were also eligible to participate in the study if they had knee stiffness >30 minutes but had been diagnosed with knee osteoarthritis through radiographs or a health care practitioner. This inclusion criterion was added as an amendment to the study, as a number of participants with a confirmed diagnosis of osteoarthritis were being excluded due to stiffness slightly exceeding 30 minutes. These participants were contacted either from either our database of previous participants or were recruited from the Osteoarthritis Chronic Care Program at Royal North Shore Hospital thus already having a confirmed diagnosis of osteoarthritis. Participants also required ownership of a smartphone with internet access in order to download the OA Coach app. The exclusion criteria for the study were as follows: a diagnosis of inflammatory arthritis, such as rheumatoid arthritis or gout, and any comorbidities or medical conditions that would prevent participation in the physical activity component of the app.

Intervention

All participants received a Fitbit tracker (Fitbit Inspire 2) in the post and instructions on how to download the OA Coach app on their personal smartphones and link the Fitbit tracker. The OA Coach app is freely available on app stores; however, its access remained password-protected during the evaluation period. Participants were instructed to wear the Fitbit tracker for a baseline period of 1 week and were then asked to interact with the app daily for 6 weeks. Participants were instructed to contact the study coordinator through email if they experienced any technical issues in setting up the OA Coach app or Fitbit tracker. The study coordinator aimed to resolve any technical issues through email, prior to contacting participants by phone.

Outcomes

Three sets of data were obtained from the study including baseline and 6-week online questionnaires, data from the mobile app (eg, step count, hours slept, the 21-item Depression, Anxiety and Stress Scale [DASS-21] and Pittsburgh Sleep Quality Index [PSQI] questionnaires), and qualitative feedback from surveys at 6 weeks.

Primary Outcome

The mHealth App Usability Questionnaire (MAUQ) for Standalone mHealth Apps Used by Patients was used to assess

XSL•FO
RenderX

the usability of the OA Coach app for the primary outcome [27]. The questionnaire consists of 18 statements, and participants were asked to rate their agreement with each statement on a 7-point Likert scale, ranging from strongly disagree to strongly agree [27]. To determine the usability of the app, the total score was calculated and averaged across responses, with higher scores representing higher usability.

Secondary Outcomes
